CHAPTER 33: QUESTIONS AND ANSWERS

1. The primary goal in the emergency care of a head trauma patient is prevention or reduction of secondary insults that are known to worsen outcome after traumatic brain injury (TBI). This includes acutely preventing:
   a. Hypotension
   b. Hypoxia
   c. Malnutrition
   d. All of the above
   e. Hypotension and hypoxia

Answer: e. Avoiding or reversing hypotension and hypoxia is essential in the acute management of TBI patients in the emergency department. Hypotension and hypoxia each double the risk of mortality following TBI.

2. Which of the following statements is true regarding cerebral blood flow (CBF), cerebral perfusion pressure (CPP), and intracranial pressure (ICP)?
   a. CBF autoregulation is lost below a CPP of 60 mm Hg.
   b. CPP closely parallels diastolic blood pressure.
   c. Normal ICP is 65 to 195 mm Hg.
   d. CPP = mean arterial pressure (MAP) – ICP.
   e. The only resistance to CBF is ICP.

Answer: d. CBF depends on CPP, which is the blood flow pressure gradient. CBF resistance is provided by mean systemic venous pressures and ICP, predominantly by the latter. CPP closely parallels MAP offset by ICP; thus, the formula CPP = MAP – ICP. ICP is estimated clinically by the central venous pressure unless a ventricular catheter is in place and ICP can be directly determined. CBF autoregulation is lost below a CPP of 40 mm Hg. Normal ICP is 5 to 15 mm Hg or 65 to 195 mm H_2O.

3. Which of the following parameters are associated with a worsened outcome after traumatic brain injury (TBI)?
   a. Hematocrit (Hct) <30%
   b. Temperature >38.5°C (101.3°F)
   c. Partial pressure of oxygen (Po_2) <60 mm Hg
   d. A and C
   e. All of the above

Answer: e. All of the above. The following are associated with worsened outcomes after TBI:
Hematocrit (Hct) <30%
Temperature >38.5°C (101.3°F)
Systemic blood pressure (SBP) <90 mm Hg
Po_2 <60 mm Hg

4. A 27-year-old man presents after a motor vehicle collision (MVC) with a severe closed head trauma. On examination, you calculate a Glasgow Coma Scale (GCS) score of 5 and a left dilated pupil, with a sluggish pupillary reflex compared with the right. What other finding will your examination likely reveal?
   a. Left carotid bruit
   b. Left foot weakness
   c. Loss of controlled pain/temperature sensation
   d. Right carotid bruit
   e. Right-sided hemiparesis

Answer: e. Uncal herniation is the most common posttraumatic herniation syndrome. The initial pressure compresses the third cranial nerve (CN III), causing ipsilateral pupillary sluggishness, ptosis, anisocoria, and impaired extraocular movements. Contralateral hemiparesis can develop early after an initial normal motor examination. In some cases, the contralateral uncus is compressed, resulting in ipsilateral weakness (Kernohan notch syndrome).

5. A 24-year-old man presents with a closed head injury after a motor vehicle collision (MVC). The physical examination is remarkable for a sluggish left pupil, right-sided hemiparesis, and a Glasgow Coma Scale (GCS) score of 12. What should be the most appropriate next step in this patient's management?
   a. 3% hypertonic saline IV
   b. Intubation and moderate hyperventilation
   c. Mannitol, 1 g/kg IV
   d. Methylprednisolone IV
   e. Pentobarbital IV

Answer: b. The most rapid effect on intracranial pressure (ICP) reduction is achieved via intubation and moderate hyperventilation to a Pco_2 of 30 to 35 mm Hg. The effect peaks within minutes and should be considered a short-term intervention, with an expected ICP reduction of 25%. Prolonged hyperventilation, however, is dangerous. Steroids may worsen outcome after traumatic brain injury (TBI). Mannitol is generally efficacious and exerts an effect within minutes and lasts hours. Other neuroprotective effects include volume expansion, viscosity reduction, cerebral blood flow (CBF) improvement, and free radical scavenging. Hypertonic saline data are encouraging but inconclusive; stronger data exist in the pediatric literature. Barbiturates exert a modest ICP-lowering effect because of their lowering of the cerebral metabolic rate and oxygen demand.

6. What is the minimum time after becoming asymptomatic that an individual should refrain from playing sports after a concussion if no loss of consciousness (LOC) or prolonged posttraumatic amnesia occurred at the time of injury?
   a. 24 hours
   b. 48 hours
   c. 1 week
   d. 2 weeks
   e. 1 month

Answer: c. All current recommendations for return to play after a sports-related concussion state that players with concussion should not return to play for at least 1 week after they have become asymptomatic. This is usually increased to at least a symptom-free month for an extended LOC or prolonged posttraumatic amnesia occurring at the time of the concussion.

7. A 15-year-old boy presents after being hit in the head with a baseball. He has a Glasgow Coma Scale (GCS) score of 7 and a large hematoma of his scalp, anterior and superior to his right ear. In addition, he is noted to have unequal pupils and a sluggish papillary light reflex of the right eye. Which of the following is most likely in this patient?
   a. Central transtentorial herniation
   b. Cerebellotonsillar herniation
   c. Downward transtentorial herniation
   d. Uncal herniation
   e. Upward transtentorial herniation

Answer: d. Uncal herniation is often associated with traumatic extra-axial hematomas in the lateral middle fossa of the temporal lobe. The classic signs and symptoms are caused by compression of the ipsilateral uncus of the temporal lobe on the U-shaped edge of the tentorium cerebelli as the brain is forced through the tentorial hiatus. As compression of the uncus begins, CN III is compressed; anisocoria, ptosis, impaired extraocular movements, and a sluggish pupillary light reflex develop on the side ipsilateral to the expanding mass lesion. This phase may last for minutes to hours, depending on how rapidly the expanding lesion is

changing. As the herniation progresses, compression of the ipsilateral oculomotor nerve eventually causes ipsilateral pupillary dilation and nonreactivity.

Initially, in the uncal herniation process, the motor examination can be normal, but contralateral Babinski responses develop early. Contralateral hemiparesis develops as the ipsilateral peduncle is compressed against the tentorium. With continued progression of the herniation, bilateral decerebrate posturing eventually occurs; decorticate posturing is not always seen with the uncal herniation syndrome. In some patients, the contralateral cerebral peduncle is forced against the opposite edge of the tentorial hiatus. Hemiparesis is then detected ipsilateral to the dilated pupil and mass lesion, termed *Kernohan notch syndrome,* and causes false-localizing motor findings. As uncal herniation progresses, direct brainstem compression causes additional alterations in the LOC, respiratory pattern, and cardiovascular system. Mental status changes may initially be subtle, such as agitation, restlessness, or confusion, but soon lethargy occurs, with progression to frank coma. The patient's respiratory pattern may initially be normal, followed by sustained hyperventilation. With continued brainstem compression, an ataxic respiratory pattern develops. The patient's hemodynamic status may change, with rapid fluctuations in blood pressure and cardiac conduction. Herniation that is uncontrolled progresses rapidly to brainstem failure, cardiovascular collapse, and death.

8. Central pontine myelinolysis is a potential adverse event associated with the administration of which of the following medications?
- **a.** Etomidate
- **b.** Hypertonic saline
- **c.** Mannitol
- **d.** Methylprednisolone
- **e.** Pentobarbital

Answer: b. Central pontine myelinolysis is a potentially adverse event associated with hypertonic saline administration.

9. What percentage of mild traumatic brain injury (MTBI) patients discharged from the emergency department (ED) will continue to have post concussive symptoms at 3 months and 1 year after injury?
- **a.** 5% at 3 months and 10% at 1 year
- **b.** 40% at 3 months and 50% at 1 year
- **c.** 30% at 3 months and 15% at 1 year
- **d.** 5% at 3 months and 5% at 1 year
- **e.** None of the above

Answer: c. Studies of ED patients have indicated that as many as 30% of patients with a discharge diagnosis of MTBI will have symptoms at 3 months postinjury, and up to 15% will continue to be symptomatic at 1-year postinjury.

10. Per the Canadian Computed Tomography Head Rule (CCHR) which criteria are NOT considered "High-Risk" for intracranial injury and possible neurologic intervention?
- **a.** A Glasgow Coma Scale (GCS) score that is persistently <15 after 2 hours
- **b.** Suspected open or depressed skull fracture
- **c.** Vomiting 2 or more times
- **d.** Age over 50 years
- **e.** Any sign of basal skull fracture

Answer: d. All are high risk except D. High-risk are patients age ≥65 years. Other criteria that suggest important brain injury on CT include amnesia before impact ≥30 min and dangerous mechanism (pedestrian struck by vehicle, occupant ejected from vehicle, fall from elevation >3 feet [five stairs]).

34

Facial Trauma

Ryanne J. Mayersak

KEY CONCEPTS

- The face is central to the patient's ability to breathe, eat, and communicate. Injuries to the face can have serious psychological and psychosocial consequences.
- Facial injuries may be prevented by the appropriate use of safety devices including motor vehicular seat belts, child restraints, air bags, helmets, and mouth and face guards.
- The epidemiology of facial injury is changing, with an increasing proportion of injuries occurring as a result of interpersonal violence. A careful history is required, and the possibility of abuse should be considered for every patient.
- Shock from facial trauma is rare and results only from obvious external bleeding. Facial injuries should not distract the emergency clinician from searching for other causes of shock.
- Assertive management of the airway is indicated in a patient with severe facial injuries. Surgical management (cricothyroidotomy) may be required, particularly with penetrating gunshot wounds.
- Directed facial CT scanning is the optimal imaging technique in patients with obvious injuries.
- Definitive facial treatment may be delayed, if necessary, to address other serious injuries.

FOUNDATIONS

Background and Importance

A complex structure vital to the function of the person, the face is comprised of airway openings, entry to the gastrointestinal tract, and special sensory organs, including the eyes, ears, and nose. Facial functioning is essential for eating, speaking, and effective nonverbal communication. The appearance and attractiveness of the face have significant implications for social interactions, sexual attraction, and self-esteem. Patients who have sustained facial trauma can experience long-term sequelae, including unemployment, drug and alcohol abuse, incarceration, marital difficulties, and negative body image.[1,2]

Apart from the immediate threat to the patient's airway and special sense organs, injuries to the face can have serious implications for the patient's mental health[3] and future functioning.[4] Posttraumatic patients with facial injuries often describe physical, financial, social, and psychological loss.[1,5] Multiple studies have demonstrated an association between facial trauma and psychological symptoms such as anxiety, depression, and posttraumatic stress disorder. Several screening tools exist which can be useful in assessing a facial trauma patient's psychological rehabilitation.[1] Some institutions are establishing multidisciplinary evaluations regarding interventions, as well as initiating support groups and online resources for facial trauma patients.[6,7]

Although the emergency clinician's first goal is to address life-threatening problems successfully, the care of facial injuries is aimed at optimizing the patient's function and cosmetic appearance. Four main specialties—ophthalmology, plastic and reconstructive surgery, otolaryngology, and oral and maxillofacial surgery—participate in the care of facial injuries. Early consultation with the appropriate specialist can expedite the care of facial injuries.

Anatomy, Physiology, and Pathophysiology

The face is a complex space encapsulated by a bony structure overlaid with muscle and skin. It includes several special sensory organs—the eyes, ears, nose, and mouth.

Bones

The posterior portions of the face form the anterior wall of the calvaria, placing the face and its features in close proximity with the structures of the central nervous system. The anterior facial skeleton is composed of the frontal bone, nasal bones, zygomata, maxillary bones, and mandible (Fig. 34.1). The sphenoid, ethmoid, lacrimal, vomer, and temporal bones lie deep within the facial structure, providing support and important sites for muscular attachments, including the muscles of mastication, speech, and deglutition. This musculature complex is innervated by cranial nerves IX and X.

Nerve Supply

The most anterior muscle layer includes the muscles of facial expression innervated by the seventh cranial nerve (CN), which lies just inferior to the external auditory canal. The trigeminal nerve (CN V) supplies sensation to the face through three major divisions (I–III). The ophthalmic division (CN V1) supplies the upper third of the face, including the eye and nose down to the tip. The maxillary division (CN V2) provides sensory innervation to the midface and includes the infraorbital nerve. The mandibular division (CN V3) supplies sensation to the lower third of the face.

Ears

The skeleton of the pinna is cartilage covered in closely apposed skin and rolled into a helical shape with a second ridge, the antihelix, defining the inner concha. The external auditory canal, middle ear, cochlea, semicircular canals, and superior origin of the eustachian tube all lie within the temporal bone.

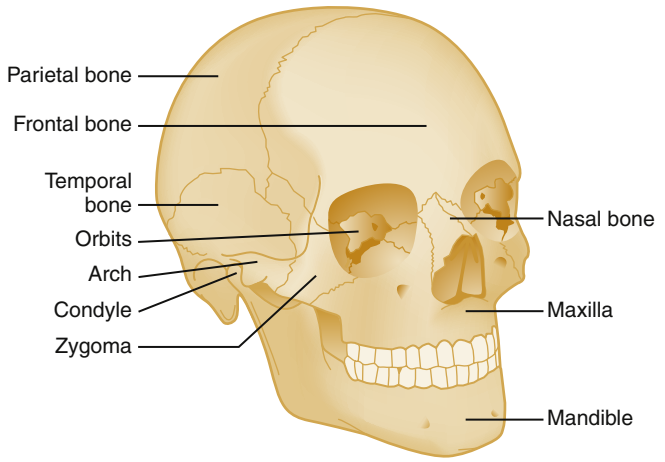

Fig. 34.1 Bones of the facial skeleton.

Eyes

The bony orbit is composed superiorly of the frontal bone. The zygoma forms the lateral wall and lateral floor of the orbit. The medial floor and anteromedial wall are formed by the maxilla. The lacrimal and ethmoid bones complete the medial wall, where the orbit is at its most delicate juncture and vulnerable to injury. The medial wall of the orbit forms the lateral walls of the intranasal space.

Nose

The nose serves as a major entryway for air and is composed of cartilage and bone covered by skin, with mucosa lining the internal surface. Alar cartilage arches over the entrances to the symmetric, mucosa-lined nares, separated by the anterior cartilage of the septum. Superiorly, the nasal bones create the bridge of the nose. With the head held in a neutral upright position, the floor of the nose is perpendicular to the ground and leads back into the nasopharynx, passing the turbinates laterally and bony septum medially. The ethmoid bone lies superiorly and crosses midline, behind the nasal bridge, to form the superior portion of the bony nasal septum and cribriform plate. The vomer makes up the inferior portion of the bony septum, and the palatine process of the maxillary bone forms the posterior floor of the nose and hard palate.

Air-containing sinuses are structural features unique to the facial skeleton. They warm and humidify inhaled air and form chambers that create the unique tone of the human voice. These sinuses develop over the period of human growth. At birth, only the ethmoid air cells and mastoid antrum are aerated. The sphenoid sinus and remainder of the mastoid air cells become aerated at approximately age 3 years. Frontal sinuses form at approximately age 6 years, and maxillary sinuses are not fully developed until age 10 years.

Mouth

The mouth serves as an entryway for the respiratory and gastrointestinal tracts. With the mouth in the closed position, the tongue fills the oral cavity. Single rows of teeth lie within the alveolar ridges of the maxilla and mandible. With the mouth closed, the teeth in normal individuals occlude, with the lower row lying just internal to the upper row. The "usual" occlusion for individuals varies widely; the patient's perception may be the best determinant of whether or not the teeth are meeting and approximating as usual. Anterior to the teeth is the vestibule, a fold of mucosa and flexible soft tissue that allows the lips to remain closed while various motor movements occur behind them. The mandible is a U-shaped bone that forms the chin and completes the lower facial skeleton. Containing the lower row of teeth, the body

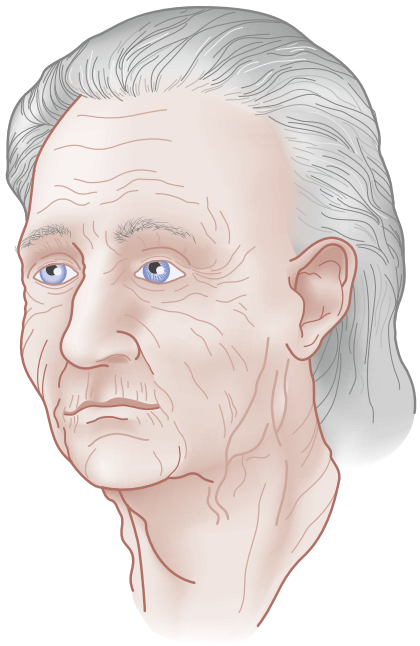

Fig. 34.2 Langer lines—lines of facial expression.

of the mandible meets in midline at the symphysis, which is completely fused by age 2 years. Posterior to the last molar, the bone turns to form the angle of the jaw and continues upward as the ramus of the mandible. At the most superior point of the ramus is the articular surface of the condyle, separated from the superior surface of the temporomandibular joint (TMJ) by an intervening meniscus of fibrocartilage. Anterior to the condyle lies a thin projection, the coronoid process, which provides the insertion point for the temporal muscle.

Temporomandibular Joint

The TMJ is complex, with the condyle of the mandible undergoing rotation and translation anteriorly during normal mouth opening (see Fig. 56.23). The function of the TMJ is preserved by a meniscus, which overlies the condyle. Essentially, the joint between the meniscus and condyle is a hinged joint, allowing rotation, and the joint between the meniscus and temporal bone is a sliding joint, allowing translation. A formal, thick joint capsule does not exist at the anteromedial portion of the joint; loose, relatively weak synovial tissue is positioned here to allow translation to occur.

Soft Tissue, Vasculature, and Specialized Glands

The skin of the face is among the thinnest of the body, draping over the underlying musculature. Facial skin falls visibly into predictable creases with age, following Langer's lines (Fig. 34.2). At the mouth, nares, and palpebral fissures, the skin is contiguous with the mucosa lining these structures. The skin of the lips is particularly thin and lined with vascular papillae, which give the lips their vermilion hue. Lips are particularly important as part of communication; understanding their movement can allow language without sound (such as lip reading).

The face is a highly vascular structure, which can have important implications for the treatment of facial injuries. With the exception of the ophthalmic artery, the superficial blood supply comes from the external carotid artery via the facial, superficial temporal, and maxillary arteries (Fig. 34.3). Soft tissue injuries and fractures that involve these vessels can lead to significant hematomas or exsanguinations. Because the face has extensive anastomotic connections across the midline and between arterial territories, however, ligation of major branches causes minimal ischemia.

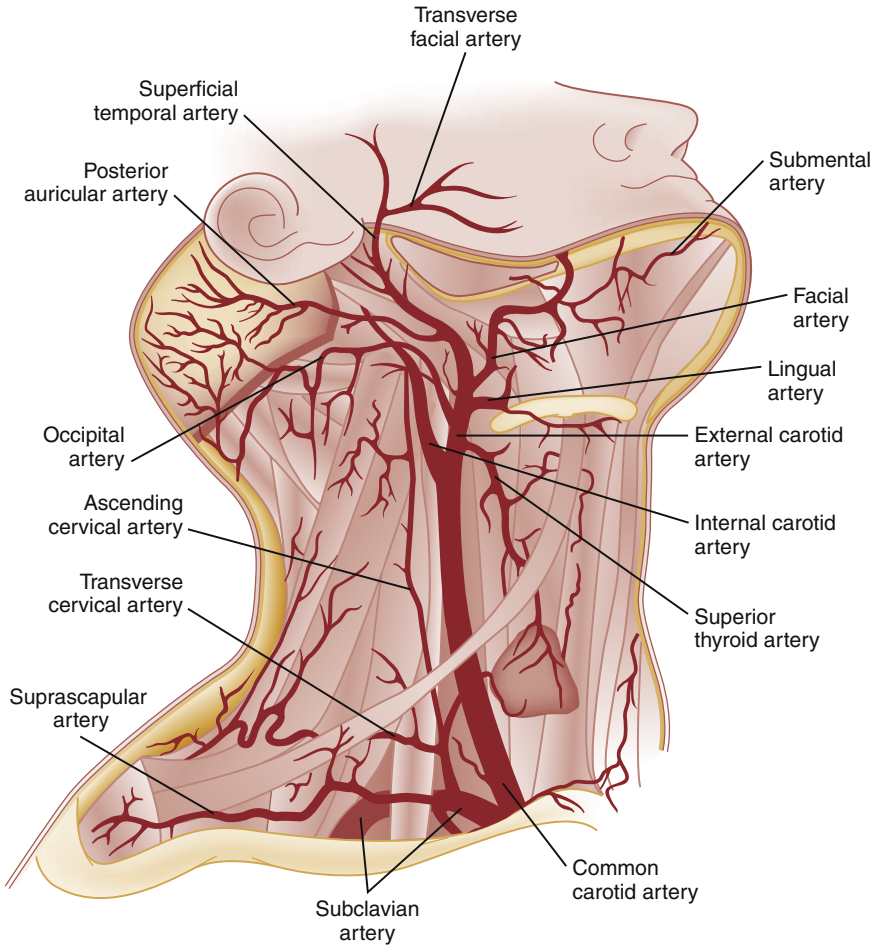

Fig. 34.3 Vessels of the face. (Adapted from Gray H. *Gray's anatomy*. Philadelphia: Lea & Febiger; 1918.)

Buried within the structure of the face are a series of glandular structures and ducts that are susceptible to injury. In the eye, the lacrimal glands lie within the orbits, superior and lateral to the globes, and secrete tears through ductules into the folds of the conjunctiva. The liquid flows medially into the puncta of the lacrimal canaliculi and drains into the lacrimal sac and then, via the nasolacrimal duct, into the nasopharynx.

The salivary system consists of the parotid, sublingual, and submandibular glands. The parotid is the largest of these glands, lying just anterior to the ear and wrapping around the mandible. The parotid is superficial to the masseter muscle and drains via the Stensen duct, a 5-cm tube that curves around the anterior edge of the masseter to enter the mouth opposite the second upper molar. In normal subjects, this duct is large enough to be palpated with the masseter clenched (Fig. 34.4). The sublingual glands lie entirely within the floor of the mouth and drain into the mouth via ductules. They surround the ducts draining the submandibular glands (Wharton ducts). The body of the submandibular gland is folded around the mylohyoid muscle so that a portion lies within the floor of the mouth and a portion lies external to it. The submandibular ducts run from the external portion of the gland to empty into the mouth on either side of the frenulum of the tongue.

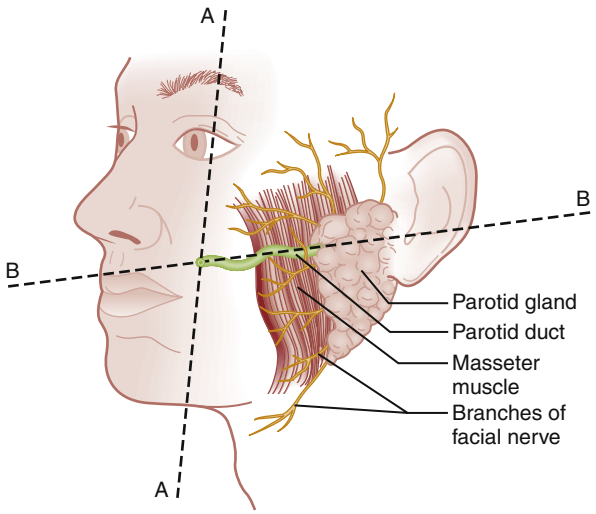

Fig. 34.4 Parotid gland and duct (Stensen), with the surrounding branches of the facial nerve. Line B approximates the course of the duct, which enters the mouth at the junction of lines A and B.

Pathophysiology

The basic mechanism of all injury is the transfer of energy, most often kinetic, to the structures of the body. When the energy overcomes the tolerance of the underlying tissue, injury results. Trauma traditionally has been classified as blunt or penetrating, but in many cases the effect is a combination of the two, such as the forehead injury (contusion and complex laceration) resulting from a child's fall against the sharp corner of a coffee table. The likelihood of injury is related to the amount of energy transferred and condition of the underlying tissue. Significant injury may result when an 80-year-old falls from standing to a carpeted floor, but it is more likely to result when the face strikes the steering wheel or dashboard in a high-speed motor vehicle collision (MVC).

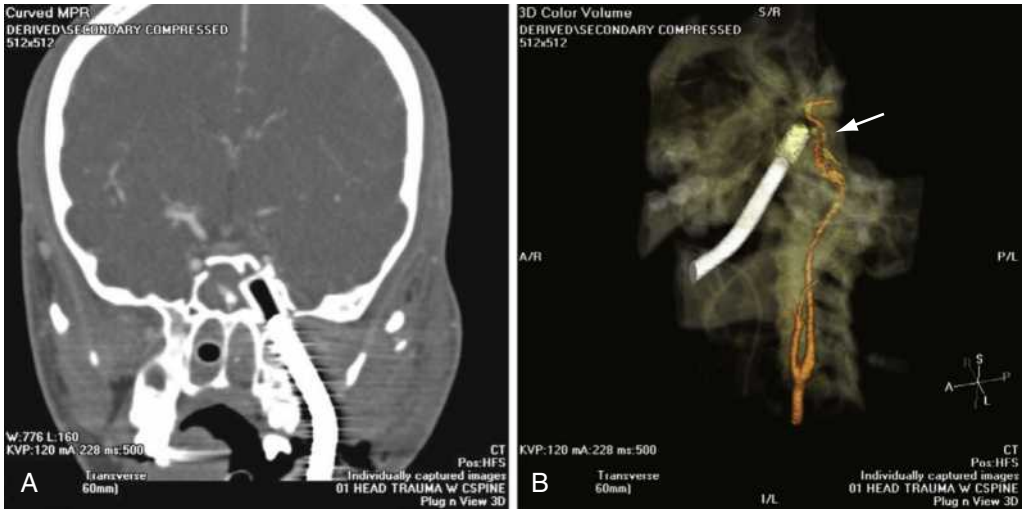

Fig. 34.5 Impalement by a turn signal lever. Computed tomography (CT) scan (A) and three-dimensional reconstruction (B) from a patient impaled through the face into the cranial cavity by the turn signal lever from his steering column when his vehicle rolled over in a single-car crash. The color three-dimensional reconstruction reveals a significant injury to the facial artery *(arrow)*.

The mechanism can be broken down into low-energy events, such as a fall from standing or walking into the corner of a piece of furniture, and high-energy events, such as an MVC. Understanding the mechanism of injury can help predict not only the severity of the facial injury but also the risk of associated cervical or brain injuries.[8] The face does little to protect the brain from traumatic injury. The incidence of traumatic brain injuries (TBI) in facial fractures has been reported to be anywhere between 11% to 80%.[9] Multiple studies have looked at predictive exam findings including Glasgow Coma Scale score less than 8 with loss of consciousness and fracture location site (upper versus midface) to demonstrate a positive correlation between TBI and facial fracture. Recent studies have suggested a significant increase in risk for brain injury among severe trauma patients with multiple facial fractures.[10-12] In addition, a recent review of over 20,000 trauma patients found that subjects with midface fractures are 2.4 times more likely to have a cervical spine injury (CSI) than patients without.[13,14] Cervical spine and brain injuries should be considered based on the trauma mechanism and presentation of the patient without allowing the presence or absence of a facial injury to change the level of suspicion.[15,16]

Penetrating trauma to the face from gunshots, stab wounds, blast debris, or impalement is often obvious and dramatic (Fig. 34.5). The emergency clinician should consider and search for associated intracranial, spinal, or vascular injuries, which are common in these cases.[17] Facial penetration from pellets (BBs) or small blast debris or shrapnel may be less obvious, and the face should be examined for these more subtle injuries. Nonlethal devices for recreation use or use by law enforcement with alternative ammunition (e.g., rubber bullets) can have substantial kinetic energy leading to significant facial and upper body trauma.[18]

Clinical Features

History

The history can provide information about the mechanism of the patient's facial injury. The history, however, may be limited in cases in which the patient's consciousness is altered by a head injury or intoxication, or under circumstances of secondary gain, involvement of law enforcement or suspicion of abuse. Patients with a clear sensorium are able to describe the events leading up to the injury and localize pain, deficits in motor or sensory function, and abnormalities of vision, hearing, taste, or smell. Although the association between facial trauma and brain or cervical spine injury has been debated, these possibilities should be considered, and the patient should be questioned regarding headache, peripheral weakness, numbness or paresthesias.

Physical Examination

Many facial injuries can be identified by simple inspection. During the primary assessment, an essential first step is attention to the patient's airway and inspection of the oropharynx. Airway compromise is often a result of intraoral trauma, and the examiner should note excessive bleeding, drooling, dysphonia, swelling of the tongue or posterior pharynx, and presence of avulsed teeth. When the patient is stabilized, a secondary survey should include a systematic examination of all facial structures and functions. Bony prominences should be palpated for abnormal motion, bony crepitus, tenderness, or step-off. Tenderness and massive swelling associated with facial trauma may preclude reliable palpation of a fracture. Consequently, areas of significant swelling should be imaged radiographically. Assessment of bony integrity includes testing for a possible Le Fort fracture. The upper incisors are grasped and pulled anteriorly. Movement of the upper alveolar ridge (LeFort type I), midface (type II), or entire face (type III) indicates a fracture (Fig. 34.6 and Fig. 34.7). Wounds may need to be palpated for underlying bony injury or foreign objects; anesthesia may be required for a thorough examination within the wound. Complex lacerations involving the cartilage of the nose or ear, eyelids, lacrimal apparatus, eyebrows, or vermilion border of the lips should be identified because their repair often requires advanced reconstructive surgical techniques.

Eyes and orbits. In addition to the examination of lacerations and contusions, the face should be evaluated for symmetry. The appearance of the zygomata may be evaluated by looking at the patient from above. This technique also draws attention to the relative position of the eyeballs. Orbital fractures may result in enophthalmos, and a large retrobulbar hematoma (Fig. 34.8) may cause exophthalmos. The anterior chamber of the globe should be inspected for hyphema or globe rupture. A complete examination of the eye requires specific testing. If the patient is able to cooperate, visual acuity should be documented. Contact lenses should be removed. In the event of a significant potential chemical exposure, the involved eye should be rapidly irrigated with saline or tap water and the pH of the residual eye fluid

measured. Fluorescein examination of the eye should be performed if there is any concern for a corneal abrasion. Victims of MVCs often have particles of glass in the conjunctiva or on the cornea, and these should be sought and removed. Extraocular motions should be tested. Blow-out fractures of the orbit may result in diplopia on upward gaze, secondary to entrapment of the inferior rectus muscle or anesthesia of the midface and upper lip in the distribution of the second division of the CN V. This often is secondary to neurapraxia resulting from a fracture through the infraorbital foramen or compression by a local hematoma (Fig. 34.9).

Oropharynx. The integrity of the mouth and nasal complex may be evaluated by listening to the patient's speech. A muffled or hoarse voice may indicate occlusion of the nose or nasopharynx, whereas dysarthria may indicate a mandibular fracture, tongue injury, or neurologic problem. Oral injury may result in progressive airway compromise, and dysphonia should alert the emergency clinician to the possible need for active airway management. The intraoral examination includes inspection of the palate, teeth, tongue, and gums and palpation with a gloved finger—the latter only if the patient is able to cooperate with the exam. The range of motion of the mandible should be determined. If the maximal incisor opening is less than 5 cm, a mandibular fracture may be present. Trismus is likely to indicate a fracture or significant hematoma within the face. If awake, the patient's impression about the normalcy of bite occlusion is a more sensitive determinant of a fracture of the mandible than the emergency clinician's clinical impression. Being able to perform a tongue blade test (grasping and holding a tongue blade between the teeth while the examiner pulls gently) is associated with a greatly reduced probability of mandibular fracture. If the patient is able to crack the tongue blade by biting on both sides of the mouth, studies have demonstrated the negative predictive value for a mandibular fracture is about 95%.[19] Injury to the parotid area should raise suspicion of disruption of the Stensen duct. The opening of the duct opposite the second upper molar should be examined for bleeding while the gland is compressed. If blood is expressed from the duct or the severed ends of the duct are identified within a facial wound, specialized repair over a stent is often required to prevent formation of a cutaneous fistula.

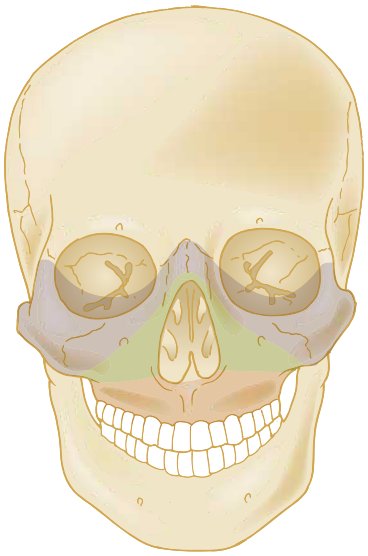

Fig. 34.6 Le Fort classification. Le Fort type 1 is shaded in *red*, Le Fort type II is shaded in *green*, and Le Fort type III is shaded in *blue*.

Ears. Otoscopy is performed to evaluate the integrity of the external canal, look for hemotympanum, and assess for otorrhea. Subcutaneous hematomas of the ear (Fig. 34.10) will require drainage. Clear fluid from the ear after trauma should raise the possibility of a cerebrospinal fluid (CSF) leak and basilar skull fracture. At the bedside, a drop of the fluid may be placed onto filter paper to demonstrate the halo or double ring sign where a rapidly advancing halo of clear fluid around red blood defines a positive test result (Fig. 34.11). This quick bedside test has a sensitivity above 85% when concentrations of blood products and other fluids are relatively equivalent, but does not differentiate between CSF and saline, saliva, or other clear fluids. Leaks can also be detected easily by β_2-transferrin electrophoretic examination, high-resolution computer tomography (HRCT), magnetic resonance cisternography

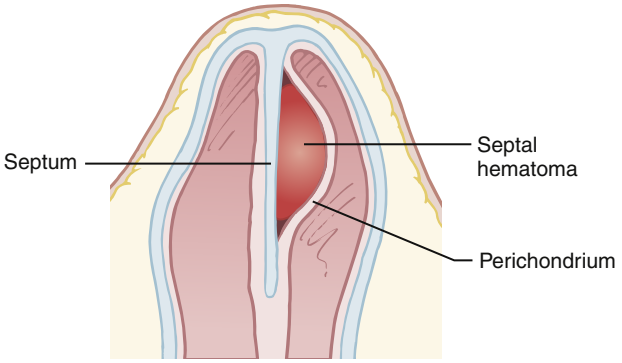

Fig. 34.12 Septal hematoma.

with contrast, and surgical exploration; however, these methods can be timely, costly, or invasive.[20,21]

Nose. The nose is palpated for tenderness, crepitus, or abnormal movement; then each naris is held closed in turn to ensure that the patient is able to breathe through either side. The septum should be examined visually for the presence of a septal hematoma (Fig. 34.12), which appears as a large purple mass extending from the septum. If there is any concern about CSF rhinorrhea, the aforementioned diagnostic filter test may be performed.

Neurologic Examination

Light touch should be tested for all three branches of CN V. Motor function (CN VII) can be examined by having the patient actively wrinkle the forehead, fully open and close the eyelids, smile widely, and bare teeth. Asymmetry of these movements indicates a potential nerve injury. Peripheral injuries to CN VII should cause discernible weakness in the forehead as well as the orbital and oral musculature, whereas central injuries will result in preserved forehead function because of crossing fibers distal in the course of the nerve. In an altered

Fig. 34.13 Facial Contusion. (A) Day 1 with small abrasion and ecchymosis. (B) Day 3 development of periorbital swelling and ecchymosis secondary to gravity. (C) Day 7 continued progression while healing.

or uncooperative patient, CN V (the ophthalmic branch of the trigeminal nerve) and CN VII can be quickly assessed by testing the corneal reflex.

DIFFERENTIAL DIAGNOSES BASED ON ANATOMIC SITES

Soft Tissue Injuries and Lacerations

Soft tissue injuries to the face present an acute cosmetic concern for the patient. Areas of injury may be contused, lacerated, or abraded. When cleaned of any debris, abrasions may be covered in a thin layer of antibiotic ointment and left exposed or covered. Patients with significant debris tattooing will benefit from topical lidocaine for anesthesia before vigorous scrubbing to remove embedded material. A delay in the removal of embedded material will result in further injury due to epithelialization. The patient should be cautioned to anticipate the development of periorbital swelling or ecchymosis over time, if contusions involve the brow, forehead, or bridge of the nose (Fig. 34.13). Head elevation and use of cold compresses may limit the degree of swelling and bruising.

Cosmesis is a priority for patients with facial lacerations and they may request facial specialty services for even minor wounds. Depending upon the size, shape, depth and location of the wound and the commitment of time dedicated to repair, consultation or referral to consultants (otolaryngology or plastic reconstructive surgery) may be appropriate if available. Children and patients with behavioral problems may require sedation to allow sufficient control for a cosmetic repair. Repair of facial wounds in uncooperative patients who are acutely intoxicated may be delayed until they are clinically sober enough to cooperate for the procedure.

The general principles and approach to wound management can be referred to in Chapter 50. Facial wounds should be explored for depth, foreign bodies, and underlying fractures, after appropriate anesthesia has been achieved. Field or facial nerve blocks can be used to minimize local distortion of wound edges. Irrigation may not be necessary in simple, clean facial wounds closed within 6 hours. For nongaping wounds smaller than 3 cm, a single-layer closure may be sufficient. For gaping wounds deeper than the dermis, subcuticular buried sutures of absorbable materials should be placed to close any potential space and relieve any tension on the skin. For simple skin closure, tissue adhesive is faster, less painful, results in equally effective cosmetic results in adults and children, and can be used to close the skin over deeper sutures. Tissue adhesive use is contraindicated to repair complicated wounds (stellate lacerations), animal bites, mucosal surfaces, or across mucocutaneous junctions or high tension areas. Compared with sutures, tissue adhesive has the additional benefit of not requiring later removal, but care must be taken not to glue the eye, nares, or mouth closed unintentionally.[22,23]

Antibiotic therapy use in the management of facial injuries continues to be debated and is highly variable in clinical practice. Given the increasing concerns for antibiotic resistance, minimizing infectious complications, and concern for rising health care expenses, attention has turned to appropriate antibiotic stewardship. Antibiotics are not required for simple facial wounds, which rarely become infected, and are best managed with copious irrigation and careful débridement. Bite wounds, wounds with any evidence of devascularization, wounds through and through the buccal mucosa, wounds involving the cartilage of the ear or nose, wounds with extensive contamination, and the immunocompromised patient are exceptions to this rule. Antibiotics should be selected on the normal bacterial flora that is associated with the affected area.[24-26]

Mouth

Lip lacerations are common and require special consideration to maintain the appearance of the lip edge or vermilion border and natural architecture of the philtrum. Because infiltration of even a small volume of local anesthetic may distort and blanch the soft tissue, marking the vermilion border (with nonpermanent ink) before anesthesia facilitates a cosmetic repair. To minimize any divots and maximize cosmesis and function, wounds that include the muscular layer should be closed in multiple layers. Skin may be closed with nylon or other nonabsorbable sutures; the lip and mucosa should be closed with absorbable sutures. Lip lacerations are not amenable to closure with wound adhesives.

Through-and-through lacerations of the mouth should be closed in layers, beginning with the intraoral mucosa and working outward in layers toward the skin. After closure of the mucosal layer, copious

irrigation of the external wound is indicated to remove lingering bacteria that otherwise might be incorporated into the wound. Prophylactic treatment with penicillin has been shown to decrease the risk of infection after significant through-and-through lacerations. Lacerations that approach the parotid (Stensen) or submandibular (Wharton) duct should be evaluated before intervention for ductal integrity. Saliva milked from the gland should be thin and clear and exit the duct readily. If a duct is involved or there is any doubt, a facial specialist should be consulted for evaluation and repair.[27]

Small lacerations of the tongue or oral mucosa do not require repair. Lacerations that gape (including deep tongue lacerations), collect food, and are likely to heal with a significant divot or thick scar that may hinder eating and speaking functions require repair. Deep or gaping lacerations of the tongue or oral mucosa should be closed (in layers, if necessary) with absorbable sutures that do not require removal. To facilitate repair, an assistant may be needed to expose the laceration by grasping the tongue between gauze and holding a segment outside the mouth. Some advocate placing a thick temporary suture through the distal tongue (after appropriate anesthesia) to facilitate this exposure. Discharge instructions for intraoral lacerations, whether or not they are repaired, should include gentle cleansing (swish and spit) with a mild antiseptic.

Cheeks

Contusions of the cheek should raise concern for an underlying zygomatic or maxillary fracture. Lacerations of the lateral cheek may involve the parotid gland or Stensen duct. Failure to identify and repair ductal injury results in retention of salivary fluid and enlargement of the gland or formation of a cutaneous fistula. Lacerations in the area anterior to the tragus may include injury to the facial nerve, and a careful neurologic examination should be carried out before closure. Langer lines change from mostly horizontal in the superior cheek to diagonal at the nasolabial fold, then curve convexly around the mouth; these changes should be taken into consideration when débridement is required as part of a complex laceration repair.

Nose

Because of its anterior position, soft tissue injuries to the nose are common. Almost any nasal trauma can result in epistaxis. In general, epistaxis is controllable by pinching the cartilaginous anterior nose closed between two fingers and holding compression for approximately 10 minutes. If it is not controlled, anterior packing is indicated. Intranasal inspection is required with nasal injuries to assess for a septal hematoma, which appears as a dark purple or bluish mass against the septum. Hematomas require drainage because they are associated with necrosis of the septum if left untreated. Simple incision and expression of the clot followed by anterior packing are sufficient. Traditional teaching has been that any patient with nasal packing should receive prophylactic antibiotics to cover *Staphylococcus* and *Streptococcus* spp. to prevent sinusitis and toxic shock syndrome. Toxic shock syndrome is a rare but measurable complication of postoperative nasal packing; however, the incidence with primary packing is unclear. There is no evidence that prophylactic antibiotics change this infectious risk. Although there is limited data, systemic prophylactic antibiotics have shown no benefit with nasal packing and are unnecessary.[28] A topical antibiotic, such as chlorhexidine-neomycin (Naseptin), can be used and is a more cost-effective alternative.

Because of the location and structure of the nasal bridge, fractures of the thin bones of this area are common. Patients with contusion or tenderness over the bridge of the nose may be assumed to have a fracture of the nasal bones. If the nose is acceptably straight on initial evaluation, there is no septal hematoma, epistaxis is controlled, and the patient is able to breathe out of each naris, no further evaluation is required emergently for isolated nasal injuries. Dedicated radiographs of nasal bones have little clinical value.

Swelling over the bridge often precludes determination of the acceptability of the appearance at the time of injury. The patient may be provided with a referral for outpatient specialty follow-up in 3 to 5 days if the appearance at that time, when the swelling has subsided, is still unacceptable. In a series of surgically repaired simple nasal bone fractures, septal fractures were present in more than 50% of cases. CT scanning does not provide any advantage in diagnosing septal fractures and should be reserved for evaluating patients suspected of having other, more complex fractures.[29]

Children with nasal fractures may have premature closure of sutures and uneven growth, particularly of the vomeroseptal line. In a child, no imaging studies are indicated for isolated nasal injuries, but a consultant should evaluate swelling and tenderness over the nose, preferably within 3 days with a repeat examination in 7 days once the area of swelling has decreased.[30,31]

Simple lacerations of the nasal skin may be closed with sutures or tissue adhesive. If needed, anesthesia may be achieved with a nerve block of the infraorbital or supratrochlear nerves. The large pores typically present in the area of the nasal ala increase the likelihood of stitch abscesses after laceration closure in this area. Closure with an absorbable running subcuticular suture may limit the risk of this outcome. If involved, the cartilaginous portions of the ala should be closed in a separate layer with absorbable 4-0 sutures. For lacerations through and through the nose, repair should be carried out from the mucosal layer outward, with copious saline solution irrigation between layers.

Ears

Blunt trauma to the ear may cause hematoma formation in the subperichondrial potential space. Such hematomas are the prelude to the development of a so-called "cauliflower ear" and should be drained by aspiration. Re-accumulation of the hematoma is prevented with a compressive dressing of the ear, but reexamination by a specialist is crucial, and re-aspiration should be performed as necessary.

Ear lacerations often involve the cartilage. The ear may be anesthetized with a field block; 1% lidocaine without epinephrine can be used as a local anesthetic for direct infiltration of the ear. 1% lidocaine with epinephrine can be utilized for a regional block. Simple skin wounds may be closed in a single layer. Lacerations to the underlying cartilage should be repaired with absorbable material. If there is significant degloving or loss of overlying tissue, a facial specialist should be consulted. Portions of aural cartilage may be saved temporarily in a distant dermal pocket for later reconstruction. Because cartilage is avascular, chondritis, when it occurs, requires extensive débridement and is disfiguring. No randomized trials have been performed, but when the cartilage of the pinna requires repair, antibiotic prophylaxis covering typical skin flora as well as *Pseudomonas* is recommended. Compressive ear dressings (splints) are indicated after any significant repair. Ear injuries occurring before age 1 year or injuries to both ears in children are less common and should raise the suspicion of abuse.[32]

Eyes

Simple eyelid lacerations may be repaired in a single layer. Wound adhesives should be used with caution anywhere near the eye; care must be taken not to glue the eyelids open or shut. Lacerations that involve deeper structures, loss of tissue, or the lid margin should be referred to a consultant. The integrity of the lacrimal apparatus can be assessed by instilling fluorescein into the eye and assessing for dye in the wound. A facial consultant should repair any injury to the sac or lacrimal duct.[33]

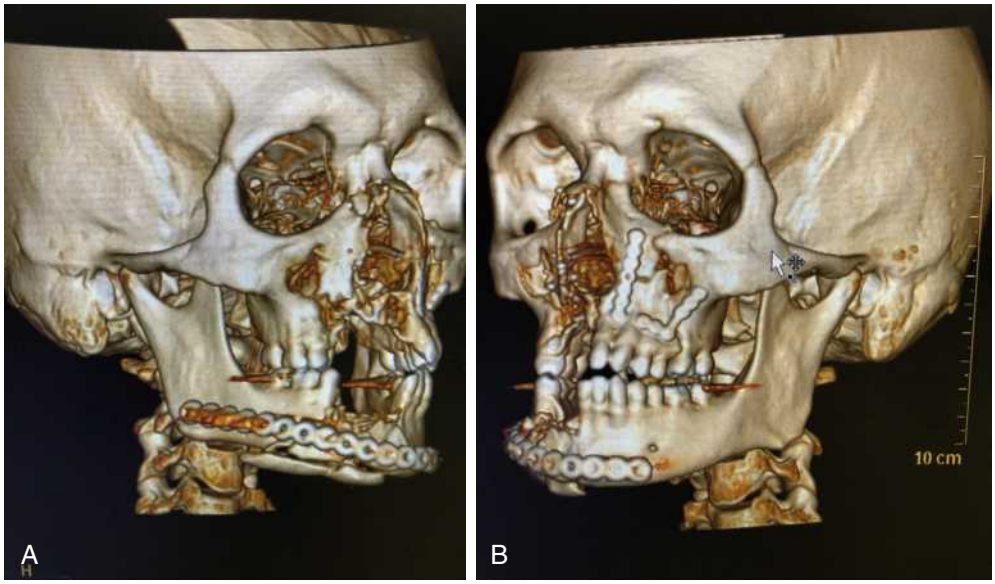

Fig. 34.14 3-D CT image of partial repair of a GSW with microplates.

Eyebrow lacerations are common because of the overhanging supraorbital ridge. Careful wound exploration should be performed to assess the integrity of the underlying bony structure. No shaving should be performed because the brow hairs may not regrow, and the hairs are necessary for realignment. If débridement is required, it should be done parallel to the hair follicles (skived) rather than perpendicular to the skin. This approach minimizes the bald area of the scar. Closing the deeper muscular layers preserves the normal expressive function of the brow. Injuries to the globe are further discussed in Chapter 57.

Fractures and Dislocations

For the emergency clinician, the key to facial fractures is accurate diagnosis and appropriate referral. Many nondisplaced or minimally displaced facial fractures may be managed on an outpatient basis, with definitive repair or fixation delayed several days. In adults, fractures develop firm fibrous union within approximately 10 to 14 days; however, definitive repair is performed most easily before day 7. Facial fractures in young children are relatively rare and may be incomplete or greenstick fractures. Fibrous union in these cases is rapid; early reduction (within 3 days) is recommended.

Broad-spectrum antibiotics treating sinus and nasal pathogens are indicated for open fractures and fractures that violate a sinus. Patients with fractures through the nasoethmoid (NOE) complex that violate the maxillary bones or floor of the orbit should be cautioned to avoid sneezing and blowing the nose because these activities force air out into the soft tissues of the face.

Surgical repair of simple nasal fractures may be performed closed and the nose splinted internally or packed. Repair of fractures of the floor of the orbit, when necessary, may require the placement of a silicone patch to occlude the opening into the maxillary sinus. Operative repair of most other fractures of the face is performed with the use of small metal plates (microplates), screws, or wires to stabilize fragments by attaching them to unbroken segments of bone and if possible, reconstructive efforts are made to preserve facial symmetry. Complex facial fractures may have to be repaired in a staged fashion, depending on the patient's degree of injury and amount and quality of the bone remaining (Fig. 34.14). Much of this surgery is best accomplished when the fragments are still freely mobile but initial swelling has been reduced, on postinjury days 3 to 5.

Forehead

Fractures through the superior forehead may occur above the level of the frontal sinus and represent skull fractures rather than facial fractures and should be addressed with special attention to risk of injury to the underlying brain. Unlike other skull fractures, frontal skull fractures often require repair for cosmesis alone. More often, fractures in this area involve the anterior portion of the frontal sinus. If even minimally displaced, these fractures require elevation for cosmesis. Fractures through the anterior wall of the frontal sinus are likely to continue through the posterior wall, and CT scanning should be performed to assess for this complication; if present, a CSF leak should be assumed until proved otherwise. CSF leaks into the frontal sinus may also manifest in a delayed manner, days or years after the initial injury. For many frontal sinus fractures, complex repair or surgical obliteration may be required to treat this complication.

Orbit

The most common simple fracture of the orbit is a blow-out fracture of the orbital floor, often caused by a fisted blow or ball striking the globe, increasing intraorbital pressure enough to force orbital contents through the floor. This injury may happen without other significant bony facial injury (Fig. 34.15). When displaced, the bony fragments are depressed and sag into the underlying maxillary sinus. If the inferior rectus muscle is entrapped in the defect, the patient is unable to elevate the globe on the affected side, resulting in diplopia on upward gaze. Stretching or compression of the infraorbital nerve, which passes through the floor, may cause anesthesia over the anteromedial cheek and upper lip. Because signs of entrapment may result from contusion and edema and be self-limited, immediate repair is not necessary, but follow-up evaluation is recommended. Repair typically is performed 1 or 2 weeks after the injury for persistent enophthalmos or diplopia. Because of the acute limitation in the visual field, discharge instructions for patients with acute diplopia should include patching for comfort and a request not to drive until the diplopia is resolved.

Fractures of the medial orbital wall, through the lamina papyracea, are often associated with nasal injury or a more general midface fracture, particularly with telescoping of the midfacial skeleton. Herniation of orbital contents into the ethmoids may occur. Patients with orbital fractures with a medial component are more likely to have ocular signs

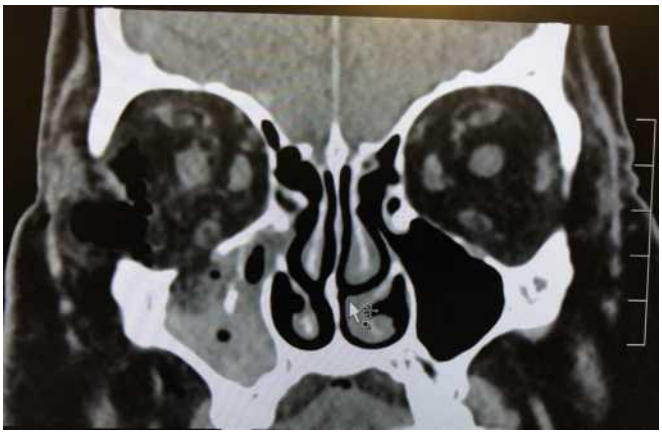

Fig. 34.15 CT imaging of a right orbital floor fracture with subtle downward herniation of the right inferior rectus muscle concerning for possible entrapment.

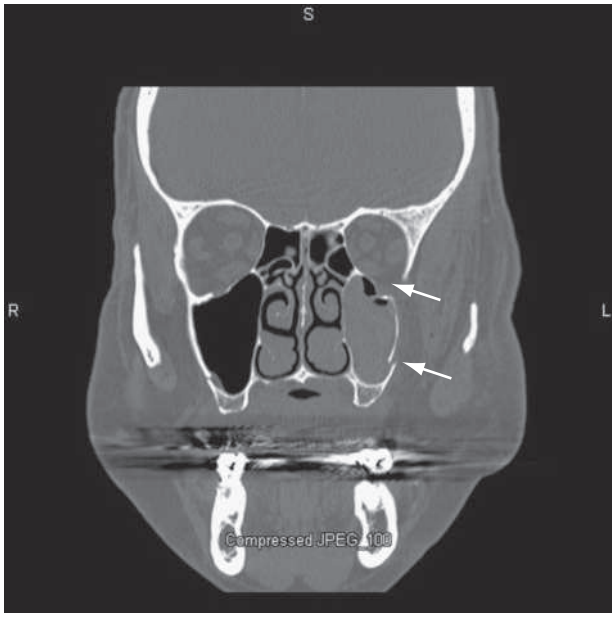

Fig. 34.16 CT scan of fractures of the left orbital floor *(top arrow)* and left lateral maxillary wall *(bottom arrow)*. There is streak artifact from dental devices.

of diplopia or exophthalmos than patients with fractures not involving the medial wall. Fractures involving the superior orbit and the base of the frontal sinus include issues described previously concerning anterior skull injuries. Herniation of orbital structures into the frontal sinus is rare.

Many orbital fractures involve more than one wall of the orbit and may be present in a constellation with complex midface fractures (Fig. 34.16). Several classification schemes aimed at improving communication among emergency clinicians, radiologists, and maxillofacial surgeons have been proposed, but no classification system has been generally accepted.

Injury to the orbit, particularly fractures, can cause a hematoma to form within the orbit, behind the globe. If significant in size, a retro-orbital hematoma can elevate retro-orbital pressure, causing acute exophthalmos and a compartment syndrome of the retro-orbital space. Stretching of the retinal artery limiting flow to the retina or neurapraxia of the retinal nerve may cause decreased visual acuity or blindness.

Fig. 34.17 Coronal slice from maxillofacial CT scan of a patient with blunt facial trauma. Acute comminuted fractures of the outer table of bilateral frontal bones, bilateral nasal bones, bony nasal septum, nasal spine, bilateral orbital floor, bilateral lateral and medial orbital walls, roof of the right orbit, posterior wall of the right sphenoid sinus, bilateral pterygoid plates, and anterior, medial, and posterolateral walls of the bilateral maxillary sinuses are noted. There is extraconal air bilaterally. There is near-complete opacification of bilateral maxillary sinuses and bilateral ethmoid air cells with hyperdensity within, suggestive of blood products. There is opacification of bilateral frontal and sphenoid sinuses with hyperdensity within, suggestive of blood products. Endotracheal and orogastric tubes are noted.

Orbital emphysema (Fig. 34.17) associated with fractures of the medial wall or floor rarely results in a space-filling lesion with the same effect. This is a true emergency and drainage of the air or blood via lateral canthotomy with cantholysis may be necessary to save the patient's vision. Needle aspiration of entrapped air may also be attempted, but this may be best left to an ophthalmology consultant, given the proximity of the globe.[34]

Midface

Tripod (or trimalar) fractures are among the simplest fractures of the midface and include fractures of three bones—the lateral orbit, zygoma, and maxilla (Fig. 34.18). Typically caused by a direct blow, these fractures are often displaced and require operative stabilization. If left untreated, the area may sink posteriorly and inferiorly, giving an unacceptable appearance of facial asymmetry emphasized by the inferior position of the orbit and malar flattening. On initial physical examination, there may be a large contusion over the cheekbone, enophthalmos, or malocclusion of the upper teeth. Fractures through the anterior wall of the maxillary sinus may denervate the maxillary teeth because the dentoalveolar nerves transverse through this area.

More complex fractures of the midface are classified with the Le Fort system, although many complex fractures defy this simple system. Other classification systems exist. One system has divided the face into a matrix of vertical and horizontal beams to describe the fracture patterns. Another system has utilized CT scan findings to describe low- and high-impact fractures. Despite the Le Fort system's

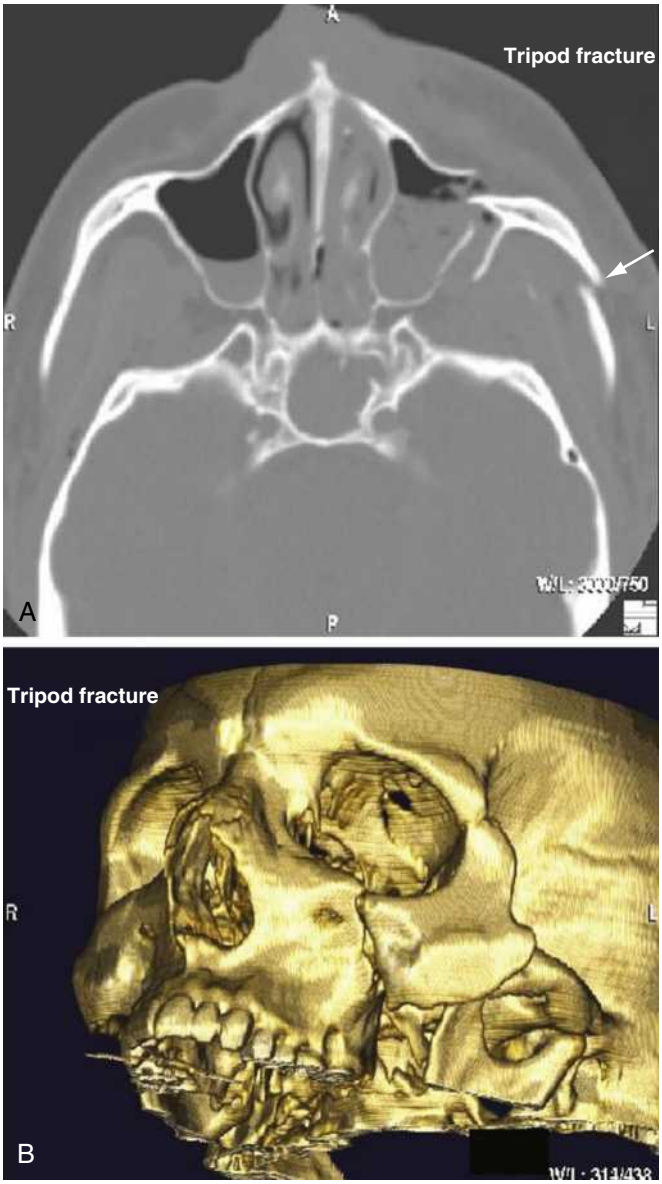

Fig. 34.18 Tripod fracture. (A) CT scan. (B) Three-dimensional reconstruction.

limitations in describing comminuted, complex fracture patterns, it is still the most accepted classification method used. All Le Fort fractures involve the pterygoid plate, and the injury pattern can be unilateral, bilateral, or a combination. A Le Fort I fracture involves a transverse fracture through the maxilla above the roots of the teeth and may be unilateral or bilateral. Patients may report malocclusion, and the maxilla may be mobile when the upper teeth are grasped and rocked. A Le Fort II fracture is typically bilateral and pyramidal in shape. It extends superiorly in the midface to include fractures of the nasal bridge, maxilla, lacrimal bones, orbital floor, and rim. In these cases, the nasal complex moves as a unit with the maxilla when the teeth are grasped and rocked. With CT scanning, the full extent of comminution can be appreciated. Simple Le Fort III fractures are rare and involve fracturing of the connections between the elements of the skull and face (craniofacial dysjunction). These fractures start at the bridge of the nose, extend posteriorly along the medial wall of the orbit (ethmoids), along the floor of the orbit (maxilla), and through the lateral orbital wall, and finally break through the zygomatic arch. Intranasally, they extend through all the lesser bones to the base of the sphenoid and frequently are associated with a CSF leak.[27]

Significant force to the bridge of the nose may fracture the deep naso-orbitoethmoid (NOE) complex without creating a formal Le Fort pattern. Fractures to the central portion of the ethmoid bone (cribriform plate) are likely to be associated with a CSF leak and commonly result in anosmia.

If possible, patients with a CSF leak should have the head elevated 40 to 60 degrees. Head elevation minimizes the intracranial pressure, with the idea of reducing CSF flow and allowing the leak to seal. Often, these patients are treated with antibiotics; however, this practice is controversial, and most of the studies supporting their use involve small, local case series. Although the evidence is equivocal, it is recommended that appropriate prophylactic antibiotics be used in patients who may be immunosuppressed, have an indwelling device, or have an open contaminated wound.[25,26] Neurosurgeons should be involved in the care of patients with CSF leaks, although many leaks will resolve spontaneously.[20]

Fractures involving the deeper structures of the midface may be associated with significant bleeding into the nose or oropharynx. Anterior nasal packing may be performed safely in the adult patient with multiple trauma. Even a 10-cm anterior pack should not reach the skull base in a skeletally mature person. Significant or massive bleeding into the posterior nasopharynx presents a complex problem and occurs in less than 1% of patients with midface fractures. It may be treated with nasal packing and immediate fracture reduction. The use of a long balloon catheter (or Foley catheter) for the control of posterior bleeding should be avoided unless a skull base fracture has been ruled out and the patient's anatomy well understood. The unintended positioning of these items within the intracranial or intraspinal space during blind nasal insertion has been well documented and, when the face is grossly distorted, preinsertion measurement or other methods of preventing this outcome have not been adequately tested. A recent case report documented an intracranial location on CT imaging of a 9-cm Rapid Rhino, placed in the field for epistaxis, secondary to the patient's extensive facial injuries.[35] An alternative method for containing posterior nasal bleeding is to provide compression by packing the area with gauze (soaked with tranexamic acid or TXA) by hand from the oropharynx after intubation.

Zygoma

Isolated fractures of the zygoma are relatively rare, usually the result of a direct blow, and often displaced. Because the condyle of the mandible may disturb zygomatic fragments while moving, fractures with significant displacement are likely to result in trismus or discomfort with mouth opening. Surgical repair is usually required to return the cheekbone to an acceptable position.

Mandible

Fractures of the mandible can result from any significant force applied to its U shape. Because of its shape, multiple fractures may result from a single blow, and the fracture sites may be distant from the site of impact.[36] Depending on the location of the fractures, the patient may have trismus (fractures of the coronoid process, neck, or rami), dental malocclusion, swelling, and tenderness intraorally or externally. Anesthesia of the lower lip may occur if there is damage to the inferior dental nerve.

Fractures of the symphysis, body, angle, or rami usually require early splinting, typically by the placement of arch bars to accomplish interdental fixation, commonly resulting in wiring the jaw shut. Fixation limits fracture motion, decreases the patient's discomfort and, if the fracture is minimally displaced, may provide complete fracture

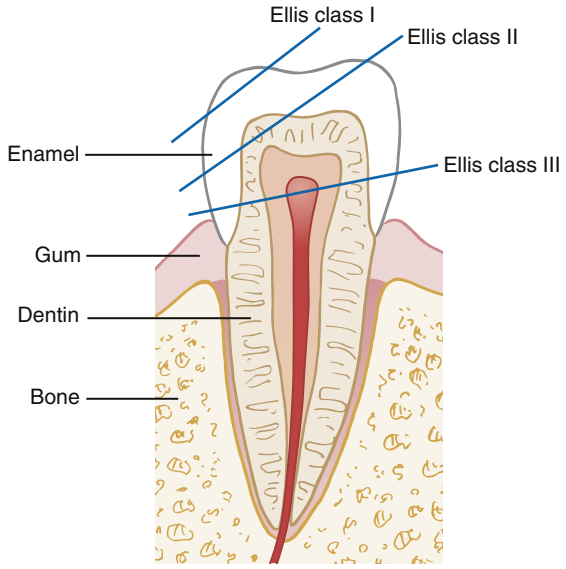

Fig. 34.19 Ellis classification of tooth fractures.

care. Impacted and nondisplaced fractures occasionally are treated with a soft diet and pain control, and fractures of the coronoid alone usually require no intervention, but these decisions should be made in consultation with an oral surgeon or other specialist. Arch bars may be placed in the ED or operating room, typically by an oral and maxillofacial surgery consultant. Fracture reduction may require the extraction of teeth adjacent to the fracture line. Patients with open fractures often require antibiotics and hospitalization. When the fractures are closed and adequate stabilization can be obtained, elective operative repair can be performed as an outpatient procedure in 3 to 5 days.[37]

Pediatric mandibular fracture management depends on the type of fracture (condylar is the most common injury site) and the dental and skeletal developmental phase. Conservative management with soft diet, pain control, and close observation is often utilized for non-displaced uncomplicated fractures. Early closed reduction and shorter immobilization times are usually favored when necessary secondary to the rapid healing time and high osteogenic potential of children compared to adults. Because of the frequency of growth disturbances, children in a mandibular growth phase, younger than 4 or older than 11, who have sustained a blow to the chin and who have any trismus or tenderness over the TMJ should be assessed with Panorex imaging for a condylar fracture and referred appropriately.[31]

Dental and Alveolar Trauma

Trauma to the teeth may occur with or without other facial injury. In the setting of caries, tooth fractures may occur with eating foods. Tooth fractures are classified by the Ellis system. Class I fractures involve only the enamel of the tooth, are not painful, and can await dental evaluation on an outpatient basis. Class II fractures expose the yellow dentin and may be painful. These also can await dental care but may be covered with a dressing of calcium hydroxide and aluminum foil. Class III fractures expose the dental pulp, seen as a red line or dot, and are exquisitely painful. These require early evaluation by a dentist or endodontist (Fig 34.19).

Sufficient energy to the area avulses teeth from their sockets. Multitrauma patients, particularly patients who are intoxicated, required to be supine for cervical spine immobilization, or neurologically impaired, should have avulsed or mostly avulsed teeth removed from the mouth and placed externally in saline to prevent aspiration of the tooth. In a

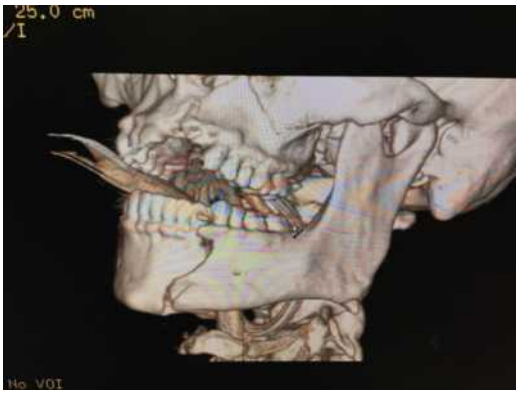

Fig. 34.20 Left comminuted fracture of the parasymphyseal mandible involving the alveolar ridge and extending to the root of the first mandibular molar. An endotracheal tube is also present.

critically ill multitrauma patient, avulsed teeth should be among the lowest priorities and are reimplanted only if the care of other injuries allows it, and there is little risk of aspiration if the teeth loosen.

To perform a reimplantation, the emergency clinician disturbs the socket as little as possible, gently rinses off the tooth (the root should not be wiped), and places it into the socket where it clicks into place. If the tooth is only partially avulsed, extruded, or laterally luxated, it should not be removed; it should be reimplanted or relocated. Intruded teeth should not be manipulated. Reimplantation can be painful and may require local anesthesia with a regional dental block. Alternatively, the area of a single socket may be anesthetized by placing approximately 0.5 mL of 1% lidocaine with epinephrine into the buccal sulcus and gum on the outer side of the alveolar ridge. After reimplantation, the tooth requires stabilization with acrylic splint or wiring to the adjacent teeth. Appropriate antibiotics such as penicillin and tetanus immunization prophylaxis should be given, as well as dental follow-up for possible root canal if the reimplantation does not take.

It may take weeks to assess the final success of reimplantation. The extra-alveolar time, periodontal state, and storage process are important factors in the initial success. Teeth that are successfully reimplanted within 20 to 30 minutes have fewer complications, including signs of inflammation and bone resorption. Studies also have shown that age is a factor in root resorption of teeth that have prolonged avulsion times.[38,39]

In children, the front maxillary incisors are frequently avulsed in facial injuries. After reimplantation, these teeth may ankylose and fail to grow normally, requiring later extraction or orthodontic intervention for cosmesis. This situation is most common in children aged 6 to 10 years with avulsed adult teeth.

Efforts should be made to ensure that the aspiration of avulsed teeth is ruled out after significant trauma, especially if the patient is intoxicated or is neurologically impaired. A chest x-ray examination may be used for screening for aspiration in an acute event. If the tooth is visualized below the diaphragm on radiograph, it does not require retrieval. Teeth lodged in a bronchus or the esophagus require bronchoscopic or endoscopic retrieval. Aspirated teeth result in pulmonary abscess formation unless removed.[36]

Fractures through the alveolar ridge may result in a group of teeth being dislodged and out of position, often leaning inward. These teeth require stabilization with wire or acrylic splinting after fracture reduction has returned the teeth to their correct location. The involved teeth may or may not survive after such a fracture, and follow-up with a dentist or oral surgeon is required (Fig. 34.20).

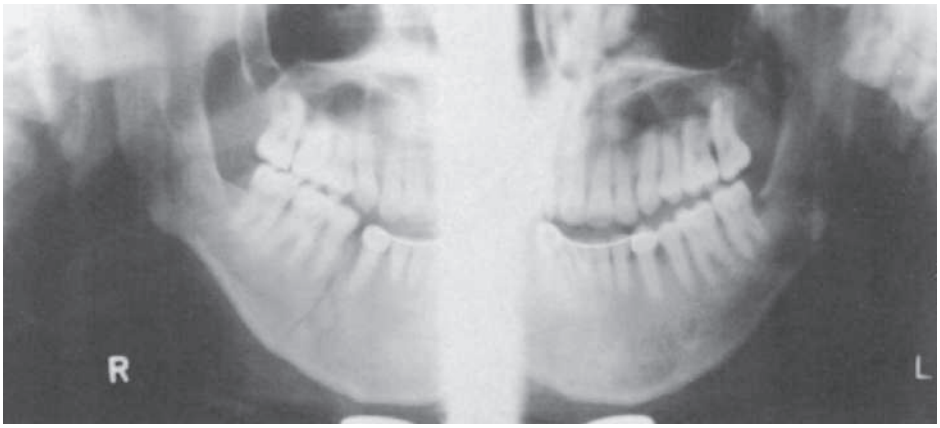

Fig. 34.21 Panoramic radiograph of the mandible shows fractures through the left angle and right body. A dental appliance is in place on the lower incisors.

Temporomandibular Joint

Trauma to the TMJ may tear the meniscus or injure the collateral ligaments holding it in a normal position. This injury can cause the meniscus to fail to translate normally, resulting in clicking or popping as it catches up to the condyle or inability to open the mouth fully because the meniscus fails to translate completely. Patients without fracture but with acute pain and difficulty with mouth opening should be placed on soft foods, asked not to yawn or struggle to open their mouths widely, and referred to an oral surgeon with expertise in TMJ pathology. Pediatric patients with posttraumatic internal derangements of the TMJ are prone to asymmetry of facial growth and retrognathia.

Anterior dislocation of the TMJ can occur after any activity that involves spontaneous wide opening of the mouth. When the condyle is out, spasm of the muscles of mastication prevents spontaneous reduction. Significant trauma is more likely to cause a fracture-dislocation. Simple dislocation may be unilateral or bilateral, and the patient may report being unable to close the mouth. In unilateral dislocation, the jaw is rotated laterally away from the affected joint; bilateral dislocation causes significant protrusion of the jaw. The jaws of these patients are often locked in an open position causing drooling and difficulty handling secretions. Speech is often garbled by the patient's inability to touch the tongue to the roof of the mouth or maxillary teeth. There is a depression in the area of the affected TMJ on inspection of the patient's facial contour.

If the mechanism of injury suggests a fracture, the area should be imaged with plain radiograph or Panorex examination before reduction is attempted. For reduction of a simple dislocation, the patient should be seated upright. For leverage to be maximized, the best position may be for the patient to be seated in a regular chair, with the operator standing in front of the patient. As in dislocations of other joints, adequate analgesia and sedation are required for success. With the thumb or index finger placed into the buccal sulcus on either side of the mouth, the angle of the jaw is pressed downward while the symphysis is rotated (chin) upward and backward. Care should be taken not to place fingers along the crowns of the teeth; when relocation occurs, spasm of the muscles of mastication snaps the mouth shut with force. If this is the only location possible for the emergency clinician's fingers, gauze wrappings should be placed to protect them from injury.

DIAGNOSTIC TESTING

Imaging

The choice of imaging for facial fractures depends on the patient's stability, patient's ability to cooperate, and availability of various options. The two main options are plain radiograph examination for isolated injuries and CT scan. Fractures are better visualized with CT than with magnetic resonance imaging (MRI), so MRI is not an optimal imaging choice. In patients in whom a fracture or penetrating injury is obvious from the physical examination, high-resolution CT (HRCT) is the imaging modality of choice. Head CT scans do include portions of the facial skeleton, but in 35% of trauma patients operative facial injuries are missed. A dedicated facial HRCT should be considered for patients with severe trauma, altered sensorium, and positive physical exam findings such as swelling, ecchymosis, wounds, lacerations, and bleeding. Technical components such as slice thickness, field of view, and reformatting capability available with dedicated facial CT imaging aids in treatment management including surgical planning.[40-43] For a complete evaluation, CT scans of the face should include axial, coronal, and sagittal reconstructions. The accurate interpretation of facial CT scans require attention to bones, sinuses, orbital contents, and soft tissue and should be reviewed by a radiology consultant.

CT imaging is the first choice for all patients in whom a midface fracture is suspected. However, when cross sectional imaging is not immediately available, patients with a low to moderate pretest probability of a midface or maxillary fracture and who are stable and able to cooperate, can be screened with a single facial radiograph (using a Waters or occipitomental view). CT imaging is indicated if the radiograph is positive for a fracture or air-fluid level is noted in any sinus.

The U shape of the mandible and presence of nearby bony structures make isolating the mandible on flat film difficult. Simple radiographs of the mandible are less sensitive than Panorex radiographs and particularly tend to miss fractures of the condyle (Fig. 34.21). If available, Panorex imaging is indicated for a first episode of TMJ dislocation, isolated mandibular fractures, dental fractures, or fractures of the alveolar ridge. In children, if fracture of the condyle is suspected, coronal CT is more sensitive and specific than Panorex studies. Although the traditional teaching has been that the mandible's shape results in "two fractures if it is fractured at all," a case series using CT evaluation found that 40% of mandibular fractures are unifocal.

For patients with complex fractures, new imaging techniques, such as 3D volume rendering, orbital volumetry, and cone beam CT, may help improve surgical planning and esthetic outcomes. In displaced orbital fractures, use of CT data to measure orbital volumes has shown that after repair, an orbital volume greater than 4% larger than on the unfractured side is associated with visible postoperative enophthalmos. This method is most useful in predicting which patients might benefit from operative repair. In conjunction with more standard two-dimensional facial CT scans, three-dimensional CT scans seem to

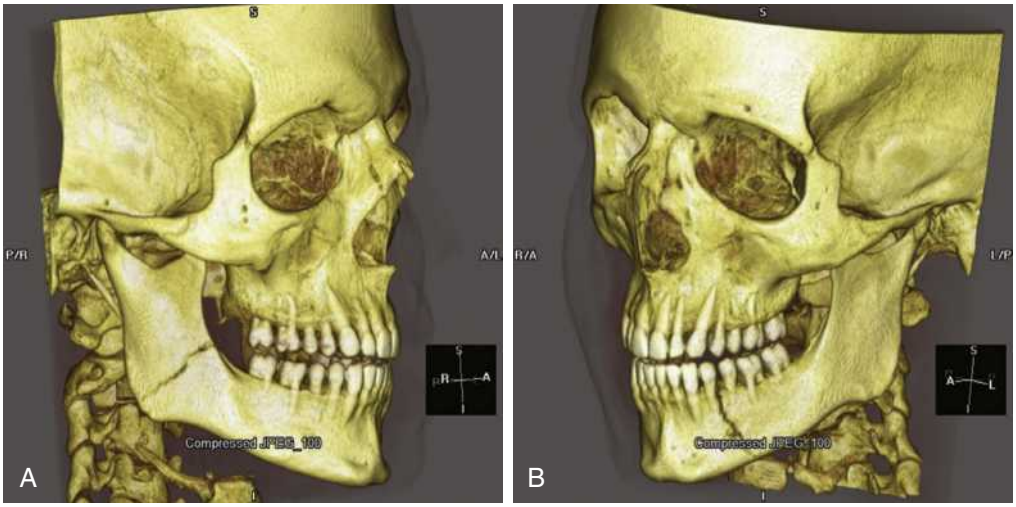

Fig. 34.22 (A–B) Three-dimensional CT reconstructions of minimally displaced mandibular fractures in the same patient as in Fig. 34.5.

TABLE 34.1 Blunt Cerebrovascular Injury (BCVI) Screening Criteria (The Denver Health Medical Center Criteria)

Risk Factors		Signs and Symptoms
High-energy traumatic mechanism	Severe facial fractures (LeFort II or III)	Arterial hemorrhage of neck, nose, or mouth
Complex skull fracture	Mandible fracture	Cervical bruit in patients <50 years of age
Severe traumatic brain injury (TBI) or GCS <6	Hanging or clothes-line neck injury	Expanding cervical hematoma
Seatbelt injury with abrasions, swelling, or pain	TBI with thoracic injuries	Neurologic deficits not consistent with CT examination
Thoracic injuries	Blunt cardiac rupture	Focal neurologic deficit
Scalp degloving	First rib fractures	Stroke on CT or MRI imaging

improve the diagnosis and aid preoperative planning for patients with complex fractures of the midface (Fig. 34.22).[44]

Blunt cerebrovascular injury (BCVI) incidence is still not fully known, with a reported 1% to 2% in the in-hospital trauma setting. CT angiography (CTA) should be used as a screening and diagnostic tool when evaluating for BCVI. This is an evolving area in which 20% of injuries are still missed until patients become symptomatic and are often outside the therapeutic window, with potentially devastating neurologic consequences. BCVI requires a high index of suspicion (Table 34.1) and should be considered in any patient with a cervical spine fracture, neurologic examination that does not fit the diagnostic picture, and patients with Horner syndrome. Additional considerations include LeFort II or III fractures (severe facial injuries), skull base fractures, or soft tissue injuries of the neck. The gold standard for diagnosis is angiography; however, CTA should be considered as part of the initial trauma evaluation protocol (Fig. 34.23).[45-47]

Patients with tenderness and swelling isolated to the bony bridge of the nose who do not have a septal hematoma, can breathe through each naris, and have a straight nose, do not require nasal bone radiography in the ED because imaging results would not alter treatment. If these criteria are not met, early reduction by a specialist or referral for surgical intervention may be indicated, and evaluation by plain films or ultrasonography (for truly isolated injuries) or CT scanning (if concern for other injuries exists) is indicated.[48] Plain radiograph examination may also be performed in the setting of legal concerns. If there is concern for a foreign body in a superficial wound, two standard x-ray

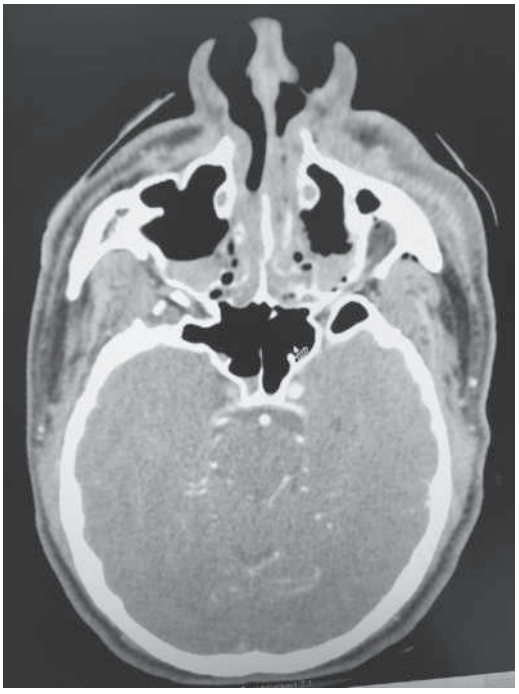

Fig. 34.23 CT angiography slice of the head and neck from a moped accident patient. There is no flow seen in the right internal carotid artery, suggestive of a blunt cerebrovascular injury.

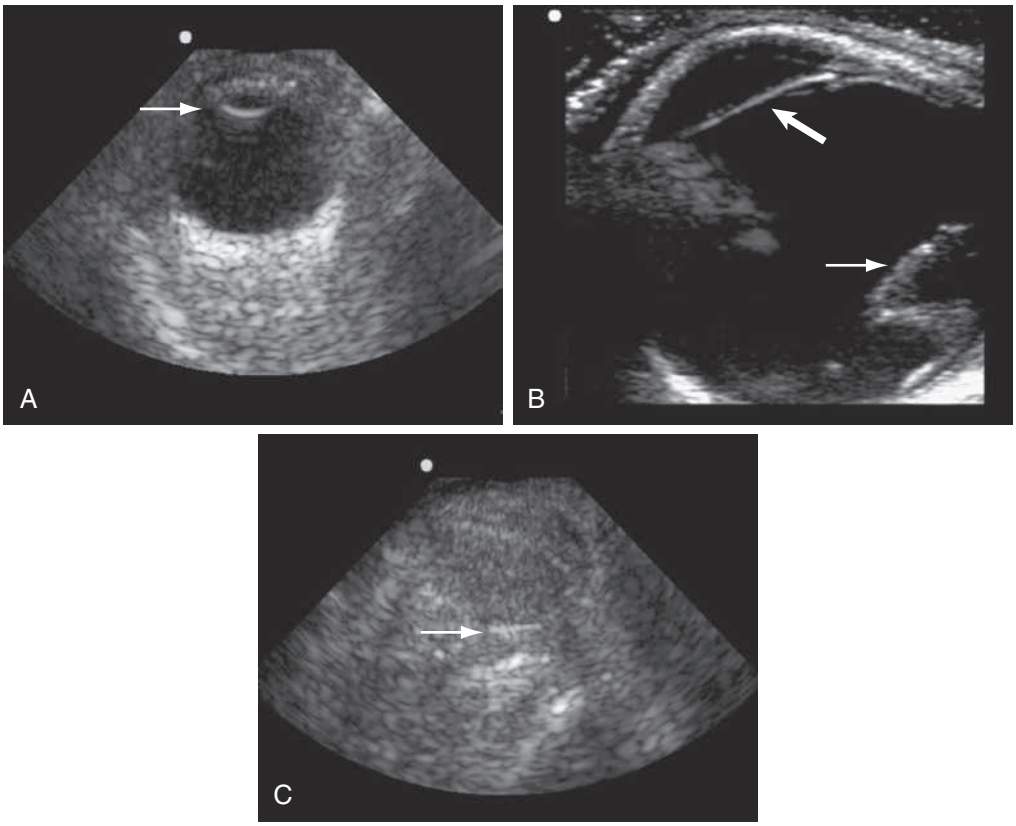

Fig. 34.24 Bedside sonograms of the eye. In each image, a small *white dot* is placed to identify the front of the eye, and *thin arrows* identify the lens. (A) Normal eye. (B) Detached retina. The large arrow is pointing to the lens of the eye, and the smaller arrow is pointing to the detachment. (C) Ruptured globe *(arrow)*. (Courtesy Dr. Keith Boniface.)

views (Waters and Caldwell, or occipitofrontal views) are indicated to triangulate the position of the observed foreign material.

Patients with suspected ocular injuries may benefit from bedside ultrasound as a noninvasive and cost-effective diagnostic tool, particularly if there is a need for urgent operative management of other injuries and no time for a dedicated facial CT scan. The different acoustic impedances of the orbit's anatomic structures make this modality operator-friendly, and an ultrasound of the eye can readily detect lens dislocation, vitreous hemorrhage, retinal detachment, and globe rupture (Figs. 34.24 and 34.25).[49] The operator should position the transducer in a transverse orientation, scanning in a cephalad to caudad direction, making sure to scan the entire anatomy of the eye, and using special care to minimize the pressure exerted over the eye, especially when evaluating for a specific ocular emergency. Prior findings have suggested that high-resolution ultrasound has a 94% correlation with axial and coronal CT imaging in the detection of orbital fractures and emphysema. A recent study demonstrated the high sensitivity and specificity of ultrasound in identifying traumatic ocular injuries including lens dislocation and retrobulbar hematoma compared to CT imaging.[50]

MANAGEMENT

Management of facial injuries occurs within the overall resuscitation of the patient (Table 34.2). Unless the airway is threatened or exsanguination is a concern, treatment of most facial injuries can be deferred until more life-threatening injuries have been stabilized. Care of the patient with penetrating trauma to the face should center on standard trauma care, with initial attention focused on maintenance of a patent airway, adequate ventilation, and systemic perfusion.

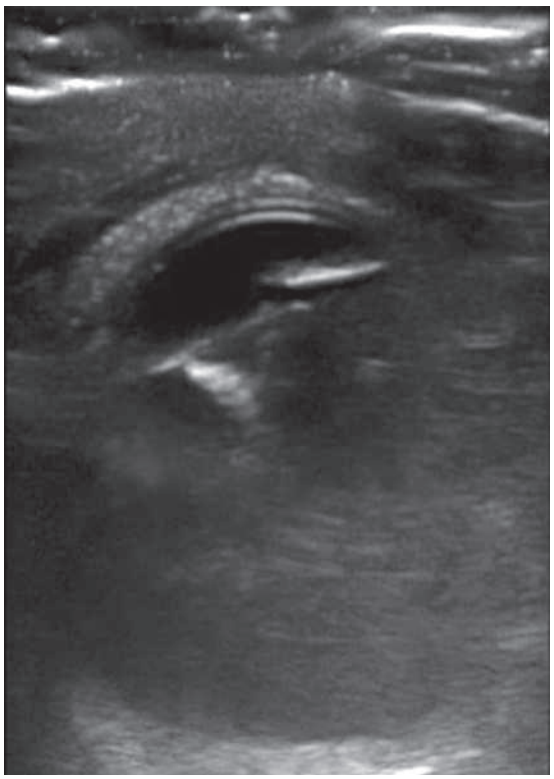

Fig. 34.25 Ultrasound image of a globe rupture with lens dislocation. At the top of the image, the cornea is visible, and just below that is the dislocation, with hemorrhage visible posteriorly.

TABLE 34.2 Key Concepts in the Clinical Approach to Facial Injuries

ASSESS ABCS AND INTERVENE APPROPRIATELY

HISTORY CAN HELP DIRECT YOUR EVALUATION (VISION LOSS, NUMBNESS, CHANGE IN BITE)

INSPECT AND EXAMINE

Injury Site	Presentation	Imaging	Management
Frontal Bone	1. Significant traumatic mechanism 2. AMS 3. Tenderness and edema over frontal bone, CSF rhinorrhea	CT scan imaging: head, C-spine, and max-face	1. ATLS protocol 2. Consultation with appropriate subspecialties
Orbital	1. Ocular deformity (exophthalmos) 2. Limited ocular movements 3. Visual symptoms	CT scan imaging of the orbits with thin-sliced helical cuts	1. Ophthalmologic evaluation 2. Follow up in 1 week 3. Avoid nose blowing or sneezing with a closed mouth
Nasal	Most commonly fractured facial bone 1. Deformity 2. Swelling and tenderness 3. Epistaxis	Imaging not necessary for isolated injury US is useful Complex and/or associated injuries require CT scan	1. Treat any septal hematoma and epistaxis 2. Closed reduction can be considered 3. Otolaryngology follow-up
Midface	1. Tenderness 2. Deformity 3. Bleeding 4. Malocclusion 5. Paresthesias	CT scan with 2-mm axial and coronal cuts, consider orbital imaging if needed	1. Control bleeding 2. Surgical consultation
Mandibular	Second most common injury 1. Trismus 2. Bleeding 3. Ecchymosis 4. Fractured or loose teeth, abnormal bite 5. Paresthesia	Panorex imaging for an isolated injury and in pediatric cases High clinical suspicion and concern for other injuries CT scan	1. Control bleeding 2. Dental involvement should be treated as an open fracture with appropriate antibiotics 3. Surgical consultation

Out-of-Hospital Care

The indications for airway management of a patient with a facial injury are the same as those for other patients. Does the patient have a currently patent airway and, if so, can the patient be expected to maintain an airway without intervention? If the answer to either question is "no," the patient needs to be intubated. If other injuries preclude the patient from ventilating appropriately, intubation is also required.

Patients with expanding hematomas after facial injury present a particular dilemma. Injuries to the facial vasculature may cause significant hematomas that can extend into the neck or down to the supraclavicular area. Such hematomas greatly distort the normal anatomy of the pharynx and neck, making intubation and cricothyroidotomy particularly difficult. If the patient has a patent airway, he or she can speak without difficulty, and the transport time is expected to be short, no intervention should be performed. The receiving institution should be notified so that planning and set-up can begin in anticipation of a difficult airway. If intubation must occur in the field, awake orotracheal intubation should be considered. If certified in its use, emergency medical services personnel should be ready to perform a surgical airway as needed. Gunshot wounds to the lower third of the face are particularly likely to require intubation for airway protection, and a significant proportion of these require a surgical airway.[51,52]

In the setting of significant facial trauma, active bleeding can obscure the view and make intubation considerably more challenging. Double suctioning may be required, which involves an assistant holding one suction catheter in the posterior oropharynx while the operator uses a second device more anteriorly or inferiorly, as needed during the procedure. Conversely, patients with fractures of the mandible may be easier to intubate because increased mobility of the mandible may allow wider opening of the mouth.

BOX 34.1 LEMON Criteria[1]

L = Look externally (facial trauma, large incisors, beard or mustache, large tongue)
E = Evaluate the 3-3-2 rule (incisor distance, 3 fingerbreadths; hyoid-mental distance, 3 fingerbreadths; thyroid to mouth distance, 2 fingerbreadths)
M = Mallampati (Mallampati score > 3)
O = Obstruction (presence of any condition such as epiglottitis, peritonsillar abscess, trauma)
N = Neck mobility (limited neck mobility)

[1] Patients in the difficult intubation group have higher LEMON scores.

Patients with multiple injuries should be resuscitated following Advanced Trauma Life Support (ATLS) protocol, and those who require intubation should have a LEMON assessment (Box 34.1) followed by rapid-sequence intubation, which has a higher success rate and fewer complications. Some alternative airway techniques may include submental or submandibular intubations or anesthesiology-assisted intubations with the use of adjuncts such as the C-Mac, GlideScope or lighted stylet.[53-57]

Control of local bleeding is the other significant out-of-hospital consideration in facial trauma. In many areas, external compression is sufficient to control bleeding during transport. Epistaxis and significant intraoral bleeding can be more difficult to manage. Even in the setting of significant nasal trauma, the soft portions of the nares can be

compressed to stop anterior nasal bleeding. In an awake alert patient with intraoral bleeding, 4- × 4-inch gauze packing may be placed into the buccal space to provide control. If these maneuvers are insufficient, and the patient's injuries require spinal immobilization, intubation may be a necessary first step to control intraoral or nasopharyngeal bleeding. After intubation, large amounts of gauze can be placed via the mouth into the oropharynx and nasopharynx to obtain control via direct pressure.

If out-of-hospital personnel suspect a ruptured globe, special protection against compression of the eye (shielding) should be provided in the field. Avulsed parts, including the ears, tip of the nose, teeth, or completely avulsed flaps, should be transported with the patient in saline-soaked gauze.

Completely avulsed teeth should be removed and carried with the patient during transport. Neurologically alert, unimpaired patients may be able to carry avulsed teeth in their mouths, held between the gum and buccal mucosa. Patients who are neurologically impaired, are intoxicated, require cervical spine immobilization, are nauseated, or cannot be transported upright should not be transported with avulsed teeth held in the mouth. In such cases, the risk of aspirating the teeth outweighs any other concerns, and the teeth should be transported in a container with sterile saline. Incompletely avulsed teeth should be left in place and not manipulated.

Emergency Department Treatment

The initial evaluation in the ED should focus on assessment and control of the airway. In the setting of significant distortion of the mouth, oropharynx, or upper neck by avulsion or hematoma, the awake fiberoptic method may optimize the chances of a successful intubation. When there is significant distortion of the oropharynx or larynx, a laryngeal mask airway may not achieve a sufficiently tight fit to allow ventilation. Emergent cricothyroidotomy is the procedure of choice if timely endotracheal intubation is not possible.

Unless there is life-threatening hemorrhage from the face, facial injuries can be safely left to the secondary survey after the airway has been secured. The emergency clinician should avoid being distracted by a facial injury and search instead for head, neck, chest, abdominal, pelvic, and extremity injuries. In-depth ocular examinations and other special testing should not be performed until other serious injuries have been managed emergently.

Significant bleeding can often be controlled by compression. If compression fails, hemostasis can be achieved in the ED by ligation of the relevant vessel. Great care should be taken, however, not to clamp or tie structures blindly deep within the face because serious iatrogenic injury of nerve or ductal structures could result. Massive uncontrollable bleeding from facial fractures occurs rarely and is best treated with arterial embolization, if available.[58] Intraarterial vasopressin has also been suggested as an option for hemostasis. Tranexamic acid may also be effective in controlling hemorrhage from facial trauma.[59,60]

In the rare case of acute exsanguination from a facial wound, the external carotid artery can be emergently ligated. This ligation is best accomplished with surgical assistance.[61]

Bite wounds, gross contamination, or significant tattooing from foreign bodies should be addressed definitively as soon as possible, given the needs of the patient's other injuries. Definitive treatment of simple soft tissue injuries can be left for 24 hours, if needed, after irrigation and temporary approximation. Ideally, facial fractures are treated early, before significant swelling occurs, or after several days, when return of more normal facial contours can aid in the repair. The need for tetanus prophylaxis should be considered for all open wounds. If the injury is an animal bite, the need for rabies prophylaxis should be considered. Because the rabies virus is transmitted to the brain along nerve axons, and symptomatic disease theoretically may occur sooner with wounds of the head, face, and neck, initiating rabies treatment within 5 days of the injury is recommended.[22]

Because lead poisoning has been reported from the ingestion of shotgun pellets in patients with primarily facial injuries, consideration should be given to looking for the presence of pellets in the gastrointestinal tracts of these victims. A plain radiograph of the abdomen will suffice. Early endoscopic removal of the pellets should limit future toxicity.

The final part of the physical examination when dealing with facial trauma is the importance of documentation. Facial injuries may be evidence of assault, domestic violence, or child abuse. Careful documentation of findings, including photographs, drawings, or both, not only communicates initial findings to other health care specialists but also can provide crucial legal evidence because many of these cases have forensic implications or result in litigation.

DISPOSITION

The decision to discharge or admit patients with facial trauma depends on their associated injuries, general injury severity, and plans for treatment. The emergency clinician has the expertise to manage the initial resuscitation and stabilization of patients with facial trauma. It is recommended that early consultation with the appropriate surgical specialists occur once the patient has been stabilized. Antibiotics should be considered in cases of severe facial trauma or open fractures. Telemedicine has opened the door for real-time discussions with appropriate surgical consultants, allowing the review of imaging and provision of treatment recommendations and potentially avoiding hospital-to-hospital transfers for isolated facial injuries.[62] Patients with isolated facial trauma who have been appropriately stabilized with no airway concerns can be discharged with close outpatient follow-up.

CHAPTER 34: QUESTIONS AND ANSWERS

1. A nasal fracture complication that requires urgent treatment is:
- **A.** Periorbital swelling
- **B.** Septal hematoma
- **C.** Laceration
- **D.** Epistaxis
- **E.** Subcutaneous edema

Answer: B. A septal hematoma is a collection of blood within the nasal septum that can occur following trauma. A septal hematoma should be drained promptly to avoid the risk of developing a septal abscess or ischemia of the septal cartilage leading to a saddle nose deformity. With the use of an anesthetic, the hematoma can be aspirated or incised, drained, and packed to avoid reoccurrence.

2. A patient with a mandibular fracture may complain of:
- **A.** Trismus
- **B.** Epistaxis
- **C.** Paresthesias of the inferior eyelid, nose, and upper lip
- **D.** Ocular muscle entrapment
- **E.** Postnasal drip and sweet taste in the mouth

Answer: A. Individuals with mandibular fractures may report pain with chewing, abnormal bite, jaw malalignment, paresthesias of the lip and chin area, trismus, oral bleeding, and dental injuries. An orthopantomogram (Panorex) has 92% sensitivity in the diagnosis of a mandibular fracture; however, when there is high clinical suspicion or concern for associated traumatic injuries a facial CT scan should be obtained. Epistaxis can be seen with isolated nasal fractures as well as maxillary fractures. Postnasal drip and a sweet taste in the mouth could be related to a CSF leak, which can be seen in frontal and nasal bone fractures. Ocular muscle entrapment can be related to orbital and midface fractures.

3. A patient presents following a physical altercation complaining of eye pain, decreased vision, and swelling. On physical examination he is noted to have periorbital ecchymosis, swelling, and tenderness, an irregular, tear-shaped pupil, and a collection of blood in the anterior chamber of the eye. Which of the following diagnostic or treatment options should be avoided?
- **A.** CT imaging of the face
- **B.** Ophthalmologic consultation
- **C.** Prophylactic antibiotics
- **D.** Thorough eye examination including tonometry
- **E.** Medications for pain and nausea and place patient in semirecumbent position

Answer: D. The patient is presenting with a history of blunt trauma and examination findings consistent for a globe rupture. A thorough history including mechanism and anticoagulant use should be obtained. CT imaging should be performed to look for additional traumatic injuries. The patient should be medicated for pain and nausea to avoid any increase in intraocular pressures resulting in possible aqueous fluid loss. Prophylactic antibiotics are initiated to prevent secondary endophthalmitis. The affected eye should not be manipulated, a rigid shield should be used for protection, and ophthalmology should be emergently consulted.

4. Cribriform plate fractures can be associated with:
- **A.** LeFort I fracture
- **B.** CSF rhinorrhea
- **C.** Dental alveolar fractures
- **D.** Ageusia
- **E.** Tripod fractures

Answer: B. Cribriform plate fractures are commonly associated with severe traumatic injuries including TBI and CSI. Symptoms can include tenderness, swelling, bleeding, CSF rhinorrhea, and anosmia. More complex midface fractures, LeFort III, or significant nasal trauma affecting the NOE complex are associated with fractures of the cribriform plate. ATLS guidelines should be followed when evaluating this patient. CT imaging including head, C-spine, and face are obtained and a CTA to evaluate for blunt cerebrovascular injury is often performed. Appropriate specialists (neurosurgery) should be consulted and involved in the patient's care.

35

Spinal Trauma

Kian Preston-Suni and Amy H. Kaji

KEY CONCEPTS

- NEXUS or CCR decision rules may be used to determine the need for radiographic imaging in the awake, evaluable trauma patient.
- CT scanning is preferred over plain radiography in the evaluation of the trauma patient with potential spinal injury, especially if axial imaging is needed for evaluation of other injuries.
- Suspicion for an anterior cord syndrome warrants prompt neurosurgical consultation because it is a potentially surgically correctable lesion.
- Neurogenic hypotension is a diagnosis of exclusion in the trauma victim and should not be considered the cause of hypotension unless the presence of coexisting hemorrhagic shock, cardiac tamponade, or tension pneumothorax has been eliminated.
- Because neurogenic hypotension can lead to hypoperfusion and secondary spinal cord ischemia, prolonged, severe hypotension (systolic blood pressure < 70 mm Hg) should be prevented and treated.
- Methylprednisolone or any other corticosteroid is not beneficial in the treatment of acute spinal cord injury (SCI) and should not be used.
- Emergency department management of SCI includes care to prevent further cord injury, pressure ulcers, bladder distention, and gastric distention.

FOUNDATIONS

Background and Importance

According to the National Spinal Cord Injury Statistical Center, motor vehicle collisions (MVCs) account for 39% of all spinal injuries.[1] Speeding, alcohol intoxication, and failure to use restraints are major risk factors. The next most common cause of spinal cord injury (SCI) is falls, followed by acts of violence (primarily gunshot wounds) and sporting activities. Approximately 80% of victims are male, and the average age at injury is 43 years. The lifetime cost to care for SCI victims ranges from over $1 million if older than 50 years, with incomplete motor function, to over $5 million for those younger than 25 years, with complete paraplegia. The total cost to society from lifelong medical expenses and lost productivity for all ages and types of spinal injuries is estimated to be more than $5 billion. The devastating emotional and psychological impact is incalculable.

Injuries of the soft tissues supporting the cervical spine can result in chronic pain and disability. The term *whiplash-associated disorder* (WAD) has been used to describe these injuries because of the flexion-extension movement of the neck that results from rear-end MVCs, the most common cause of a WAD.[2] Due to the large number of people sustaining these injuries, the annual costs associated with a WAD exceed $230 billion, which is more than the combined costs associated with spinal cord and brain injuries caused by MVCs.

Anatomy and Physiology

The human spine consists of 33 bony vertebrae—7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one), and 4 coccygeal (usually fused into one; Fig. 35.1). These 26 individual units are separated from one another by flexible intervertebral disks and connected to form a single functioning unit by a complex network of ligaments (Fig. 35.2). The vertebral column protects the spinal cord, which extends from the midbrain to the level of the second lumbar vertebra.

Spinal injuries involve fractures in 85% of cases. In the remainder, 10% are ligamentous injuries without fracture, and 5% are SCIs without a radiographic abnormality (SCIWORA), in which the spinal cord is injured directly without radiographic evidence of bony or ligamentous injury. Stability of a spinal injury refers to the resistance to displacement of fracture fragments or, in the case of ligamentous injury, the entire vertebral unit. There are several classification systems for assessing the stability of subaxial spinal column injuries (Table 35.1), including the Allen Ferguson classification, AO Spine classification, Denis Classification and the Thoracolumbar Injury Classification and Severity Score (TLICS). According to a survey of the members of the Spine Trauma Study Group of the International Spinal Cord Society, practical implementation is evenly distributed among the classification systems, although the AO Spine classification has higher reliability than TLICS.[3,4]

Pathophysiology

Classification of Spinal Column Injuries

Acute spinal injuries are classified according to the mechanism of trauma—flexion, flexion-rotation, extension, and vertical compression (Table 35.2).

Flexion. Atlanto-occipital and atlantoaxial joint dislocation can occur with or without associated fractures of the odontoid (Fig. 35.3). The basion-axial interval (BAI) and basion-dens interval (BDI) are normally less than 12 mm, with larger values suggestive of atlantoaxial joint dislocation (Fig. 35.4). When the ratio of the distance from the basion to the midvertical portion of the posterior laminar line of the atlas over the distance from the opisthion to the midvertical portion of the posterior surface of the anterior ring of the atlas is greater than 1, subluxation is suggested (Fig. 35.5).

In pure flexion injuries below C2, a longitudinal pull is exerted on the strong nuchal ligament complex, which usually remains intact.

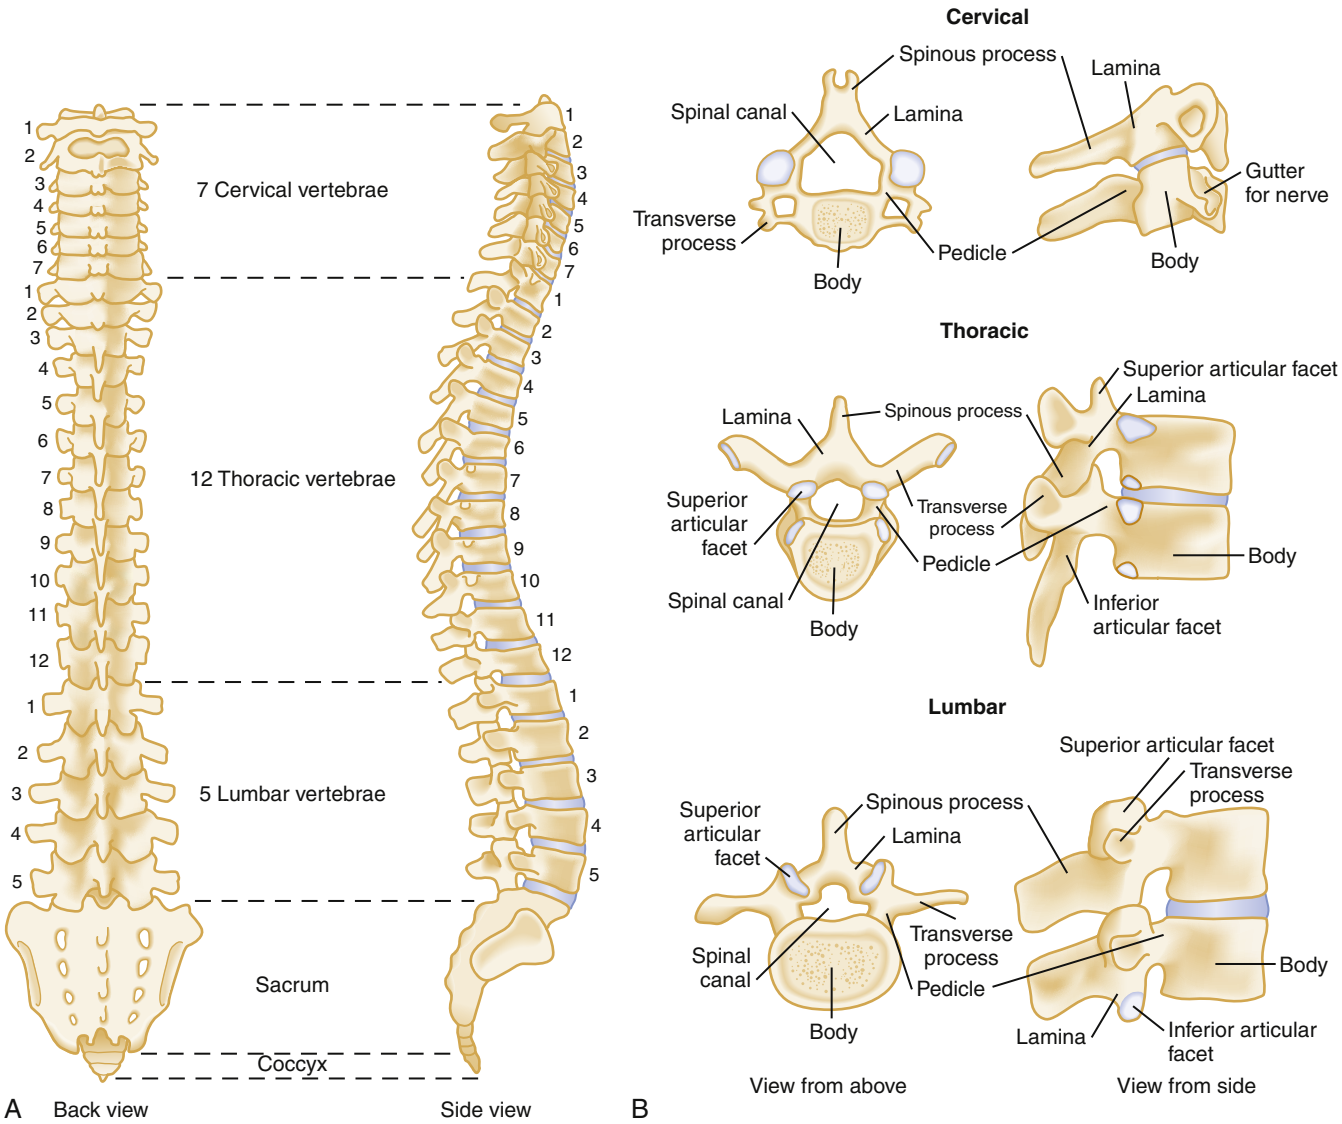

Fig. 35.1 (A) Vertebral column. (B) Typical vertebrae.

Most of the force is expended on the vertebral body anteriorly, causing a simple wedge fracture (Fig. 35.6).

Among the most unstable spinal injuries, the *flexion teardrop fracture* results from severe flexion forces causing subluxation and disruption of the longitudinal ligaments (Fig. 35.7).

The *clay shoveler's fracture* derives its name from an injury caused by the abrupt head flexion that clay miners experienced when tossing a heavy shovelful of clay and having the clay stick to the shovel. This force, transmitted through the supraspinous ligament, results in a stable avulsion fracture of the spinous process (Fig. 35.8).

Pure spinal subluxation begins posteriorly in the nuchal ligament and proceeds anteriorly to involve other ligaments (Fig. 35.9).

Bilateral facet dislocations occur when a greater force of flexion causes soft tissue disruption to continue anteriorly to the annulus fibrosis of the intervertebral disk and anterior longitudinal ligament, resulting in extreme instability (Fig. 35.10).

Chance fractures of the lumbar spine occur with a combination of distraction and flexion forces with an axis of rotation anterior to the vertebral body (Fig. 35.11).

Flexion-distraction injuries are similar to Chance fractures, but are characterized by an axis of rotation posterior to the anterior longitudinal ligament (Fig. 35.12). These injuries generally occur in the lumbar spine from forced deceleration in an MVC while restrained with a lap belt. As in Chance fractures, intra-abdominal injuries are common.[5]

Shear injury. Trauma to the head directed in an anteroposterior (AP) direction may result in fracture of the odontoid process above the transverse ligaments (type I) or, more commonly, at the base of the odontoid process where it attaches to C2 (type II; Fig. 35.13). Slight angulation of the force may result in extension of the fracture into the body of C2 (type III; Fig. 35.14).

Flexion-rotation. *Rotary atlantoaxial dislocation* is an unstable injury visualized best on open-mouth odontoid radiographs (Fig. 35.15) or computed tomography (CT) scan.

A *unilateral facet dislocation* is caused by both flexion and rotation. The rotational component of this injury occurs around one of the facet joints, which acts as a fulcrum. Simultaneous flexion and rotation cause the contralateral facet joint to dislocate, with the superior facet riding forward and over the tip of the inferior facet

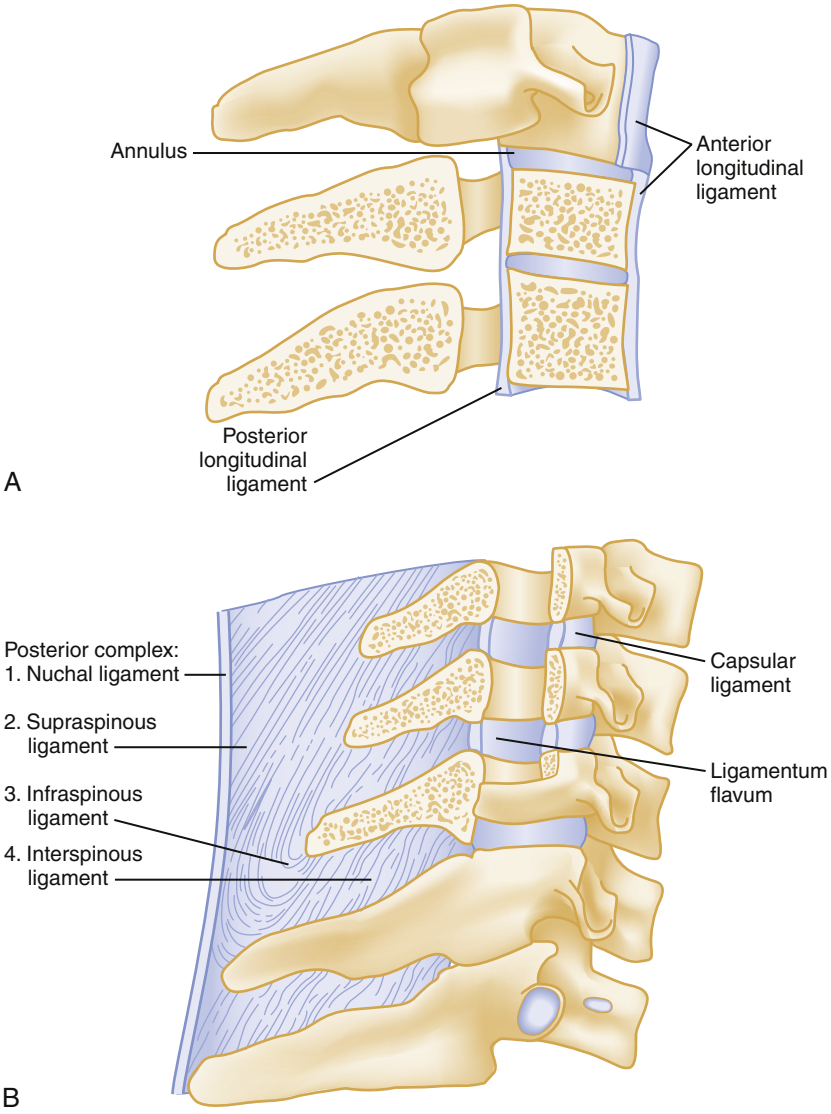

Fig. 35.2 (A) Ligaments of the anterior column. (B) Ligaments of the posterior column.

TABLE 35.1 Spinal Injury Classification Systems

Classification System	Characteristics
Allen Ferguson	Categorized by mechanism: compressive flexion, vertical compression, distractive flexion, compressive extension, distractive extension, lateral flexion
AO Spine	Classified by injury mechanism, segment of spine involved, severity of injury, associated neurologic deficit and complicating factors including instability, risk of nonunion, comorbidities, and vascular injury
Denis	Three-column model: injury to single column does not preclude SCI, injuries to two columns are unstable in one direction, and injuries to all three are highly unstable. • anterior column: anterior longitudinal ligament and anterior half of vertebral body and disk • middle column: posterior longitudinal ligament and posterior half of vertebral body and disk, spinal cord, laminae and pedicles, articulating facets, transverse processes, nerve roots, and vertebral arteries and veins • posterior column: spinous processes, nuchal ligament, interspinous and supraspinous ligaments, and ligamentum flavum
Thoracolumbar Injury Classification System (TLICS)	Characterized by injury mechanism, neurologic involvement and status of the posterior ligamentous complex

TABLE 35.2 Classification of Spinal Injuries

Mechanism of Spinal Injury	Stability	Radiographic Features	Other Features
Flexion			
Wedge fracture	Stable: posterior column intact. Unstable if > 50% vertebral body height or contiguous wedge fractures	Diminished height of anterior vertebral body with increased concavity, increased bony density, prevertebral swelling	
Flexion teardrop fracture	Extremely unstable: anterior and posterior ligaments disrupted	Wedge-shaped fragment of anteroinferior cervical vertebral body	Generally associated with neurologic injury
Clay shoveler's fracture	Stable: involves only spinous process	Oblique spinous process fracture, lower cervical spine	Seen in MVCs and direct blows to spinous process. Requires symptomatic care only
Subluxation	Potentially unstable if significant ligamentous injury	Ligamentous rupture without bony injury	Rarely associated with neurologic injury
Bilateral facet dislocation	Always unstable	Inferior facets of upper vertebra pass up and over superior facets of lower vertebra. Spine displaced anteriorly above injury	
Atlanto-occipital dislocation	Unstable: minimal muscle or ligamentous support	BAI or BDI > 12 mm Power's ratio > 1	
Anterior atlantoaxial dislocation with or without fracture	Unstable: minimal muscle or ligamentous support	Disruption of normal position of atlas on dens	
Odontoid fracture with lateral displacement	Unstable: associated ligamentous injury	Typically, oblique fracture	
Fracture of transverse process	Stable	Upper lumbar spine most common location	Cervical fractures are associated with vertebral artery injuries
Chance fracture	Usually stable: when involving only posterior column. May extend to middle column with high energy mechanism	Horizontal fracture through vertebral body, laminae, pedicles, transverse processes, and spinous process	Commonly associated with intra-abdominal injuries, cord injury rare
Flexion-distraction injury	Unstable: all three columns involved	Compression fracture of vertebral body with distraction of posterior elements	Also known as seatbelt injury
Shear			
Odontoid fracture	Type I: Usually stable unless apical and alar ligaments injured Type II: Generally unstable Type III: Unstable	Type I: Tip avulsion Type II: Fracture through base of odontoid Type III: Through odontoid, extends into lateral masses. Can extend laterally into articular facet	Type I: Uncommon Type II: Nonunion common Type III: Lowest rate of nonunion due to larger surface area
Flexion-Rotation			
Unilateral facet dislocation	Stable	Mild anterolisthesis, misaligned spinous processes	May have neurologic injury
Rotary atlantoaxial dislocation	Unstable: ligamentous injury	Asymmetry of lateral masses relative to odontoid	
Extension			
Posterior neural arch fracture (C1)	Unstable	Compression of posterior elements	
Hangman's fracture (C2)	Unstable	Bilateral pedicle fractures of axis	
Extension teardrop fracture	Usually stable in flexion as posterior elements intact; unstable in extension	Triangular fracture of anteroinferior corner of vertebral body	Appears similar to flexion teardrop
Posterior atlantoaxial dislocation, with or without fracture	Unstable	Odontoid process posterior to ring of atlas	Seen in high-velocity injuries
Vertical Compression			
Bursting fracture of vertebral body	Stable: all ligaments remain intact	Comminuted vertebral body on sagittal CT with typically > 40% compression, vertical fracture of vertebral body seen on coronal CT, bony fragments may enter canal	May be missed on plain radiography. Can cause anterior cord syndrome

and coming to rest within the intervertebral foramen. In this position, the dislocated articular mass is mechanically locked in place, making this a stable injury even though the posterior ligament complex is disrupted.

Any cervical fracture or dislocation may cause torticollis; however, torticollis may also be caused by a benign process such as a muscle spasm. It may be difficult to differentiate the two and in the setting of trauma, CT scan (Fig. 35.16) or oblique radiographs may be necessary to demonstrate the dislocated facet joint (Fig. 35.17).

Due to the varying shapes of the articular processes, different types of flexion-rotation injuries result. In the cervical region, where articular processes are small and almost horizontal, unilateral facet dislocations occur, whereas in the lumbar region, in which articular processes are large and nearly vertical, unilateral facet dislocation is rare. Instead,

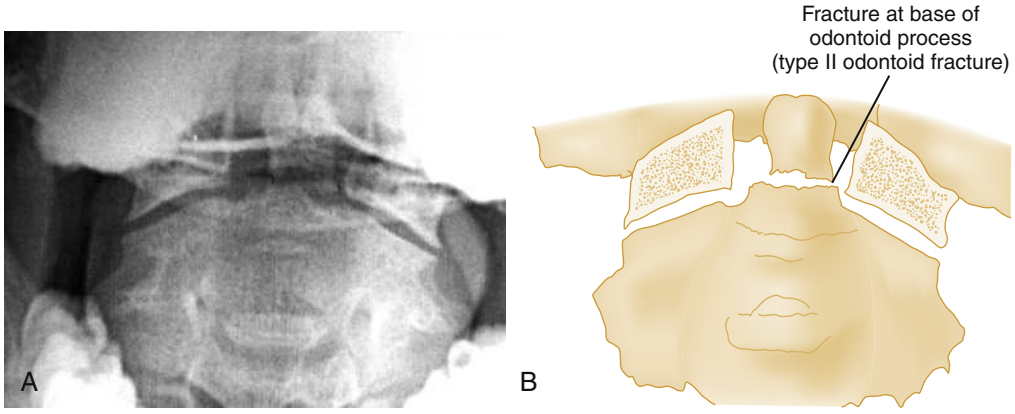

Fig. 35.13 (A and B) Odontoid fracture with lateral displacement. Mechanism—flexion; stability—unstable. The tip of the odontoid process is laterally displaced in this lateral flexion injury.

one or both articular processes fracture, and the upper vertebra swings forward. Commonly seen in the thoracolumbar and lumbar regions, this rotation fracture-dislocation is unstable (Fig. 35.18).

Extension. Fracture of the posterior neural arch of the atlas (C1) results from compression of the posterior elements between the occiput and spinous process of the axis (C2) during forced neck extension (Fig. 35.19). The injury is characterized by an intact anterior arch and transverse ligaments.

The *hangman's fracture*, or traumatic spondylolysis of C2, occurs when the cervicocranium—the skull, atlas, and axis functioning as a unit—is hyperextended as a result of abrupt deceleration (Fig. 35.20). Cord damage is usually minimal because the AP diameter of the neural canal is greatest at C2, and the bilateral pedicular fractures permit spinal canal decompression.

The *extension teardrop fracture* occurs when abrupt extension of the neck causes the anterior longitudinal ligament to pull the anteroinferior corner of a vertebral body away from the remainder of the vertebra. Often occurring in lower cervical vertebrae (C5–C7) from diving accidents, this injury may be associated with a central cord syndrome (see later) and is caused by the ligamentum flavum buckling into the spinal cord.

Vertical compression. Vertical compression injuries occur in the cervical and lumbar regions, which are capable of straightening at the time of impact. When forces are applied from above (skull) or below (pelvis or feet), one or more vertebral body endplates may fracture. The nucleus pulposus of the intervertebral disk is forced into the vertebral body, which is shattered outward, resulting in a burst fracture (Fig. 35.21). While often stable, fracture fragments may impinge on or penetrate the ventral surface of the spinal cord (Fig. 35.22).

The C1 *Jefferson fracture* occurs when a vertical compression force is transmitted through the occipital condyles to the superior articular surfaces of the lateral masses of the atlas, driving the lateral masses outward (Fig. 35.23).

Rarely, vertical compression fractures may result in isolated fractures of the articular pillar or vertebral body.

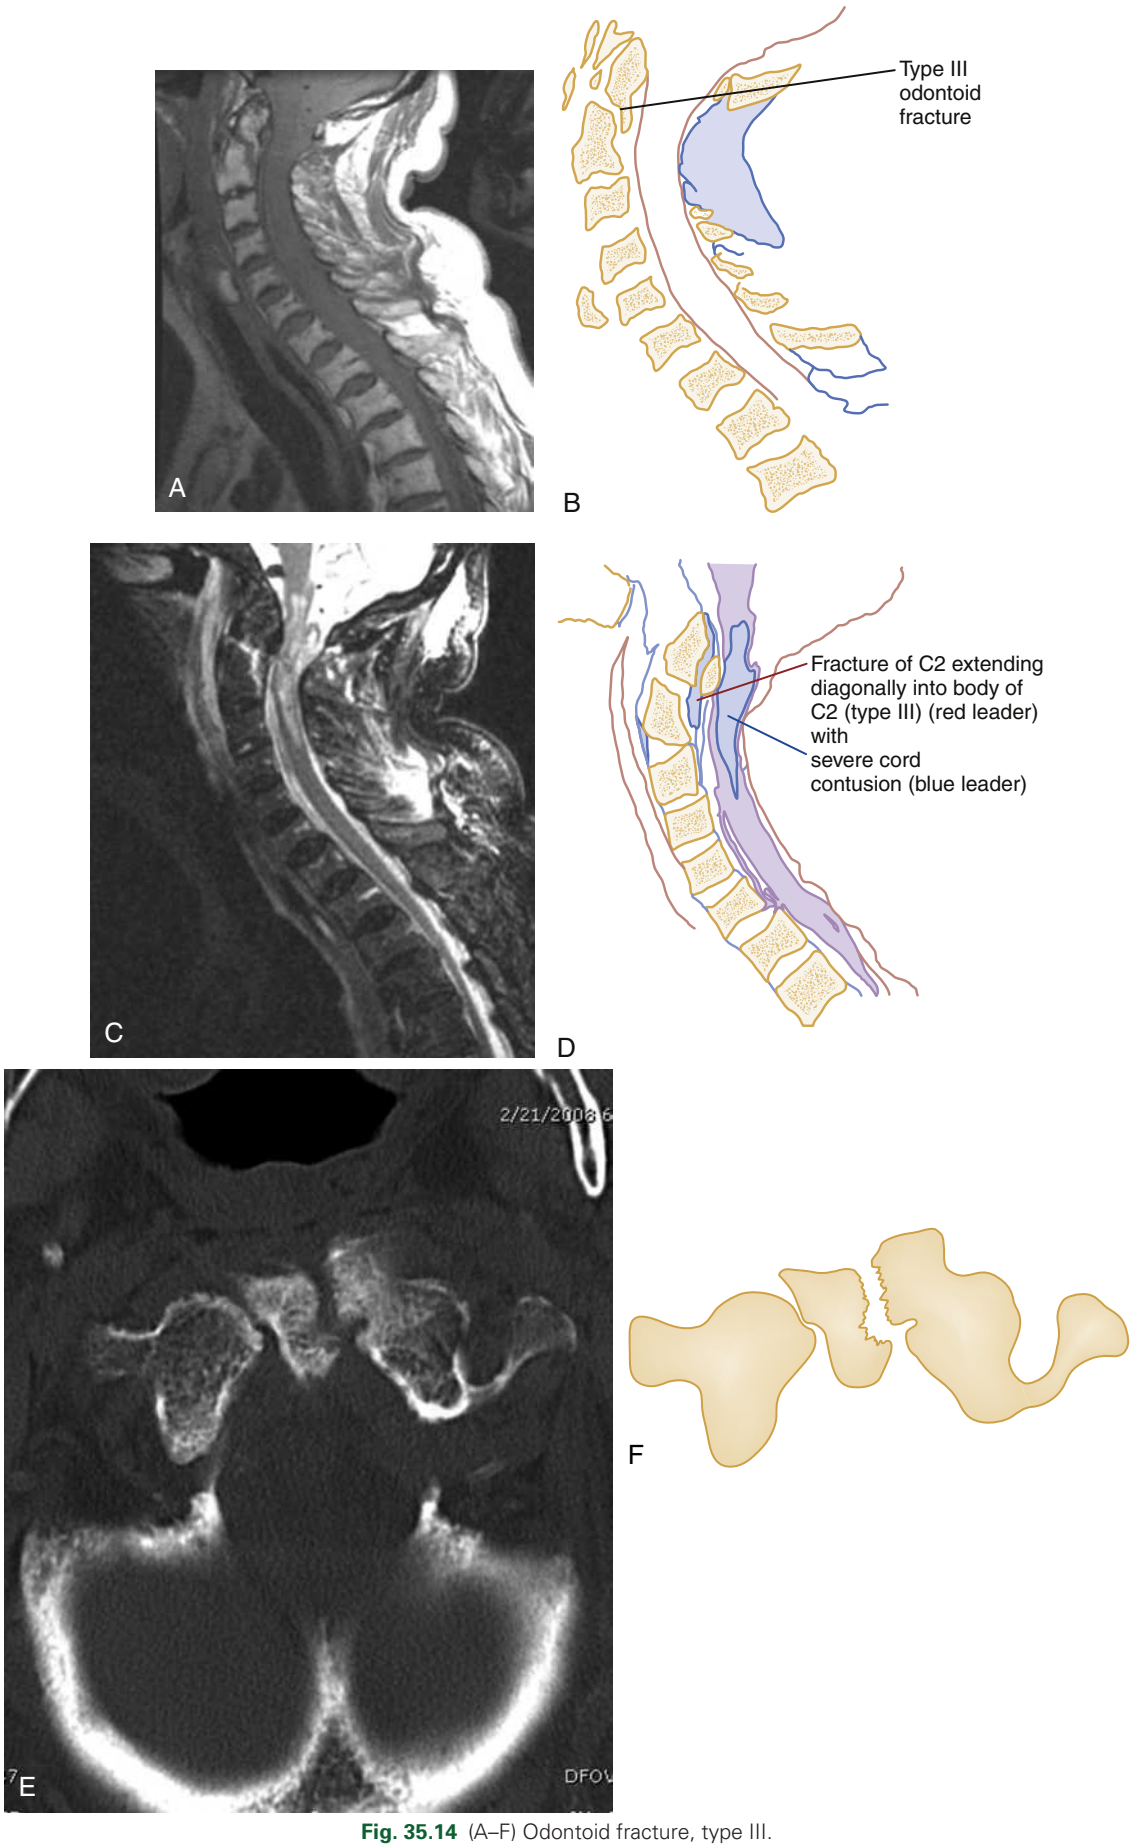

Fig. 35.14 (A–F) Odontoid fracture, type III.

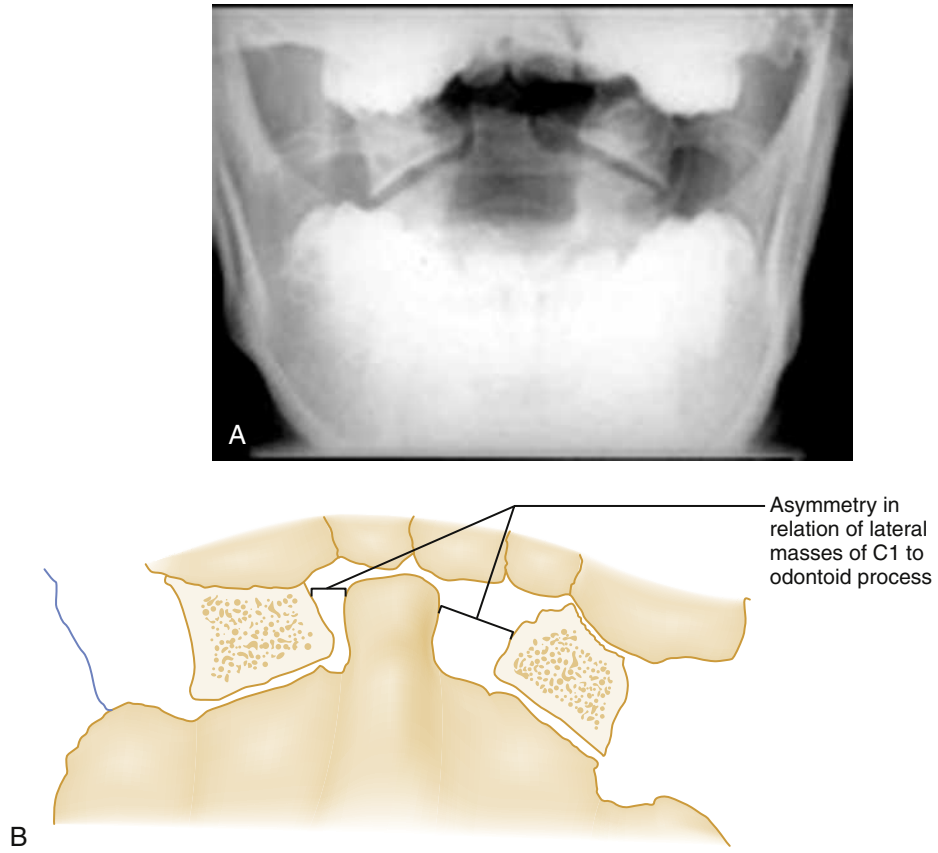

Fig. 35.15 (A–B) Rotatory subluxation of C1 on C2. Mechanism—rotation; stability—unstable. There is marked asymmetry in the relationship of the lateral masses of C1 to the odontoid process. Rotation causes the right lateral mass to appear slightly larger (farther from the x-ray film) than the left (closer to the x-ray film).

Fig. 35.16 Unilateral facet dislocation on CT.

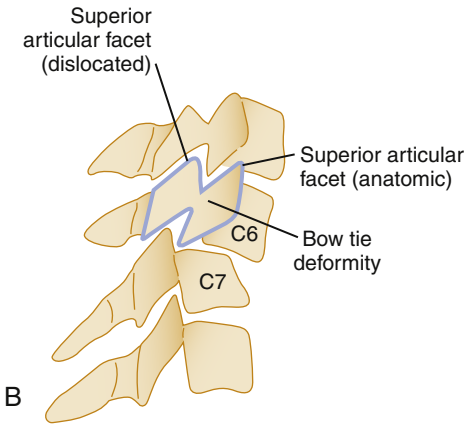
Classification of Spinal Cord Injuries

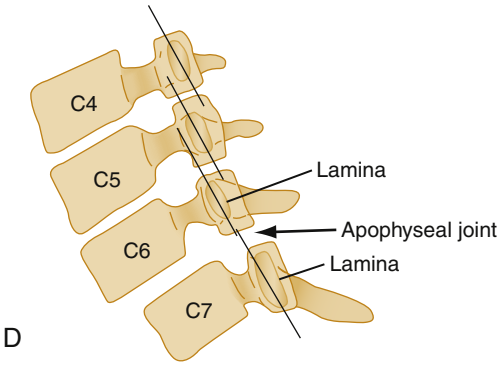
Primary spinal cord injury. The spinal cord may be injured by three broad categories of injury patterns. First, penetrating trauma or massive blunt trauma with disruption of the vertebral column causes transection of neural elements. Because spontaneous regeneration within the central nervous system following damage is poor, such injuries are irreversible. Less severe blunt trauma may have similar effects resulting from a displaced bony fragment or herniated disk injuring the cord.

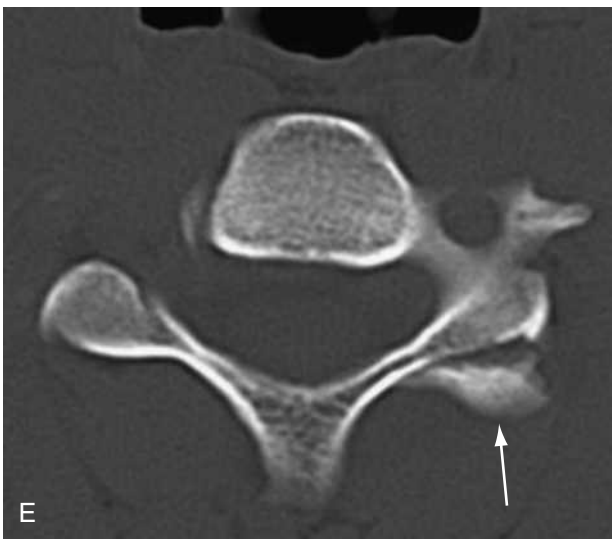
Second, when patients with cervical osteoarthritis and spondylosis, particularly older adults, are subjected to forcible cervical spine extension, the spinal cord may be injured secondary to compression between an arthritically enlarged anterior vertebral ridge and a posteriorly located hypertrophic ligamentum flavum (Fig. 35.24). This injury frequently results in a central cord syndrome.

The third mechanism is primary vascular damage to the spinal cord. The spinal cord may be compressed by an extradural hematoma, particularly in patients who are on anticoagulants or have bleeding disorders. Vascular injuries should also be suspected when there is a discrepancy between the clinically apparent neurologic deficit and known level of spinal injury. For example, a lower cervical dislocation may compress the vertebral arteries as they travel within the spinal foramina of the vertebrae, resulting in thrombosis of the anterior spinal artery that originates from both vertebral arteries at C1 (Fig. 35.25). On physical examination, such an injury may erroneously appear to be localized to the level of C1 or C2. Also, the great radicular artery of Adamkiewicz, originating from the aorta and often entering the spinal canal at the level of L1, sends branches as cephalad as T4. Therefore, a lumbar fracture or dislocation can produce a neurologic deficit as high as T4.

Secondary spinal cord injury. The maximum neurologic deficit after blunt spinal cord trauma is often not seen on initial examination and







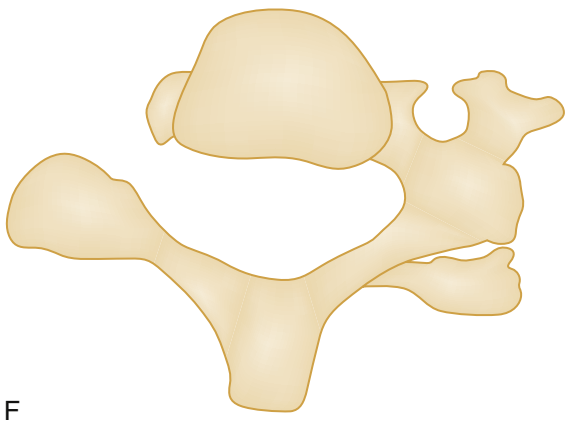


Fig. 35.17 Unilateral facet dislocation. Mechanism—flexion and rotation; stability—stable. may, instead, progress over many hours. Studied extensively in animal models, the histopathology of secondary SCI is now thought to be due to a complex cascade of biochemical events that result in progressive ischemia of gray and white matter during the postinjury period (Fig. 35.26). Other factors, such as hypoxia, hypotension, hyperthermia, and hypoglycemia, also affect the ultimate extent of SCI.

Classification of Cervical Soft Tissue Injuries

Blunt force trauma can injure one or more of the soft tissues of the neck (see Chapter 36), including ligaments, muscles, intervertebral disks, zygapophysial facet joints, dorsal root ganglia and vertebral arteries. Although injuries of these tissues have been documented in biomechanical, animal, and human autopsy studies, a validated diagnostic

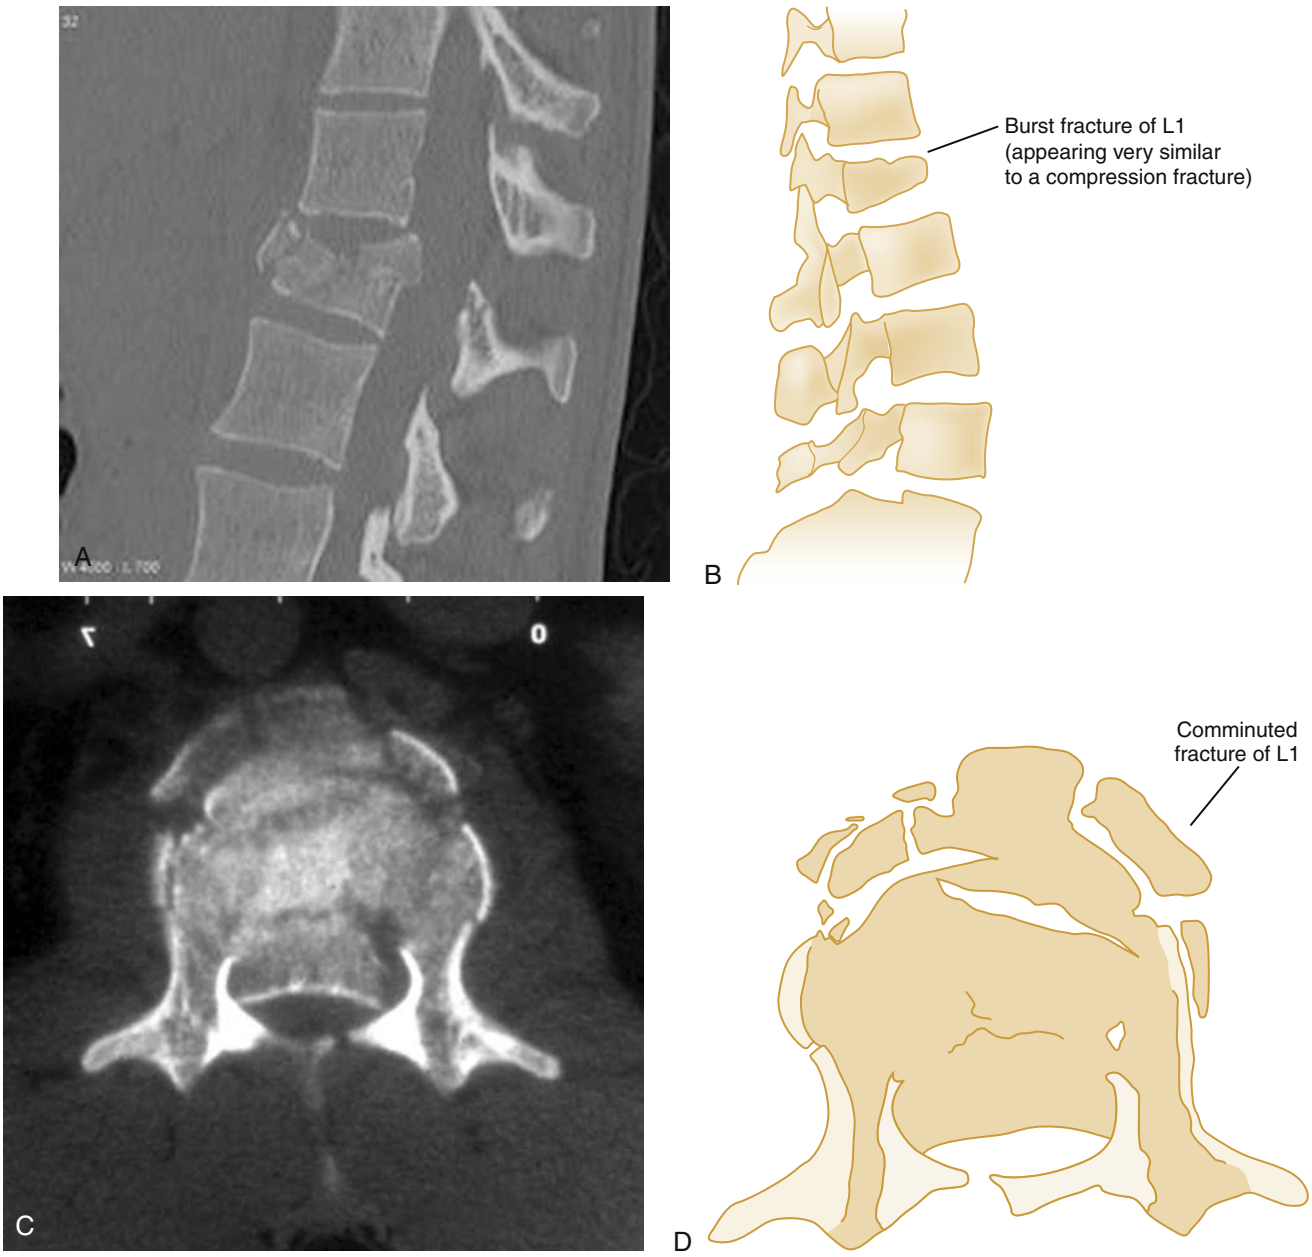

Fig. 35.21 Burst fracture of a vertebral body. Mechanism—vertical compression and flexion; stability—unstable. test is only available for facet injuries. The cardinal symptom of a WAD is neck pain but neck stiffness, neck and arm paresthesias, and dizziness are commonly reported. Table 35.3 shows the Quebec Task Force classification of WADs, the most common classification used worldwide.[2]

CLINICAL FEATURES

Neurologic Evaluation

Observation and careful inspection may reveal signs of possible spinal involvement of an injury. Significant head and facial trauma have a 5% to 10% incidence of associated cervical spine injuries. Scapular contusions suggest a rotation or flexion-rotation injury of the thoracic spine. Chest and neck abrasions from automobile shoulder belts and lower abdominal markings from lap belts indicate possible blunt carotid and vertebral injuries, as well as spinal, intrathoracic, and intra-abdominal injuries. As occurs with falls from considerable heights, injuries to the gluteal region, calcaneal fractures, and severe ankle fractures suggest a compression type of spinal injury.

Because the diaphragm is innervated by the phrenic nerve, which originates at C3–C4, an abdominal breathing pattern may provide an important clue to an upper cervical injury. The presence of *Horner syndrome*, characterized by unilateral ptosis, miosis, and anhidrosis, may result from disruption of the cervical sympathetic chain, usually between C7 and T2. Priapism may occur with severe SCI, and is often associated with spinal shock, a transient reflex depression of the spinal cord below the level of the injury.

Pain may be present in the sensory dermatome corresponding to the injured spinal level. For example, a C2 lesion may cause occipital

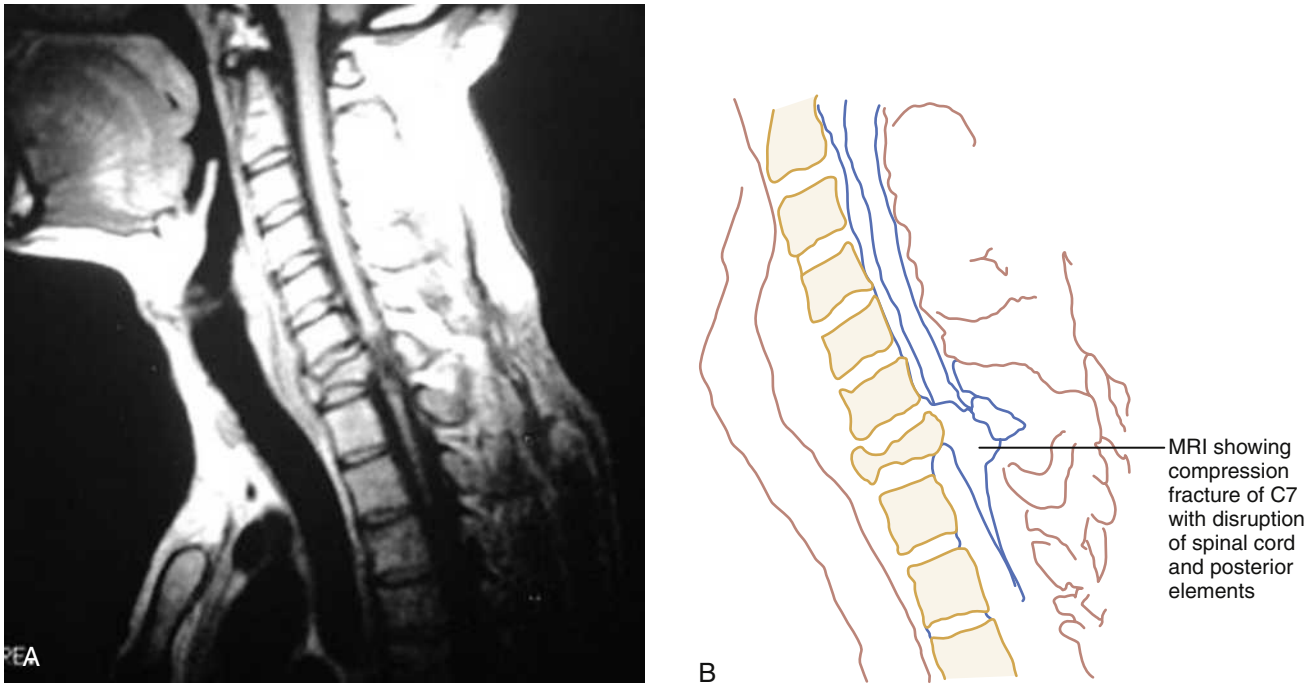

Fig. 35.22 (A–B) MRI scan showing a burst fracture of C7 with complete spinal cord disruption.

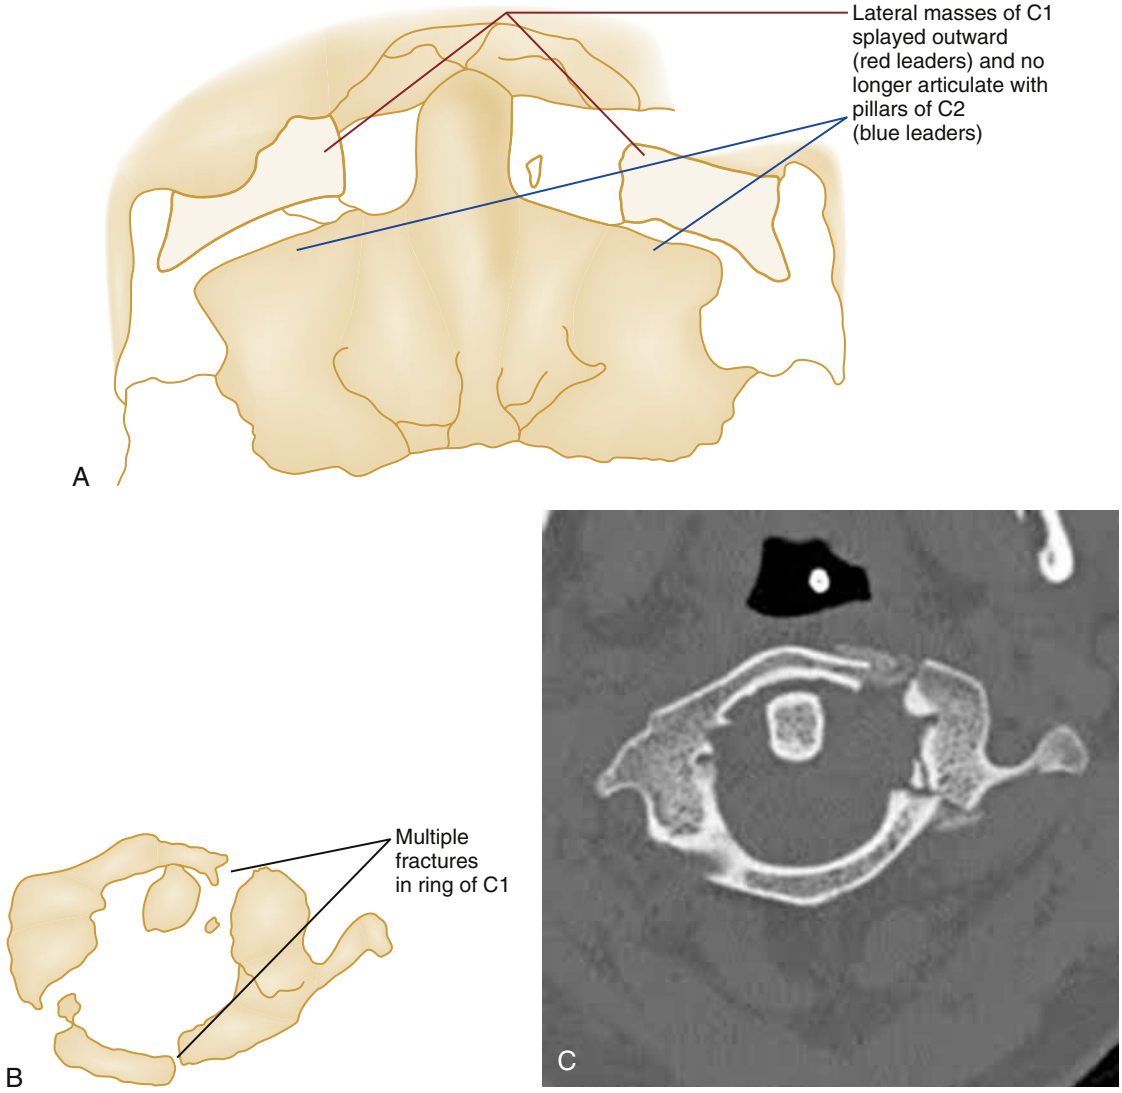

Fig. 35.23 Jefferson fracture. Mechanism—vertical compression; stability—unstable. (A–B) Bilateral lateral displacement of the lateral masses of C1 with respect to the articular pillars of C2 confirms a Jefferson fracture and differentiates it from fracture of the posterior neural arch of C1 on an anteroposterior view. Fig. 35.24 Older patients subjected to extension forces can sustain cervical spinal cord injury as a result of compression of the spinal cord between the posterior hypertrophic ligamentum flavum and arthritically enlarged anterior vertebral bodies.

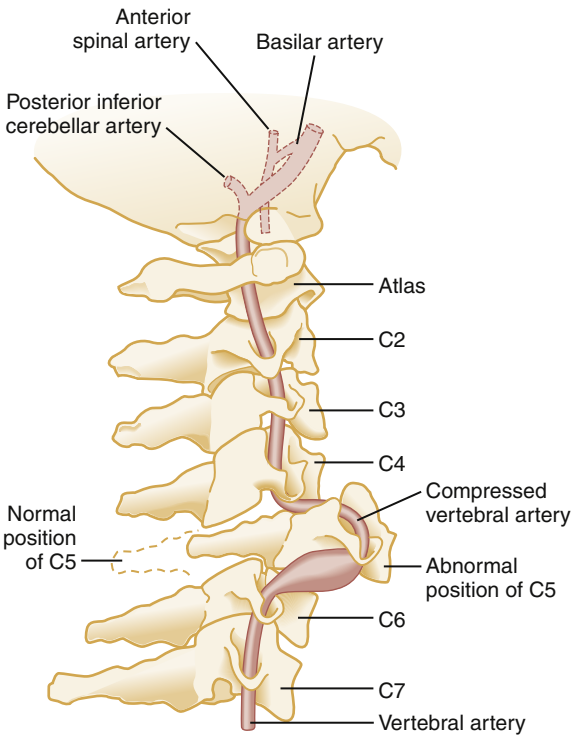

Fig. 35.25 Mechanism of vascular injury of the spinal cord resulting from cervical vertebral injury.

pain, whereas discomfort overlying the trapezius muscle, particularly in the absence of signs of local trauma, suggests a C5 injury. Certain medical conditions predispose patients to spinal injury. For example, patients with Down syndrome are predisposed to atlanto-occipital dislocation, whereas those with rheumatoid arthritis are prone to rupture of the C2 transverse ligament.

Palpation of the entire spine and paraspinal musculature may reveal areas of tenderness, deformity, or muscle spasm. A step-off may be appreciated with severe subluxation. Widening of an interspinous space indicates a tear in the posterior ligament complex and a potentially unstable spinal injury.

Because a single motion is often governed by muscles innervated by multiple spinal segments, localizing a spinal lesion based solely on motor function is extremely difficult. Testing the presence and strength of those motions outlined in Table 35.4, however, provides a rapid baseline assessment. When a deficit is noted, the motor and neurologic examination should be repeated because progression of dysfunction may occur. Even the most minimal of motor response should be elicited and documented, because any response improves prognosis. A slight toe flicker in an otherwise paralyzed individual indicates that the patient may again eventually walk unassisted.

The presence of cord-mediated deep tendon reflexes can be helpful as a localizing diagnostic aid (Table 35.5). Typically, muscle paralysis associated with intact deep tendon reflexes indicates an upper motor neuron (spinal cord) lesion, whereas paralysis associated with absent deep tendon reflexes indicates a lower motor neuron (nerve root or cauda equina) lesion. This differentiation is important because the

TABLE 35.3 Quebec Task Force Classification of Whiplash-Associated Disorders

Grade	Description
0	Whiplash injury but no pain, symptoms, or signs
1	Delayed neck pain, minor stiffness, nonfocal tenderness only, no physical signs
2	Early onset of neck pain, focal neck tenderness, spasm, stiffness, radiating symptoms
3	Early onset of neck pain, focal neck tenderness, spasm, stiffness, radiating symptoms, and signs of neurologic deficit
4	Neck complaint (grade 2 or 3 above) and fracture dislocation

(Adapted from Sterling S. Physiotherapy management of whiplash-associated disorders [WAD]. *J Physiother* 2014;60:5-12.)

latter condition may be caused by a surgically correctable lesion. After the initial period of areflexia, reflexes gradually return after 1 to 3 days and, after 1 to 4 weeks, patients with SCI will manifest characteristic hyperreflexia and spasticity. Reflexes are typically absent during the initial phase of spinal shock in the emergency department (ED).

TABLE 35.4 Spinal Motor Examination

Level of Lesion	Resulting Loss of Function
C4	Spontaneous breathing
C5	Shrugging of shoulders
C6	Flexion at elbow
C7	Extension at elbow
C8–T1	Flexion of fingers
T1–T12	Intercostal and abdominal muscles[1]
L1–L2	Flexion at hip
L3	Adduction at hip
L4	Abduction at hip
L5	Dorsiflexion of foot
S1–S2	Plantar flexion of foot
S2-S4	Rectal sphincter tone

[1]Localization of lesions in this area is best accomplished with the sensory examination.

Sensory function can be quickly evaluated through the use of a structured approach (Table 35.6) or graphic dermatome chart (Fig. 35.27).

TABLE 35.5 Spinal Reflex Examination

Level of Lesion (At or Above)	Resulting Loss of Reflex
C6	Biceps
C7	Triceps
L4	Patellar
S1	Achilles

TABLE 35.6 Spinal Sensory Examination

Level of Lesion	Resulting Level of Loss of Sensation
C2	Occiput
C3	Thyroid cartilage
C4	Suprasternal notch
C5	Below clavicle
C6	Thumb
C7	Index finger
C8	Small finger
T4	Nipple line
T10	Umbilicus
L1	Femoral pulse
L2–L3	Medial aspect of thigh
L4	Knee
L5	Lateral aspect of calf
S1	Lateral aspect of foot
S2–S4	Perianal region

After locating an area of hypesthesia, one should move the sensory stimulus from areas of decreased sensation upward, rather than the reverse, because patients are more sensitive to the appearance of sensation than to its disappearance. A cotton swab may be used to assess sensitivity to light touch, a posterior column function. A pin should be used to assess pain, which is an anterior spinothalamic tract function. Even in the presence of complete motor paralysis, the presence of islands of preserved sensation within an affected dermatome or below the level of dysfunction indicates potential for functional recovery. An accurate baseline sensory examination is imperative because cephalad progression of hypesthesia is the most sensitive indicator of deterioration. When this is observed in the cervical region, one should anticipate impending respiratory failure and preemptively secure the airway.

Spinal Cord Lesions

Complete Spinal Cord Lesions

A complete spinal cord lesion is defined as total loss of motor power and sensation distal to the site of an SCI. Functional motor recovery is rare with a complete cord syndrome that persists for longer than 24 hours. Before making the diagnosis of a complete cord syndrome, however, two points should be considered. First, any evidence of minimal cord function, such as sacral sparing, excludes the patient from this group. Signs of sacral sparing include perianal sensation, preserved rectal sphincter tone, and flexor toe movement. Any of these signs indicates a partial lesion, usually a central cord syndrome, and the patient ultimately may have substantial functional recovery, including bowel and bladder control and eventual ambulation.

Second, a complete spinal cord lesion may be mimicked by a condition termed *spinal shock,* which may persist for weeks. Spinal shock results from a concussive injury to the spinal cord that causes total neurologic dysfunction distal to the site of injury. The end of spinal shock is heralded by the return of the bulbocavernosus reflex, which is a normal cord-mediated reflex elicited by placing a gloved finger in the patient's rectum and then squeezing the glans penis or clitoris or by tugging gently on the Foley catheter. An intact reflex results in rectal sphincter contraction. Absence of this reflex indicates the presence of spinal shock, during which time the patient's prognosis cannot be accurately assessed.

Incomplete Spinal Cord Lesions

Approximately 90% of incomplete spinal injuries can be classified as one of three clinical syndromes—the *central cord syndrome*, *Brown-Séquard syndrome*, and *anterior cord syndrome* (Fig. 35.28). The most common is the central cord syndrome, often seen in patients with degenerative arthritis who suffer neck hyperextension (Table 35.7). Extreme hyperextension can also injure the vertebral artery causing a posterior inferior cerebellar artery syndrome resulting in ischemia to the lateral medulla (Fig. 35.29, and see Table 35.7).

DIFFERENTIAL DIAGNOSES

The differential diagnosis of spinal injuries includes peripheral nerve injuries that may mimic sensory or motor deficits from a central lesion. For example, compression of the superficial peroneal nerve from a fibular fracture may result in a foot drop, but impingement of a lumbar spinal nerve root from a lumbar vertebral fracture could also result in weakness in dorsiflexion. As noted, ligamentous injury in SCIWORA is also a consideration. Muscle contusions and strains around the neck, thorax, and lumbosacral regions would also be part of the differential diagnosis. Finally, a diagnosis of exclusion, conversion disorder, can result in apparent manifestations of sensory and motor deficits that may initially be confused and attributed to spinal injuries.

DIAGNOSTIC TESTING

Radiographic Evaluation

Indications

Emergency clinicians have historically taken a liberal approach to imaging the cervical spine in the setting of trauma because failure to recognize an SCI may result in devastating neurologic consequences. In an effort to standardize clinical practice and reduce avoidable radiographic imaging, two clinical decision rules were developed. The first rule to be developed, the National Emergency X-Radiography Utilization Study (NEXUS) Low-Risk Criteria (NLC), was based on a multicenter prospective observational study involving almost 35,000 trauma patients seen at 21 EDs in the United States. The decision instrument required patients to meet five criteria to be classified as having a low probability of injury (Box 35.1). The decision rule identified all but 8 of the 818 patients who had spinal injuries. Two of these patients had a clinically

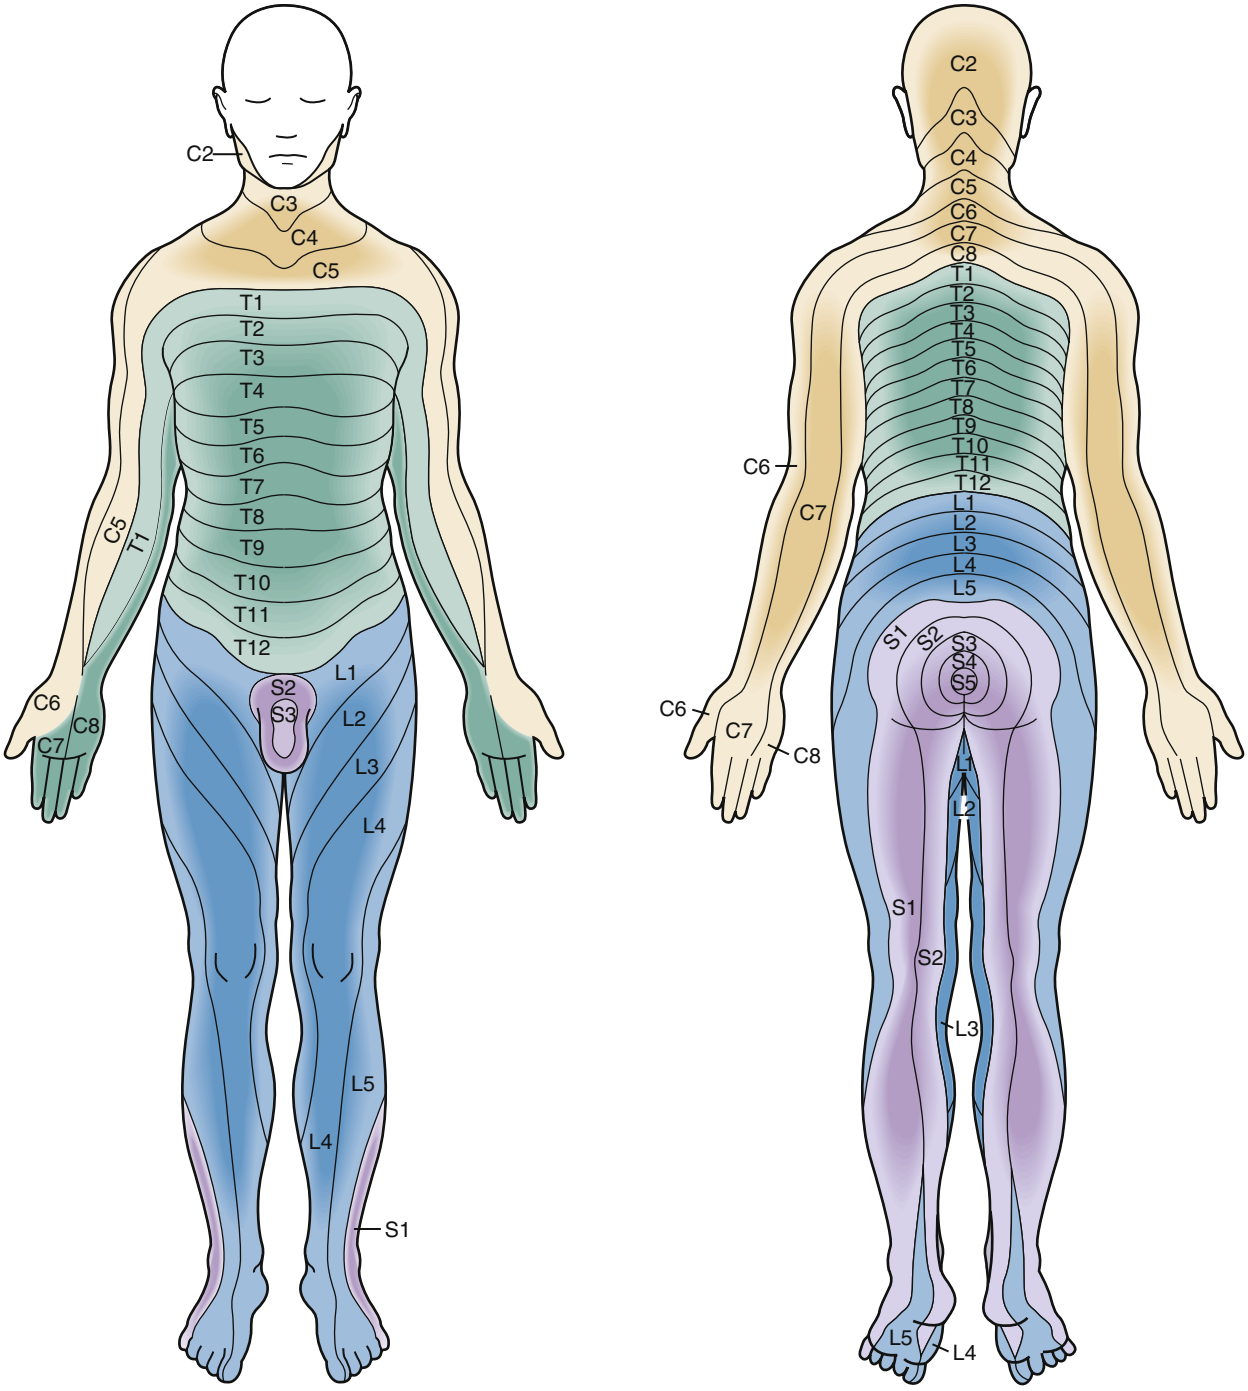

Fig. 35.27 Sensory dermatomes.

significant injury, only one of whom required surgical stabilization, and neither sustained a permanent neurologic injury. Sensitivity, specificity, and negative predictive value of the NLC were 99.6%, 12.9%, and 99.8%, respectively.

Owing to concerns about the low specificity of the NLC, the Canadian C-Spine Rule (CCR) was developed using 25 selected clinical predictor variables associated with spine injury. In 2003, the CCR was prospectively studied and compared with the NLC in nine Canadian tertiary care hospitals. Of 8283 patients, 162 were found to have clinically significant injuries, and the sensitivity, specificity, and negative predictive values of the CCR were, respectively, 99.4%, 45.1%, and 100%. The CCR is composed of the following three questions:

1. Are there any high-risk factors that mandate radiography?
2. Are there any low-risk factors that allow safe assessment of range of motion?
3. Is the patient able to rotate his or her neck actively 45 degrees to the left and to the right?

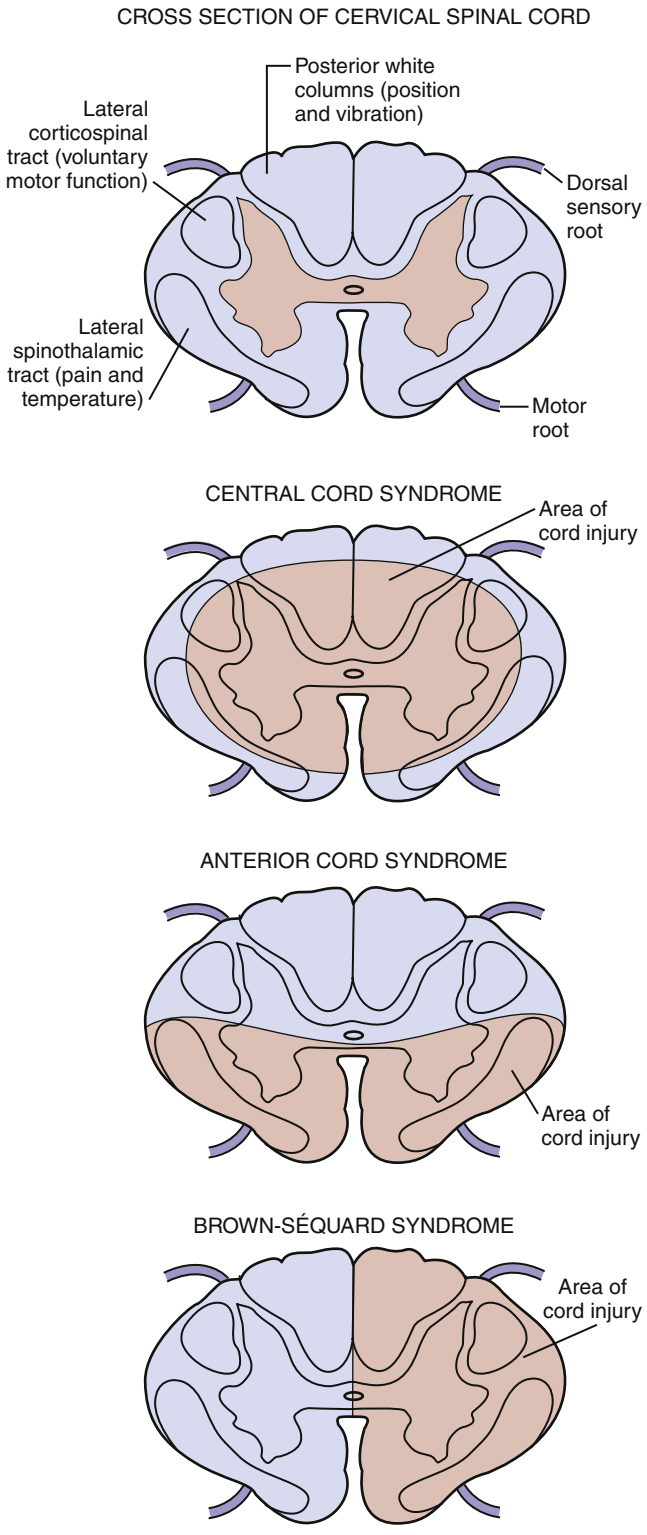

Fig. 35.28 Incomplete spinal cord syndromes.

According to the CCR, patients with no high-risk factors, any low-risk factor, and the ability to rotate the neck do not require radiographic evaluation (Box 35.2). Although the NEXUS criteria are more widely used in the United States, there is controversy regarding which of the two rules to implement; a systematic review demonstrated better diagnostic accuracy for the CCR. There are methodologic differences in the respective study designs, such as different inclusion and exclusion criteria. Nonetheless, both rules have been well-validated and are sensitive, and the use of either rule decreases the number of unnecessary radiographs while rarely missing clinically significant injuries.

A validated clinical decision rule for imaging in thoracolumbar spine (TLS) injuries does not yet exist, although it is recognized that the clinical examination alone is inadequate to exclude TLS injuries.[6] A prospectively derived rule found the absence of back pain, midline tenderness, and neurologic deficit in combination with age under 60 and low-risk mechanism were 98.9% sensitive for clinically significant TLS injuries, but validation of these findings is required before the rule is appropriate for clinical use.[7]

Cervical Plain Radiographs

Due to the widespread availability and superior test characteristics of CT imaging in the United States, spinal plain radiographs are now rarely obtained, especially when CT is ordered to visualize a different body part. Furthermore, plain radiographs have been shown to be inadequate to visualize the entire cervical spine in up to 72% of cases, thus necessitating CT scanning. However, plain radiographs are often used outside the United States, and there is concern regarding cost and exposure to medical radiation from CT. When compared to plain radiographs, CT respectively confers a 10- to 14-fold increase in radiation exposure to the skin and thyroid.

Thus, in light of the cost and radiation exposure, plain radiographs of the cervical spine may be obtained in patients who sustain a relatively minor mechanism of injury but fail the NLC and CCR criteria, and do not warrant CT of the head or other body parts. On plain radiographs, the C7–T1 vertebrae may be obscured in muscular or obese patients, as well as in patients with spinal lesions causing paralysis of the muscles that act to depress the shoulders. In this case, a swimmer's view of the lower cervical vertebrae, or CT scan, is often needed. The cross-table lateral view of the cervical spine is the most helpful x-ray, but its inadequacy as the sole view is well documented. The diagnostic yield is significantly increased when the AP and odontoid views are included. The NLC has shown that a technically adequate three-view trauma series will fail to diagnose significant spinal injury in only 0.07% of patients with injuries and in only 0.008% of patients with unstable injuries. Note that once a CT scan is performed, however, plain radiographs do not add any further clinically relevant information and should not be obtained.

Flexion-extension (F/E) views are rarely indicated in the acute evaluation of a patient presenting to the ED after acute trauma. F/E views have poor test characteristics for the detection of ligamentous cervical spine injuries and are inferior to MRI.

Thoracolumbar Plain Radiographs

Plain films of the thoracolumbar spine have inferior sensitivity for detection of fractures when compared with CT imaging and a higher dosage of radiation exposure. The posterior cortex is poorly visualized on plain film which causes some injuries to be inaccurately classified as stable, and causes some burst fractures to be misidentified as compression fractures.

Interpretation of spinal plain radiographs. The inspection of the lateral cervical spine film should be methodical and complete. It is helpful to remember the ABCs of interpreting the lateral film, where *A* stands for alignment, *B* for bony abnormalities, *C* for cartilage space assessment, and *s* for soft tissues (Figs. 35.30, 35.31,

TABLE 35.7 Incomplete Spinal Cord Injuries

Incomplete Cord Injury	Mechanism	Exam Findings	Prognosis
Central Cord Syndrome	Neck hyperextension buckles ligamentum flavum causing concussion of central cord. Spinothalamic and pyramidal tracts affected	Upper > lower extremity weakness and loss of pain and temperature sensation	>50% regain ambulation, bladder and bowel function. Hand function regained is variable.
Brown-Séquard Syndrome	Hemisection of cord usually from penetrating injury, more rarely from cervical spine lateral mass fracture	Ipsilateral loss of motor, position, and vibration sense. Contralateral loss of pain and temperature sensation	Contralateral motor, bladder and bowel function maintained. Most regain ambulation
Anterior Cord Syndrome	Hyperflexion causing cord contusion from bone fragment or herniated disk, or anterior spinal artery injury	Motor paralysis and hypalgesia below level of injury. Preservation of position, light touch, and vibratory sensation	Potentially surgically correctable, prompt neurosurgical consultation warranted. Variable recovery within 24 hours of surgery but minimal thereafter.
Cauda Equina Syndrome	Injury to nerve roots below the L2 level	Perineal or bilateral leg pain, bowel or bladder dysfunction, perianal anesthesia, urinary retention, diminished rectal sphincter tone, bilateral leg weakness	Variable recovery of bladder and bowel function
SCIWORA	Mechanism uncertain, but possibly ligamentous laxity allowing transient spinal subluxation, cord stretching and vascular compromise	Brief episode of upper extremity weakness or paresthesias followed by neurologic deficits appearing hours to days later[22]	Variable depending on severity of deficits present and rate of resolution[23]
Posterior Inferior Cerebellar Artery Syndrome	Vertebral artery injury from extreme hyperextension causing ischemia to lateral medulla (see Fig. 35.29)	Dysphagia and dysphonia from ipsilateral paralysis of pharynx and larynx, hiccups, nausea and vomiting, vertigo, cerebellar ataxia, contralateral loss of pain and temperature sensation	More favorable than other ischemic strokes, often recover ADLs despite persistent gait instability
Horner's Syndrome	Injury to sympathetic fibers in cervical spine	Ipsilateral ptosis, miosis, and anhidrosis	Dependent on other structures affected by injury
Spinal Trigeminal Tract Injury	Arterial injury from extreme hyperextension	Dejeuene onion skin analgesia of the face	Dependent on other structures affected by ischemia

and Table 35.8). Pseudosubluxation in infants and children is attributed to immature muscular development and a hypermobile spine. Thus, if a high cervical injury is suspected in a child, the posterior cervical line, which connects the points bisecting the bases of the spinous processes of C1 and C3, should be used (Fig. 35.32). If the base of C2 lies more than 2 mm anterior or posterior to the posterior cervical line, an injury at that level should be suspected. Odontoid and AP views should also be assessed for signs suggestive of fracture.

Advanced Imaging: Computed Tomography and Magnetic Resonance

The CT scan is the technique of choice for the evaluation of acute spine trauma because of its superior test characteristics and time efficiency in the radiology department when compared to plain radiography.[8] CT imaging permits examination without moving the patient from the supine position and is thus preferable in terms of fracture stabilization, airway control, and other life support measures. CT can also identify bony fragments, acute disk herniation, foreign body, paraspinal hematoma, or extramedullary hematoma. Thus, routine plain radiographs in many centers are reserved for the alert patient with minor trauma. In addition to those undergoing CT imaging of other body parts, CT is preferred when plain radiographs are difficult to interpret because of abnormal anatomy, such as in older adults with degenerative disease or the patient with rheumatoid arthritis. Additionally, rotational and distraction injuries resulting in atlanto-occipital dislocations may be missed on plain x-ray. For patients who have a severe mechanism of injury, unless CT is not available, we support the practice guidelines from the Eastern Association for the Surgery of Trauma, which recommend that CT imaging from the occiput to T1 be used as the primary screening. Because fractures in contiguous and noncontiguous vertebrae are fairly common, CT scans should be obtained to visualize the entire cervical spine.

Fractures involving the transverse foramina or C1–C3 are associated with vertebral artery dissection or thrombosis in up 22% of cases, as well as basilar artery stroke. When such fractures are identified, we recommend further study by magnetic resonance angiography (MRA), CT angiography (CTA), or four-vessel angiography to evaluate for blunt cerebrovascular injury (BCVI). Recognition of the risk factors for BCVI and dedicated vascular imaging allow for the early detection of these potentially occult injuries (Box 35.3). An in-depth discussion of BCVI is found in Chapter 36.

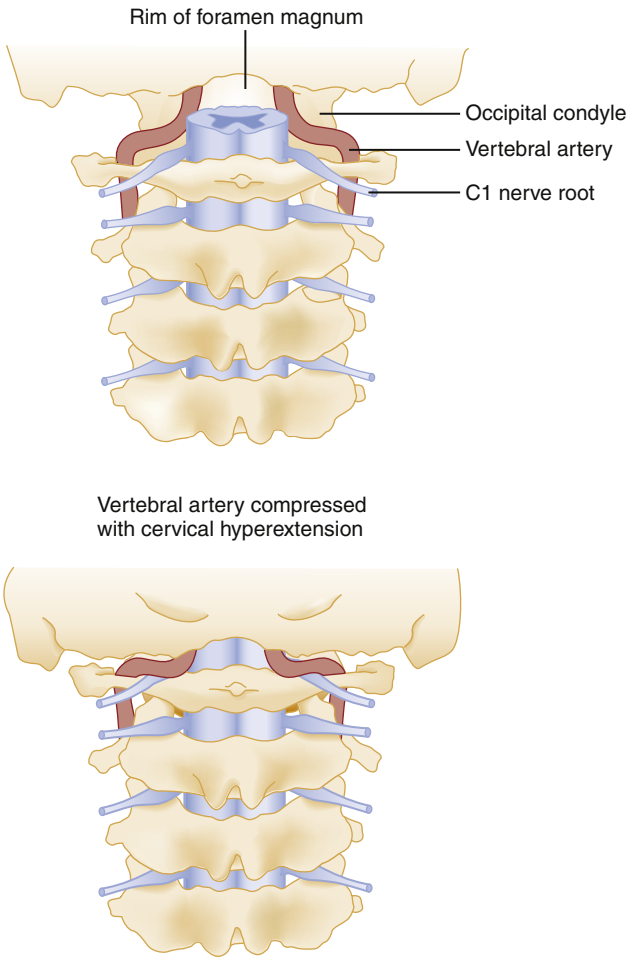

Fig. 35.29 Mechanism of vertebral artery injury in extension injuries of the cervical spine.

BOX 35.1 Nexus Criteria for C-Spine Imaging

- No midline spinal tenderness present
- No focal neurologic deficit present
- Normal alertness
- No intoxication present
- No painful distracting injury

BOX 35.2 Canadian C-Spine Rule

High Risk Mandating Radiography

Age > 65

Dangerous mechanism of injury or

Sensory deficit in extremities

Dangerous mechanisms include:

- Fall from ≥ 1 meter or five stairs
- Axial load (e.g., diving)
- MVA ≥ 100 km/hr, rollover or ejection from vehicle
- MVA involving recreational vehicle
- Bicycle collision

Low Risk Factors Allowing for Range of Motion Assessment

- Simple rear-end MVA
- Sitting position in the emergency department
- Ambulatory at the time
- Delayed onset of neck pain
- Absence of midline cervical spine tenderness and
- Able to rotate neck 45 degrees to L and R

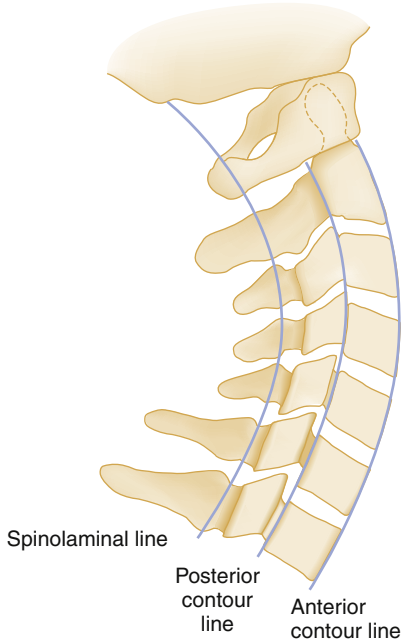

Fig. 35.30 Normal structural relationships of the lateral cervical spine.

Vertebral images reconstructed from CT scans of the abdomen and pelvis obtained for the evaluation of chest and abdominal injuries have sufficient sensitivity to detect fractures without additional dedicated CT imaging of the thoracolumbar spine.[9] CT is also thought to be adequate to clear cervical spines, even in the obtunded blunt trauma patient. The Eastern Association for the Surgery of Trauma issued a clinical practice guideline conditionally supporting the clearance of the cervical spine after negative CT imaging given a high negative predictive value, although the level of evidence was deemed low-quality.[10]

Although CT has a higher sensitivity than MRI to detect fractures and dislocations at the craniocervical junction, MRI provides superior visualization of nonosseous structures directly, including intramedullary and extramedullary spinal abnormalities that potentially cause neurologic deficit (Fig. 35.33). Its major impact has therefore been in demonstrating potentially surgically correctable lesions, including acute disk herniation, ligamentous injury, bony compression, epidural and subdural hemorrhages, and vertebral artery occlusion. MRI can identify three separate patterns of SCI, including acute cord hemorrhage, cord edema or contusion, and mixed cord injury. Patients with cord edema or contusion show significant neurologic improvement, whereas those with cord hemorrhage (Fig. 35.34) fare far worse. MRI can also diagnose a developing intramedullary (posttraumatic) syrinx or subarachnoid cystic changes (Fig. 35.35). Thus, a patient who demonstrates neurologic deficit or persistent neck pain suggesting ligamentous injury or an occult spine injury, should undergo an expedited MRI, even if the initial CT scan or plain radiographs are interpreted as normal (Fig. 35.36). In the obtunded or unreliable patient, MRI may

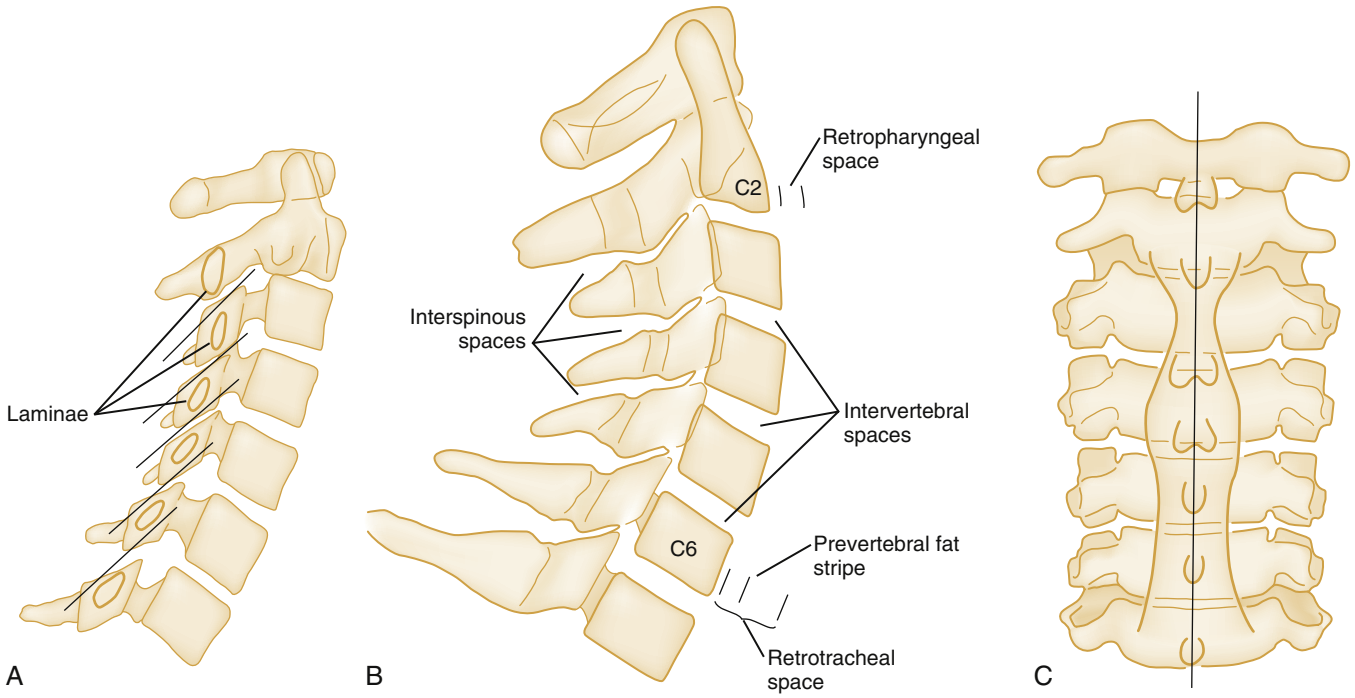

Fig. 35.31 (A) Normal structural relationships of the cervical spine laminae in an oblique view form a so-called shingles on a roof appearance. (B) In the lateral view, the intervertebral spaces and interspinous spaces should be compared with the spaces above and below for asymmetry. The retropharyngeal and retrotracheal soft tissues are measured at the C2 and C6 levels for swelling. (C) Normal relationship between soft tissues and bony structures of the cervical spine in the lateral and anteroposterior (AP) views. In the AP view, the tracheal and laryngeal air shadows should be within the midline. A straight line should connect points bisecting the spinous processes. If such is not the case, rotatory injuries are suspected.

TABLE 35.8 Interpretation of Spinal Plain Radiographs

Radiologic View	Normal Findings	Significant Findings
Cross-table lateral	Three continuous lines (see Fig. 35.30): • Anterior vertebral body margins • Posterior vertebral body margins • Spinolaminal line: spinous process bases Predental space: distance between anterior odontoid and posterior aspect of anterior C1 ring (see Fig. 35.32) • ≤3mm in adults • ≤5mm in children Cartilage spaces: Even width across each intervertebral and interspinous level Soft tissues: Retropharyngeal and retrotracheal spaces measured from anterior vertebral body to airspace (see Fig. 35.32) • C2: ≤6 mm in adults and children • C3–C4: ≤5 mm, or less than half width of vertebral body • C6: ≤22 mm in adults, ≤14 mm under age 15	Disruption of any line suggests bony or ligamentous injury Pseudosubluxation of C2 and C3 common in infants and children Widening of predental space may indicate Jefferson fracture of C1 Anterior or posterior widening of space may indicate unstable dislocation Prevertebral swelling may be only sign of hemorrhage and spinal injury Air in prevertebral space suggests aerodigestive tract injury Retropharynx may widen during expiration in children under 2 years, obtain inspiratory films
Odontoid	Open and closed mouth views of atlas and axis for diagnosing odontoid and Jefferson fractures	Fractures mimicked by nonfusion of odontoid in children, congenital odontoid anomalies in adults
Anteroposterior	Base of spinous processes should form straight line (see Fig. 35.32) Pedicles viewed end on Laryngeal and tracheal air shadows midline Regular outlines of lateral masses	Bulging mediastinal stripe from hemorrhage may be only evidence vertebral body fracture on chest X-ray Widened interpedicular distance suggests burst fracture

not be necessary to exclude unstable injuries if the CT scan is normal, according to the Eastern guidelines.[10]

MANAGEMENT

Spinal injury should be suspected in all trauma victims with an unknown or suggestive mechanism of injury associated with complaints of neck or back pain, evidence of significant head or facial trauma, spinal tenderness, signs of focal neurologic deficit, impaired consciousness, potentially distracting injuries, or unexplained hypotension.

Spinal Column Stabilization

Out-of-Hospital Care

Prehospital personnel are well versed in the care of the patient with a potentially traumatized spine, and all emergency medical services (EMS) incorporate these principles. Historically, the traditional approach to immobilization required the automatic and routine initiation at the scene of the use of a backboard, rigid cervical collar, and supportive blocks on both sides of the head with a concerning mechanism of injury. However, it has been noted that many trauma patients are unnecessarily immobilized by EMS, and immobilization can be detrimental. In addition to resulting in prolonged on-scene time and delayed transport to definitive care, the backboard can lead to pressure ulcers, increased pain, and decreased functional respiratory residual capacity. Also, cervical collars can hide other injuries, such as lacerations and hematomas, and have even been found to result in worsening vertebral distraction injuries. There is also ample evidence that EMS providers can safely apply spinal assessment guidelines, such as NEXUS.

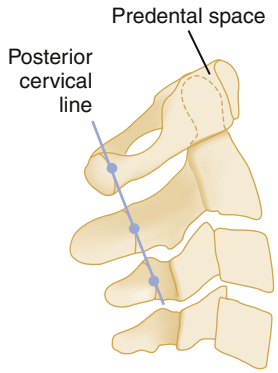

Fig. 35.32 Posterior cervical line of a normal lateral spine.

BOX 35.3 Expanded Denver Screening Criteria for Blunt Cerebrovascular Injury

Imaging Indicated if One or More Criteria Present

Signs/symptoms of BCVI:

- Arterial hemorrhage from neck/nose/mouth
- Cervical bruit in patients <50 years
- Expanding cervical hematoma
- Focal neurologic deficit
- Neurologic exam incongruous with head CT findings
- Stroke on secondary CT scan

Risk factors for BVCI (high-energy transfer mechanism):

- Le Fort II or III
- Mandible fracture
- Complex skull fracture/basilar skull fracture/occipital condyle fracture
- Severe traumatic brain injury (TBI) with GIsasgow Coma Score < 6
- Cervical spine fracture, subluxation or ligamentous injury at any level
- Near hanging with anoxic brain injury
- Seat belt abrasion with significant swelling, pain or altered mental status
- TBI with thoracic injury
- Scalp degloving
- Thoracic vascular injury
- Blunt cardiac rupture
- Upper rib fracture

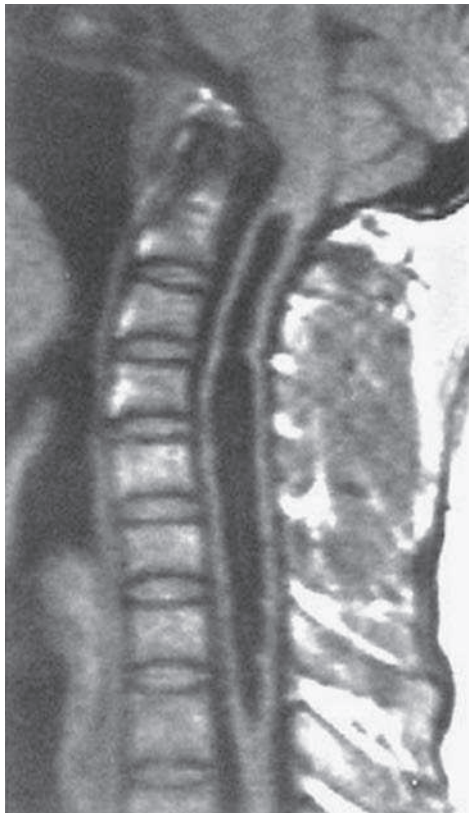

Fig. 35.35 MRI scan showing posttraumatic syrinx of the spinal cord.

Emergency Department

Trauma victims are assessed as described in Chapter 32 while maintaining immobilization. If the patient's spine can be clinically cleared by use of the NEXUS criteria or CCR, the immobilization device may be removed. If the trauma victim was wearing a helmet and the helmet was not removed in the field, the face mask, helmet, and any sports padding (e.g., shoulder pads on hockey or football players) may be carefully removed while immobilization is maintained. Ideally, at least two or three providers should be present to perform the task of helmet removal. Once the helmet and shoulder pads have been removed, a rigid collar should be placed if the patient's cervical spine cannot be cleared by use of the NEXUS criteria or CCR.

Patients with probable spinal injury who are conscious and cooperative should be immobilized until imaging has been performed. Patients who are uncooperative because of head injury, drug or alcohol intoxication, hypotension, or presence of multiple painful injuries require a deliberate approach, including the use of chemical and mechanical restraints. Suspected thoracic and lumbar spinal injuries are best managed by keeping the patient supine and immobile, using logroll precautions when needed. The goal of stabilization in cervical spine trauma is to immobilize the neck and body because any movement may extend the initial injury. If the patient is not already immobilized on a backboard, the torso should be firmly anchored to the examining table by straps or rolled sheets. Sedation, drug-induced paralysis, and intubation may be required for patients who pose a danger to themselves because of excessive movement and whose injuries otherwise will likely require intubation. Paralysis and intubation are not used simply to control patient movement or lack of cooperation. Spinal precautions should be maintained in patients with an altered sensorium until the presence of an injury can be excluded clinically or radiographically. Every effort, however, should be made to remove the patient as quickly as possible from the backboard to prevent aspiration and the development of pressure ulcers. Suctioning should be readily available to prevent aspiration. Vomiting patients should be placed on their side by logrolling while spinal alignment is maintained.

Airway Management

Cervical spine injuries often require early intubation as part of the resuscitation. Lesions above C3 may rapidly progress to respiratory paralysis, and the spread of edema from a lower injury may cause delayed phrenic nerve paralysis, as well as ascension of the neurologic injury above the level of C3. Cervical injuries may be associated with airway obstruction from retropharyngeal hemorrhage or edema or maxillofacial trauma. Medications for induction and post-intubation sedation should be chosen in order to reduce the risk of hypotension (e.g., propofol).

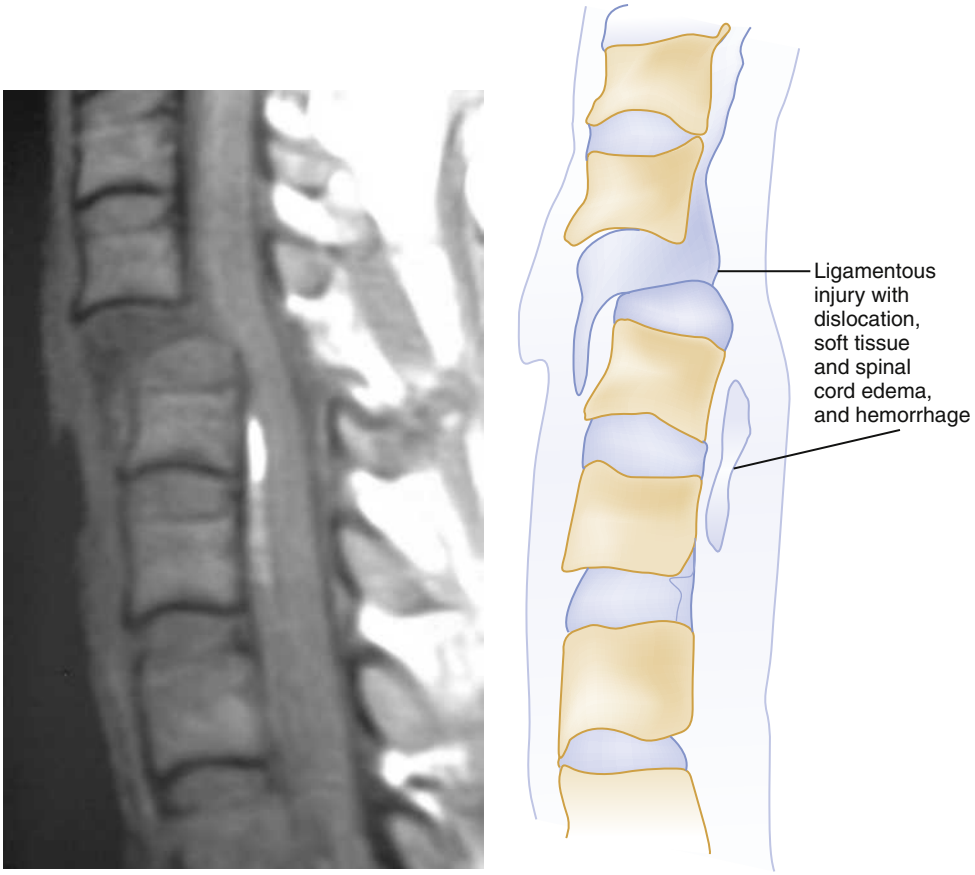

Fig. 35.36 Anteroposterior longitudinal ligament disruption. A sagittal MRI scan demonstrates ligamentous disruption between C4 and C5, with blood tracking in the anterior spinal canal.

Airway management of the trauma patient, including those with suspected spine injury, is discussed in Chapter 1.

Spinal Shock

Spinal shock is characterized by the temporary loss of neurologic function and autonomic tone below the level of an acute spinal cord lesion. Patients usually exhibit flaccid paralysis with loss of sensation, deep tendon reflexes, and urinary retention, along with bradycardia, hypotension, hypothermia, and intestinal ileus. Recovery from spinal shock, which may last from less than 24 hours to more than 2 weeks, is heralded by the return of the bulbocavernosus reflex.

Neurogenic hypotension, caused by loss of vasomotor tone and lack of reflex tachycardia, is a diagnosis of exclusion in the trauma victim. It should not be considered the cause of hypotension unless the patient is flaccid and areflexic, reflex tachycardia and peripheral vasoconstriction are absent and, most important, the possibilities of coexisting hemorrhagic shock, cardiac tamponade, or tension pneumothorax have been eliminated.

Although there is no high-quality evidence for an optimal mean arterial pressure (MAP), we recommend initiating the resuscitation of hypotensive trauma victims with a balanced crystalloid fluid infusion, as outlined in Chapter 32. Most cases of pure neurogenic hypotension are mild (e.g., systolic blood pressure > 90 mm Hg) and may not require fluid resuscitation or will respond to modest amounts of fluid.[11] Severe neurogenic hypotension (e.g., systolic blood pressure < 70 mm Hg), seen in 20% to 30% of cases, more often occurs with high cervical injuries associated with total or near-total loss of neurologic function.[12] Because hypotension can lead to hypoperfusion and secondary spinal cord ischemia, prolonged severe hypotension (systolic blood pressure < 70 mm Hg) should be prevented and treated. Fluid resuscitation is often ineffective in such patients and may result in fluid overload. Thus, when there is persistent hypotension despite fluids, we recommend vasopressor support with norepinephrine to be started at 0.05 μg/kg/min and titrated upward to a maximum dose of 1 μg/kg/min to achieve a MAP of 85 mm Hg.[13-15]

Pharmacologic Treatment for Incomplete Cord Injury

Delayed biochemical damage contributes to ongoing tissue loss and worsening neurologic function in SCI. Thus, numerous neuroprotective and neuroregenerative treatment strategies, including pharmacologic treatment, hypothermia, and decompression, have been investigated in laboratory animal studies and human clinical trials. Despite public interest and media attention on case reports of significant functional recovery after therapeutic hypothermia in SCI, evidence in support of therapeutic hypothermia is of low quality and limited to a number of case series.[16] To date, no randomized controlled trial of hypothermia in SCI has been performed, and it cannot be recommended for clinical use. Reported complications from hypothermia induction include pneumonia, thrombocytopenia, and atrial fibrillation.

Methylprednisolone, once widely recommended for use on the basis of extremely weak evidence, has been found to have no benefit and is likely, on balance, to be harmful. It is no longer recommended or used for acute spinal cord injury.[17]

Associated Injuries

Cardiopulmonary

Although cardiopulmonary deterioration in a trauma victim is usually the result of hemorrhagic shock or direct injury to the heart or lungs, pulmonary edema may also occur in response to brain injury and SCI.

Spinal cord trauma stimulates an intense sympathetic discharge with two subsequent effects. First, pulmonary capillary endothelial cells are disrupted, leading to the pulmonary capillary leak syndrome, in which pulmonary edema occurs in the presence of normal pulmonary artery pressures (<18 mm Hg). Second, marked increases in afterload may lead to pulmonary edema associated with high pulmonary artery pressures (>18 mm Hg) from ventricular dysfunction. Excessive fluid resuscitation can also contribute to pulmonary edema. Later in the recovery period, many SCI patients suffer from alternating episodes of low and high blood pressure, often with labile heart rates, termed *autonomic dysreflexia*.[18] The treatment for this is primarily supportive by addressing causative factors, such as bladder distention, pain, and hydration status.

Gastrointestinal and Genitourinary

If SCI renders the abdominal examination unreliable, an abdominal CT scan or ultrasound is often necessary. In the acute stages of SCI, the gastrointestinal tract and bladder become atonic. Thus, a nasogastric tube should be placed to prevent gastric distention and a Foley catheter inserted to prevent bladder distention and monitor fluid output. Because gastrointestinal bleeding from stress ulcers occurs in 2% to 20% of spinal trauma patients, ulcer prophylaxis with histamine H2 receptor antagonists or proton pump inhibitors should be initiated.

Skin

Denervated skin is extremely susceptible to pressure necrosis, and sores can develop in less than 1 hour on unpadded spinal carts. Therefore, backboards should be removed as soon as possible. Padding pressure areas with sheepskin or foam can help minimize decubitus ulcers.

Definitive Treatment and Prognosis

The role of prompt surgical intervention in the management of spinal injuries is currently limited to relieving spinal cord impingement caused by foreign bodies, herniated disks, bony fracture fragments, or epidural hematoma. Surgery may be necessary later to stabilize severe bony injuries or reduce spinal dislocations. The timing of surgical intervention remains controversial because there are no well-designed studies that have determined whether early (<12 hours) versus late decompression is beneficial.

Once almost uniformly fatal, major spinal injury caused death from pulmonary complications or sepsis from skin necrosis or urinary infection. The advent of antibiotic therapy made long-term survival not only possible but also expected. Today, patients with SCIs are best managed at a regional spine injury center, where a team of neurosurgeons, orthopedic surgeons, psychologists, and physical therapists can initiate rehabilitation. Specialized SCI treatment centers offer patients a chance to return to a productive life within the limits of their disability. With the exception of patients with high cervical lesions (above C5), most patients attain sufficient independence to live outside of high-level care environments.

Significant pain impacting quality of life is frequently reported after recovery from the initial injury. Pain after SCI may be nociceptive, or related to tissue injury, or neuropathic and can occur at the level of the SCI or below. Various pharmacologic agents have been investigated for the treatment of pain in SCI, with the strongest evidence supporting anticonvulsants including gabapentin and pregabalin.[19] Antidepressants may also be effective for those with co-occurring pain and depression. Opioids are effective for SCI-related pain, but caution should be exercised with their use given the often-chronic nature of pain after SCI. Nonopioid pharmacologic therapy is recommended prior to initiation of opioids in chronic pain. When given, opioids should be prescribed for a short duration at the lowest effective dose in an immediate release formulation,[20] because chronic opioid use and dependence are often preceded by an opioid prescription given for acute pain. Robotic powered exoskeleton devices have the ability to restore limited ambulatory function to survivors of SCI. Assisting patients with complete SCI with a thoracic or lower level after the initial recovery period, movements of the robotic limbs are coordinated using motion of the arms and trunk. Factors influencing function include software algorithms to generate smooth movements, and exoskeleton articulations analogous to human leg joints.[21]

BOX 35.4 Prognostic Indicators of Poor Functional Recovery Following Whiplash-Associated Disorders

Factors with Consistent Evidence for Being Prognostic Indicators for Poor Recovery

- Initial pain levels > 5.5/10
- Initial disability levels: NDI > 29%
- Symptoms of posttraumatic stress
- Negative expectations of recovery
- High pain catastrophizing
- Cold hyperalgesia

Factors with Consistent Evidence of Not Being Prognostic Indicators

- Accident-related features (e.g., collision awareness, position in vehicle, speed of accident)
- Findings on imaging
- Motor dysfunction

Factors with Inconsistent Evidence

- Older age
- Female gender
- Neck range of movement
- Compensation-related factors

NDI, Neurological Disability Index.
Adapted from Sterling S. Physiotherapy management of whiplash-associated disorders (WAD). *J Physiother* 2014;60:5-12.

DISPOSITION

Cervical Soft Tissue Injuries

Patients with cervical soft tissue injuries of the spine who have only mild to moderate discomfort without neurologic impairment or abnormal radiographic findings (WAD class 1 or 2) are best managed as outpatients. Discharge instructions should include educating the patient that pain often increases over the first 24 to 48 hours but that the symptoms will begin to dissipate thereafter. We recommend treatment with analgesics, such as acetaminophen, 650 to 1000 mg/dose, up to four times daily, not to exceed 4 gm. Although analgesic doses of a nonsteroidal antiinflammatory drug, such as ibuprofen, 400 to 600 mg/dose, is also reasonable, there is ample evidence that acetaminophen, which has fewer adverse effects on the gastrointestinal and renal systems, is equally effective, and there is no indication for antiinflammatory treatment. Additionally, we do not recommend medications with purported muscle relaxant properties, such as cyclobenzaprine, because they have not been found to provide additional benefit and have an adverse side effect profile (principally anticholinergic effects and drowsiness.). Finally, referral for follow-up with a primary care physician is indicated because up to 50% of patients experiencing neck pain after trauma will continue to have symptoms at 1 year. This is more likely in patients with WAD class 3 but can occur in patients with class 2 and rarely class 1. Box 35.4 lists the prognostic indicators of poor functional recovery in patients with a WAD.

Minor Fractures

Most patients with spinal fractures require hospitalization. Patients with isolated cervical vertebral body compression or spinous process fractures may be managed as outpatients if there is no evidence of neurologic impairment or associated ligamentous instability, and the degree of patient distress is not severe. Appropriate follow-up should be arranged for all patients because even minor spinal injuries may be associated with prolonged disability from chronic pain.

For patients with minor wedge fractures (<10% compression of the anterior vertebral body height) who do not have an associated ileus or neurologic deficit, outpatient management may be possible. However, most wedge fractures of the thoracic and lumbar spines are usually best managed in the hospital for several reasons. First, patients with these injuries usually have marked discomfort, often requiring parenteral opioid analgesia. Second, significant force is generally required to fracture thoracic or lumbar vertebrae, and associated intrathoracic or abdominal injuries are common.[5] Third, lower thoracic and lumbar fractures are associated with prolonged and occasionally delayed gastrointestinal ileus, requiring continuous nasogastric suction. Finally, older adults who have vertebral fractures and only minor associated injuries may require admission to facilitate assessment of fall risks and expedite rehabilitation.

CHAPTER 35: QUESTIONS AND ANSWERS

1. Which of the following is a stable cervical spine fracture?
- **A.** Anterior atlantoaxial dislocation without fracture
- **B.** Bilateral facet dislocation
- **C.** Flexion teardrop
- **D.** Jefferson fracture
- **E.** Unilateral facet dislocation

Answer: E. See Table 35.1 for a classification of spinal injuries according to stability.

2. A 28-year-old man is brought to the emergency department (ED) after a rollover motor vehicle collision (MVC). He is moderately hypotensive, unable to flex his elbows, and has diffuse lower extremity paralysis. What is the likely site of the lesion?
- **A.** C4
- **B.** C5
- **C.** C6
- **D.** C7
- **E.** C8

Answer: C. See Table 35.2

3. Which of the following statements regarding high-dose methylprednisolone after spinal cord injury is true?
- **A.** Dexamethasone is superior to methylprednisolone if a concurrent closed head injury is present.
- **B.** High-dose methylprednisolone should not be used to treat spinal cord injury.
- **C.** It is efficacious after penetrating injury if given within 4 hours.
- **D.** It is efficacious in cases of spinal shock.
- **E.** It is more efficacious after thoracic than after lumbar injuries.

Answer: B. Evidence that high-dose methylprednisolone is a clinically efficacious intervention in the management of acute, blunt, partial spinal cord injury is lacking and, because of severe side effects, it should not be used.

4. A 27-year-old man presents after a high-speed rollover MVC. The physical examination is remarkable for T8 motor-sensory deficit and a moderately distended abdomen that is nontender. Vital signs are heart rate, 108 beats/min, blood pressure, 88/40 mm Hg, respiratory rate, 22 breaths/min, temperature, 35°C (95°F), and oxygen (O_2) saturation, 96%. Which of the following tests or treatments is indicated?
- **A.** Baseline laboratory tests and observation
- **B.** Computed tomography (CT) scan of the abdomen
- **C.** Intravenous phenylephrine infusion
- **D.** Packed red blood cell transfusion
- **E.** Thoracolumbar spine films

Answer: B. Spinal cord injury often renders the abdominal examination unremarkable. CT, ultrasonography, diagnostic peritoneal lavage, or some combination is necessary to rule out intra-abdominal injury.

5. A 23-year-old man presents after a rollover MVC. He is brought by emergency medical services (EMS) from the scene fully restrained on a backboard, with a cervical collar. The physical examination is remarkable for moderate symmetric numbness below the neck, symmetric arm and leg weakness, intact reflexes, and diminished rectal tone. Vital signs are heart rate, 94 beats/min, blood pressure, 80/46 mm Hg, respiratory rate, 24 breaths/min, and O_2 saturation, 96%. Which of the following treatment sequences is most indicated?
   A. Crystalloid to CT scan to phenylephrine
   B. Crystalloid to focused assessment with sonography for trauma (FAST) examination to transfusion
   C. Crystalloid to phenylephrine to transfusion
   D. Dopamine to crystalloid to CT scan
   E. Transfusion to phenylephrine

Answer: B. Spinal shock should not be considered the cause of hypotension unless the patient is flaccid and areflexic. Crystalloid is the first step regardless of the traumatic hypotensive cause. The possibilities of coexisting hemorrhagic shock, cardiac tamponade, tension pneumothorax, or other life-threatening injuries should first be addressed. The absence of vasomotor activity in patients with neurogenic hypotension may mask the usual presentation of these life-threatening injuries. In this case, the lack of flaccidity and presence of reflexes argues for a non-neurogenic cause for the hypotension.

6. Which of the following is not a characteristic of flexion-distraction injuries of the lumbar spine?
   A. Compression of the anterior vertebral body
   B. Associated intrabdominal injuries are common
   C. Axis of rotation anterior to the vertebral body
   D. Unstable fracture pattern

Answer: C. Flexion distraction injuries are characterized by an axis of rotation posterior to the anterior longitudinal ligament causing compression of the anterior vertebral body and distraction of the posterior elements with failure of all three columns. It is an unstable fracture pattern with a high rate of associated intra-abdominal injuries.

7. Presence of which of the following findings warrants imaging to evaluate for blunt cerebrovascular injury?
   A. Isolated seat belt abrasion
   B. LeFort I fracture
   C. Frontal scalp hematoma
   D. Cervical bruit in 40-year-old extricated after MVA

Answer: D. A cervical bruit auscultated in a patient under the age of 50 is a sign of possible blunt cerebrovascular injury and requires dedicated arterial imaging. A seat belt sign with significant swelling, pain or altered mental status is indication for screening for BCVI, but not an isolated seat belt abrasion. Midface fractures with instability, LeFort grades II and III, are associated with BCVI. Isolated scalp hematoma is not associated with an increased risk of BCVI.

36

Neck Trauma

Kim Newton and Ilene Claudius

KEY CONCEPTS

- Significant injuries to the cerebral vessels can occur as a result of blunt or penetrating trauma to the neck.
- Blunt trauma to the neck can lead to immediate or delayed ischemic strokes, and a low threshold for imaging vessels when neurologic findings or risk factors for cervical vessel injury exist is recommended.
- A no-zone approach to penetrating neck trauma is becoming widely accepted as opposed to a zone-based selective management algorithm.
- Multidetector CT angiogram is the initial imaging modality of choice in essentially all symptomatic cases of blunt or penetrating neck trauma.
- Both penetrating and blunt neck injuries can present with minimal to no initial signs of injury; a high index of suspicion is therefore required.
- Because of the paucity of neck trauma in children, many adult algorithms have been adopted for use in the pediatric population

FOUNDATIONS

Background and Importance

Penetrating neck injuries (PNIs) comprise 5% to 10% of all traumatic injuries, but represent less than 1% of admissions to the emergency department (ED).[1] Penetrating neck trauma carries a mortality rate of up to 10%.[2] This is primarily a condition of adults; penetrating neck trauma in the pediatric patient is fortunately an uncommon entity. Of all children entered in the 2008 to 2012 national trauma data bank, only 0.3% sustained PNI with an average age just under 8 years and a predominance of male victims (70%). In this study, 44% of the injuries were caused by knives and 24% by firearms. Aerodigestive injury is most common followed by vascular injury in children below age 11 years. In the 11 to 14-year group, this ratio reverses with vascular injuries being most common. Mortality rates are reported at 5.6%.[3]

Blunt neck trauma can injure the airway, pharyngoesophageal (PE) tract, nerves or glandular tissue, but the primary concern with blunt neck trauma involves blunt cerebrovascular injury (BCVI) to the carotid or vertebral artery. The incidence of BCVI in blunt trauma is 1%; however, 53-79% of patients are asymptomatic at presentation.[4] Therefore, asymptomatic patients with high-risk injuries require screening.

Anatomy and Physiology

The neck is defined as the area extending from the skull base to the T1 vertebral body and is separated by the superficial and deep (prevertebral) cervical fascia. The latter surrounds the perivertebral muscles and delineates the retropharyngeal space. The *superficial fascia* lies between the skin and platysma muscle. Immediately deep to the platysma is the *deep cervical fascia*, which comprises four separate layers: pretracheal, investing, and prevertebral layers as well the carotid sheath. The investing layer runs circumferentially around the entire neck just deep to the platysma. It splits to encase the trapezius and sternocleidomastoid muscles. The prevertebral fascia (deep to the investing layer) extends from the neck to the thorax, while encircling the cervical spine and prevertebral muscles. The pretracheal fascia completely surrounds the infrahyoid muscles, esophagus, trachea and thyroid gland. This layer inserts on the hyoid and thyroid cartilages above and the anterior pericardium below, while coursing deep to the sternum. It has clinical significance because it provides continuity from the neck to the mediastinum, meaning that spillage from neck wounds, in particular those involving the esophagus, can result in mediastinitis. The carotid sheath is comprised of all three layers of the deep cervical fascia. Within the sheath is found the internal or common carotid artery, the jugular vein, and vagus nerve.[5]

The neck has traditionally been divided into three zones. Zone 1 extends from the sternal notch to the cricoid cartilage, zone 2 from the cricoid cartilage to the angle of the mandible, and zone 3 from the angle of the mandible to the skull base (Fig. 36.1).[6] This distinction was largely predicated on the principal that zone 2 is the most commonly injured, has the highest mortality, and is most amenable to surgical exploration.[7] However, widespread use of computed tomography angiogram (CTA) has made evaluation of this area possible without surgical exploration, rendering these distinctions less relevant, although important for communication among consultants. Furthermore, particularly in the setting of penetrating trauma, injuries often span multiple zones, and the most significant injury may lie in a different zone than the point of entry.

The neck is also divided into an anterior and posterior triangle. The anterior triangle is densely packed with vital structures including neurovascular and aerodigestive tracts. It is bordered anteriorly by the midline, posteriorly by the sternocleidomastoid muscle, and superiorly by the lower edge of the mandible. The posterior triangle is bound by the sternocleidomastoid muscle anteriorly, the clavicle inferiorly, and the anterior border of the trapezius muscle posteriorly. Excluding spinal trauma, injury to the posterior triangle often has a more favorable prognosis because of the relative paucity of vital structures.

The left common carotid branches off the aortic arch and the right off the brachiocephalic trunk. The common carotids branch into the internal and external carotids just superior to the thyroid cartilage. The internal carotid passes through the carotid canal in the temporal bone before splitting into the anterior and middle cerebral arteries.[8] Blunt injuries to the carotids occur when hyperextension-rotation mechanisms stretch the carotid over the lateral processes of the upper spine, with hyperflexion, or with a direct blow to the vessel intraorally or externally.[9] Damage to proximal structures such as the petrous portion of the temporal bone around the carotid canal can also cause damage. The vertebral arteries run cephalad through the transverse foramina starting at C6, and through the foremen magnum. Injury occurs during

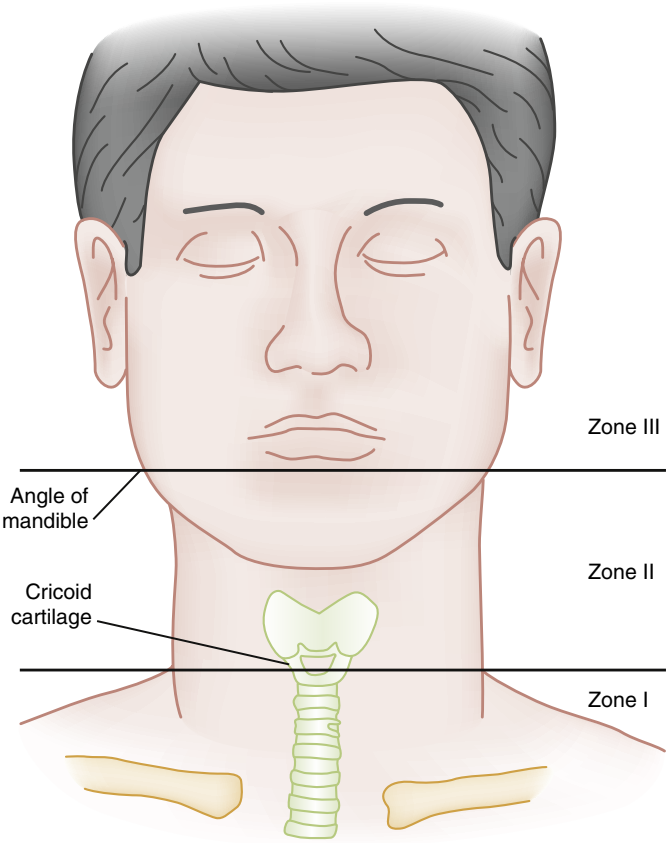

Fig. 36.1 Zones of the Neck.

damage to the transverse foramina, fractures or facet dislocations of the upper cervical vertebrae (C1 through C3), or from stretch and compression around the atlantoaxial and atlantooccipital joints.[9] Injuries to either vessel can predispose the patient to an ischemic stroke from obstruction of arterial flow.

The esophagus extends from the cricoid cartilage to the stomach (T11) and measures approximately 25 cm in the adult. It is anatomically divided into three sections: cervical, thoracic and abdominal. Physical examination alone is unreliable in diagnosing esophageal injury, and a normal examination does not exclude aerodigestive injury.

The larynx runs from the base of the tongue to the trachea, and contains the thyroid, cricoid, epiglottis and paired arytenoid, corniculate, and cuneiform cartilages. The low incidence of tracheal injury likely stems from its protected position sandwiched in-between the sternum, mandible and spine.

Pathophysiology

Vascular Injuries

The type of damage to the cervical vasculature differs according to the mechanism of injury. More than 90% of carotid injuries are caused by penetrating trauma, which can result in partial or complete vascular transection, puncture wounds, AV fistula or pseudoaneurysm[10] by direct transection or penetration injury. In addition, the concussive pressure effect resulting from the release of kinetic energy into small, contained deep neck spaces surrounding the carotid is seen with high velocity projectiles and tissue destruction remote to the projectile trajectory is expected.[4] Vascular wounds sustained from penetrating objects comprise anywhere from 10% to 25% of PNIs. The ratio of carotid to vertebral artery involvement is approximately 2:1. Carotid artery mortality rates range from 5% to 6% and it is the leading cause of immediate death in the setting of PNI due to exsanguination.[11] Extracranial vertebral artery injuries are less common with an overall incidence of 3%.[12]

Blunt trauma typically leads to vascular occlusion, dissection, and intimal flaps.[13] Up to 30% of BCVI can be bilateral.[14] Carotid injuries portend a 17% to 38% risk of mortality and 32% to 67% rate of morbidity. For vertebral injuries, these numbers are lower but still significant at 8% to 18% and 14% to 24%, respectively[8]. Two populations with distinct epidemiology are the pediatric and geriatric age groups. In one study looking at blunt injury, 23% of patients above 65 years of age with low energy falls who met screening criteria for vascular injury (detailed in the following) were diagnosed with BCVI. On the other hand, in pediatric patients, the rate of BCVI was lower than adults (0.2%),[15] but the rates of neurological morbidity (80%) and mortality (40%) were high if stroke occurs.[16] Most BCVI injury in the pediatric age group occur in teens, with only 9% impacting pre-school aged children.[17]

Pharyngoesophageal Injuries

Penetrating PE injuries are rare, and most often involve the cervical segment. Of all penetrating trauma, less than 1% results in injury to the pharynx or esophagus. Gunshot wounds comprise 54% and stab wounds 46%. Mortality rates for penetrating esophageal trauma have been reported from 4% to 8%.[18–21] Mortality rates climb significantly (exceeding 44%) when esophageal injuries occur in a trauma patient with multi-organ system involvement.[22] Diagnostic and/or therapeutic delays exceeding 24 hours are strongly associated with increased mortality.[23]

PE injuries are less common following blunt trauma, but still associated with high mortality. They occur in less than 1% of all blunt trauma and 5% of blunt neck trauma with a median age of 18 years.[24] Ten percent of laryngotracheal (LT) injuries are associated with a concurrent PE injury.[6] Falls followed by motor vehicle collisions (MVCs) are the most common mechanisms of injury, although assault is responsible for 12% of cases.[24] Mortality in patients who survive greater than 24 hours is similar regardless of whether the mechanism was penetrating or blunt.[21]

Laryngotracheal Injuries

Penetrating LT injuries most commonly result from bullets and knives. This type of injury is less common than blunt airway trauma. Penetrating LT occurs in 1% to 6% of all PNIs. These injuries can be subtle, and thus require a high index of suspicion.

In blunt neck trauma, the thyroid cartilage typically encounters forces to the neck first,[25] and is the most commonly injured, often due to direct compression or manual strangulation.[26] Laryngeal injury has been reported with sports-related neck trauma, mainly in young men.[27] Bicycle and scooter accidents are associated with posterior membranous tracheal wall injuries.[28] The cricoid cartilage is the only complete circumferential ring stenting the larynx open, leaving a patient with substantial damage to this structure at risk of airway collapse. Because the cricoid cartilage is a complete ring, there are often two fracture sites at the anterior and posterior aspects.[29] When LT separation occurs, typically, this is at the level of the cricothyroid membrane.

Hanging

Hanging is a specific type of blunt injury. Judicial hangings of the past resulted in death from cervical fractures and cord transection. Modern-day suicidal hangings rely on the external force of the ligature, which causes venous congestion and leads to unconsciousness with resultant tightening of the noose, arterial occlusion, and cerebral hypoxia. Vagal reflexes resulting from pressure on the carotid body may contribute to fatal dysrhythmias as well as increasing sympathetic

tone from pericarotid sinus pressure. Compression of the airway does not play as significant a role.

CLINICAL FEATURES

Vascular Injuries

Signs and symptoms suggesting penetrating vascular injury have been divided into two main categories: hard and soft signs of injury (Table 36.1). Differentiating between soft and hard signs in the setting of penetrating neck trauma is imperative. Hard signs are commonly seen with serious or life-threatening injuries and should prompt an immediate surgical consultation and operative intervention. Hard signs have been shown to have an 89.7% positive predictive value for the presence of vascular or aerodigestive injury.[30] Soft signs of injury are less specific but suggest the potential for a serious injury and warrant further workup. Soft signs are discovered during a thorough history and physical exam once airway stability is assured.[1] The majority of vertebral artery injuries will present without acute neurological symptoms, however any transient ischemic attack (TIA) or stroke symptoms, are specific to the vertebrobasilar artery territory.[12]

TABLE 36.1 Hard Versus Soft Signs of Penetrating Neck Injury

	Hard Signs	Soft Signs
Vascular injury	• Severe, uncontrolled hemorrhage • Refractory shock/hypotension • Large or expanding or pulsatile hematoma • Unilateral pulse deficit • Bruit or thrill (new or < 40 years old) • Neurologic deficit consistent with stroke	• Minor bleeding • Small, nonexpanding hematoma • Proximity wound
Aerodigestive injury	• Airway compromise/distress • Air bubbling through wound • Extensive subcutaneous emphysema • Stridor • Hoarse voice	• Mild hemoptysis • Mild hematemesis • Dysphonia • Dysphagia • Mild subcutaneous emphysema

Modified from Evans C, Chaplin T, Zelt D. Management of Major Vascular Injuries: Neck, Extremities, and Other Things that Bleed. *Emerg Med Clin North Am.* 2018;36:181.

The most concerning complication of BCVI is stroke. Because the development of neurologic symptoms from BCVI is frequently delayed, clinicians have both a challenge and opportunity to identify lesions prior to the development of an ischemic stroke. The untreated stroke risk following BCVI is 10% to 40% and is highest within the first 7 days.[31] When stroke occurs, it is seen on the first day following injury only one-quarter to half of the time.[32] Forty-three percent of patients will have a focal neurological finding at the time of diagnosis.[14] Strokes from blunt vertebral artery injuries occur less frequently (20% stroke risk) than those from carotid injuries, but tend to present in a slightly more delayed fashion.[9,7]

Potential presenting signs include ipsilateral headache (58% to 92%), neck pain (18% to 46%), pulsatile tinnitus, transient blindness, bruit (12% to 39%) and partial Horner syndrome (9% to 75%).[33,7] Because many patients are asymptomatic, several authors have developed screening criteria to identify patients at higher risk for BCVI, ideally prior to the development of stroke symptoms (see Table 36.2 for the two most commonly used criteria). The modified Denver and modified Memphis criteria are both well studied and commonly used to screen for BCVI. The modified Denver screening criteria include signs, symptoms and risk factors. The Eastern Society of Trauma has developed guidelines based on the Denver screening criteria.[34] In addition to the features included in these criteria, other authors have found Type 3 occipital condyle fractures[35] or mandible fractures[36] to increase the risk of BCVI. In fact, one retrospective study revealed that any facial fracture portends a three- to fourfold increased risk.[37] Risk seems to increase with increasing injury severity score, with BCVI seen in less than 3% of blunt trauma patients with ISS ≥16.[7] Some authors have found that substantial numbers of patients are missed using commonly accepted criteria. Using Denver, the probability of BCVI was 20% with no screening criteria met, 33% to 48% with one risk factor, 56% to 64% with two, 80% to 88% with three and 93% with four. Without any cervical spine fracture, there was a 3% risk of vertebral injury versus 33% with a fracture.[38] Approximately 20% to 30% of patients with BCVI have no identifiable risk factors at all.[39]

These guidelines perform poorly in children, causing both over- and under-utilization of CTA. Criteria can miss as many as two-thirds of children with brain ischemia as seen in some studies.[38] In children, injuries associated with BCVI are: basilar skull fracture (odds ratio; OR 2.21 to 3), cervical spine fracture (OR 3.6 to 3.85), jugular venous injury (OR 45.5), cranial nerve injury (OR 3.1),[9] injury severity score ≥16 (OR 2.65), brain infarct (OR 3.85), hanging (OR 8.71), LeFort fracture, facial fracture, and clavicle fracture. Seatbelt sign in isolation has

TABLE 36.2 Major Screening Criteria for Blunt Cerebrovascular Injury

MODIFIED DENVER CRITERIA		MODIFIED MEMPHIS CRITERIA
Signs/Symptoms	**Risk Factors[a]**	
• Arterial hemorrhage from neck, nose, or mouth • Cervical bruit (in patients <50 years) • Expanding cervical hematoma • Focal neurologic deficit: TIA, Horner syndrome, vertebrobasilar symptoms, hemiparesis • Stroke findings at CT or MRI • Neurologic deficit inconsistent with head CT findings	• LeFort II or III fracture • Basilar skull fracture involving the carotid canal • Cervical vertebral body or transverse foramen fracture • Cervical subluxation, or ligamentous injury at any level • Fracture at C1–C3 • Closed head injury consistent with DAI and GCS score <6 • Near-hanging with anoxia • Clothesline-type injury or seat belt abrasion with significant swelling, pain, or altered mental status	• Basilar skull fracture with involvement of the carotid canal • Basilar skull fracture with involvement of petrous bone • Cervical spine fracture • Neurologic examination not explained by brain imaging • Horner syndrome • LeFort II or III fracture pattern • Neck soft tissue injury (seatbelt sign or hanging or hematoma)

[a]Assuming high-energy mechanism.
DAI, Diffuse axonal injury; *GCS,* Glasgow coma scale.

not been associated with BCVI, but it is used in some screening criteria for BCVI.[17] A new score proposed for children (the McGovern score) was promising in an early trial, but still misclassified 19% of injured patients.

Pharyngoesophageal Injuries

Penetrating injury

In penetrating trauma, air leaking from the wound site, odynophagia, dysphagia, and gas in the deep soft tissues are the most compelling indicators of an underlying esophageal injury. Otherwise, there are no pathognomonic signs of esophageal injury based on history or physical exam. Soft signs of injury include hematemesis, odynophagia, dysphagia, subcutaneous emphysema, and blood in the saliva or nasogastric tube aspirate. Other associated findings include dyspnea, hoarseness, stridor, cough, pain and tenderness in the neck, and resistance to passive neck movement. Recent studies provide strong evidence that a normal examination coupled with CTA lacking proximity wounds while confirming the absence of deep tissue emphysema can safely exclude any surgically significant esophageal lesions.[19,40]

Blunt Injury

Blunt PE injuries are rare with little published data on clinical recognition. Signs and symptoms of penetrating PE injury may be useful in identifying patients with blunt PE injury. These injuries tend to be associated with facial fractures (16%) and traumatic brain injury (13%).[24]

Laryngotracheal Injuries

Signs and symptoms of penetrating and blunt LT injury overlap and one quarter of these patients ultimately requiring surgery will have no symptoms on arrival.[41] Delays in symptom onset can exceed 24 hours with some remaining asymptomatic.[41,42]

Penetrating injury

When symptoms exist, these can include dyspnea, dysphonia, dysphagia, hoarseness, laryngeal pain and tenderness, stridor, hemoptysis, subcutaneous emphysema, cyanosis, air escaping from the wound, significant air leaks or persistent pneumothorax following chest tube placement.[29] There is a high sensitivity for dysphonia, aphonia, stridor, hoarseness, and an irritating cough.[41]

Blunt injury

Blunt LT injuries tend to be more concerning than penetrating, with a short-term mortality of 15 to 40%.[26,42] LT injury can be associated with the following signs and symptoms: subcutaneous emphysema, air escape, external bleeding or bruising, dyspnea, hypopnea, stridor, cough, pain with phonation, dysphagia, hemoptysis, tracheal deviation, cyanosis, and nerve injury. Associated cervical spine injury occurs in up to half of patients.[42] Evaluation for hoarseness due to recurrent laryngeal nerve injury should be considered when a cricoid cartilage fracture is found because of proximity.[29]

Hanging

Patients who survive the initial hanging can suffer multi-system sequelae. Hypoxic-ischemic brain injury is the driving factor in the high mortality and neurologic morbidity. Pulmonary edema can occur from several mechanisms: centrally mediated neurogenic pulmonary edema with massive sympathetic discharge; post-obstructive from the marked negative intrapleural pressure generated by forceful inspiratory effort against an extrathoracic obstruction; and cardiogenic pulmonary edema, which is increasingly recognized as a result of hanging-associated Takotsubo cardiomyopathy. Tardieu spots, or punctate lesions left by the gravitational pressure causing capillary rupture, are helpful tipoffs to a hanging mechanism, if not already known.

Miscellaneous

Thyroid rupture can occur with blunt neck trauma and frequently involves a pre-existing goiter. This presents with painful swelling, dyspnea, or airway obstruction. The onset of symptoms can be delayed for up to 24 hours.[43]

DIFFERENTIAL DIAGNOSES

Penetrating neck trauma can result in injury to the carotid artery, vertebral artery, venous system (jugular vein), pharynx, esophagus, larynx and trachea, see Table 36.3 for mechanisms, signs and symptoms.

Blunt neck injuries can include carotid artery injury, vertebral artery injury, uncommonly venous injuries, LT injury, PE injury, injury to the thyroid gland, and nerve injuries. See Table 36.4 for mechanism, risk factors, and signs and symptoms of each.

DIAGNOSTIC TESTING

Laboratory testing in both penetrating and blunt neck trauma is largely unnecessary with the exception of serial hemoglobin testing with significant bleeding, platelet count and coagulation function testing. Faster clot formation and greater clot strength on thromboelastography is associated with a higher stroke risk in the setting of blunt trauma, but the clinical implication of this data is not yet defined.[44] In the presence of anticipated surgery or bleeding, type and cross-matched blood can be ordered from the ED. Screening radiographs of the chest and neck can be helpful to look for gas in the deep tissues or pneumothorax. An e-FAST exam can exclude pericardial effusion and pneumothorax.

Multidetector CT angiography (MDCTA) has changed the approach to blunt and PNI with CTA now the initial imaging modality of choice. This is based in part on greatly improved resolution, speed and availability, and is ultimately cost-effective.[17]

Vascular Injuries

Until the arrival of new generation scanners, digital subtraction angiography (DSA) was the gold standard for diagnosing vascular injury and in some clinical scenarios it is still useful. For example, the CTA may be normal despite a high suspicion for a vascular injury and in this instance, DSA would provide additional images for clarification. It is also possible to have an equivocal CTA in the setting of streak artifact from retained metallic foreign bodies. Further imaging would be warranted with four-vessel catheter angiography being a good follow up study. Catheter angiography can also be used when endovascular treatment is anticipated.[45] The disadvantage to DSA is that it is time-consuming, can lead to delays in definitive diagnosis, and is associated with a 0.5% of risk of stroke from the procedure itself.[33]

Penetrating Injury

Improved CTA capability has allowed better delineation of wound trajectory and proximity wounds in the setting of penetrating trauma, which has led to an evolvement in the diagnosis and management of these injuries. Despite decades of relying on a zone-based selective algorithm, current consensus supports a "no-zone" approach which uses clinical examination coupled with CTA, not the zone of injury, to arrive at the best diagnostic and therapeutic pathways.[46,47] A no-zone approach has been shown to reduce the rate of negative neck exploration and cost.[48] Patients who arrive and remain asymptomatic (no hard or soft signs of injury) with a negative CTA do not require further imaging or diagnostic testing, however a period of observation is

TABLE 36.3 Salient Features of Penetrating Neck Injuries

Injury	Mechanism	Signs/Symptoms
• Carotid/vertebral artery	• Stab wounds • Firearms • Bites, glass, other projectiles	Asymptomatic, minor bleeding, small, nonexpanding hematoma, proximity wound, severe, uncontrolled hemorrhage, refractory shock or hypotension, large or expanding or pulsatile hematoma, unilateral pulse deficit, bruit or thrill, neurologic deficit consistent with stroke. Vertebral artery specific: dizziness, vertigo, diminished coordination, disequilibrium, ataxia, nausea and/or vomiting, neck or head pain, altered sensorium, speech (dysarthria), visual deficits (double vision, nystagmus), lower cranial nerve palsies and medial or lateral medullary syndrome
Laryngotracheal injury	• Stab wounds • Firearms • Bites, glass, other projectiles	Asymptomatic, respiratory distress, dyspnea, dysphonia, aphonia, dysphagia, hoarseness, pain or tenderness over larynx, stridor, hemoptysis, subcutaneous emphysema, cyanosis, air escaping from wound, irritating cough
Pharyngoesophageal injury	• Stab wounds • Firearms • Bites, glass, other projectiles	Asymptomatic, air leaking from the wound site, odynophagia, dysphagia, hematemesis, subcutaneous emphysema, and blood in the saliva or nasogastric tube aspirate, dyspnea, hoarseness, stridor, cough, pain and tenderness in the neck, and resistance to passive neck movement

TABLE 36.4 Salient Features of Blunt Neck Injuries

Injury	Mechanism	Risk Factor	Signs/Symptoms
Carotid artery	MVC	LeFort fractures II or III, Carotid canal injury	Asymptomatic, neurologic findings, Horner syndrome, bruit, expanding hematoma
Vertebral artery	MVC	Cervical spine injury (C1–3 fracture or dislocation, any transverse foramina)	Asymptomatic, neurologic findings
Laryngotracheal injury	Direct trauma	Associated c-spine injury	Asymptomatic, subcutaneous emphysema, air escape, external bleeding or bruising, dyspnea, hypopnea, stridor, wheezing, cough, pain with phonation, dysphagia, hemoptysis, tracheal deviation, cyanosis, nerve injury
Pharyngoesophageal injury	Falls, MVC, strangulation	Facial fractures, traumatic brain injury	Extrapolated from penetrating trauma
Thyroid gland hematoma	Anterior neck trauma	Goiter	Painful swelling, dyspnea, or airway obstruction (can be delayed)
Nerve injuries	Bone fragment in facial canal	Temporal bone fracture	Facial paralysis

indicated with serial examination.[1] Regarding use of cervical spine collars with PNIs, practice management guidelines of the Eastern Association for the Surgery of Trauma do not endorse routine application for PNIs in patients lacking neurological findings.[49]

When hard signs of vascular injury, coupled with hemodynamic instability are identified, the patient is most often taken expeditiously to the operating room (OR) without imaging. In isolated instances, when hard signs of vascular injury are present in an otherwise stable patient, CTA may be indicated and beneficial prior to transfer to the operating room if delays will not be incurred.[50] Angiography can provide detailed information regarding vascular injury location and emergency surgical planning. If soft signs of vascular injury are identified, CTA is the initial imaging study of choice with a sensitivity of 90% to 100%, specificity of 98.6% to 100%, positive predictive value (PPV) of 92.8% to 100%, and an negative predictive value (NPV) of 98% to 100%.[51]

Blunt injury

For BCVI, the sensitivity of prior generation CT scan was 47% to 52%; therefore, DSA was considered the gold standard. Currently, CTA with 16-slice or better scanners have a sensitivity of 68% to 100%.[14]

Vessel wall magnetic resonance imaging (MRI) has been minimally studied but appears adequate, with agreement of 0.82 with verified BCVI.[51] MRA alone has had reported sensitivities and specificity of 50% to 75% and 67%.[52] EAST guidelines state that diagnostic ultrasound is not adequate to screen for BCVI.

Pharyngoesophageal Injuries

While CTA is a reasonable diagnostic test to begin evaluation of a patient suspected to have PE injury, both penetrating and blunt PE trauma often warrant confirmatory studies in the setting of an equivocal CTA. Esophageal barium swallow, also known as contrast swallow study or esophagogram, is a contrast enhanced X-ray modality used to better visualize the esophagus.

Typically, a water-soluble contrast agent such as diatrizoate meglumine or diatrizoate sodium (e.g., Gastrografin) is used. Barium, which has greater sensitivity than Gastrografin, is associated with risk of delayed mediastinal fibrosis in the event of contrast extravasation. In an attempt to avoid this complication while maintaining sensitivity, a thin barium swallow can follow a negative Gastrografin swallow. Most literature supports a confirmatory barium study in the setting of negative water-soluble imaging.[53]

Penetrating injury

Penetrating PE injuries are the leading cause of delayed morbidity in penetrating neck trauma.[2] Timely diagnosis and definitive treatment is

associated with decreased morbidity and mortality. Delays are defined as greater than 24 hours following injury. Morbidity includes increased use of percutaneous feeding and tracheostomy tubes, emphysema, pneumonia and sepsis.[19,54]

As the quality of CTA has improved, so has the ability to rely on this study in the context of PNI and specifically to detect esophageal injury. CTA has proven useful to delineate the wound track or bullet trajectory to determine if a proximity wound is present. Recently, literature has supported the use of CTA to search for gas in the deep fascial planes of the neck, a nonspecific finding that can be seen with pneumothorax, tracheobronchial and aerodigestive injury. This finding increases the suspicion for esophageal injury. If surgically insignificant wounds are excluded, the sensitivity and negative predictive value for deep surgical emphysema is 100% when searching for esophageal injury. Contemporary studies reveal that significant esophageal injury is essentially excluded in patients with low pre-test suspicion and in those who lack CTA proven deep surgical emphysema.[40]

CT esophagography has also been evaluated as a tool to diagnose upper digestive tract injuries including those located in the hypopharynx. A combination approach for penetrating neck trauma using both CTA and CT esophagography as a single diagnostic study, yields a sensitivity near or equal to 100% and does not interfere with a simultaneous search for vascular injury. In one study, radiologists felt confident in 65% of cervical PNI cases based solely on their CT esophagography read that further testing to exclude esophageal injury was not indicated. The sensitivity of radiology in this series was 95% with a specificity that ranged from 85% to 91%.[54] These studies require patient cooperation, which is not always possible in the acutely injured trauma patient.

When relying on esophagography, it is important to note that up to 22% of missed esophageal injuries following negative diatrizoate meglumine-diatrizoate sodium (Gastrografin) swallow studies were diagnosed with thin barium swallows.[54] Conversely, one study found that water-soluble swallow studies, when negative, are effective at excluding significant penetrating esophageal injuries.[19] This latter approach is not uniformly accepted.

Endoscopy is another modality used to diagnose esophageal injury. Both rigid and flexible scopes are available, but most operators prefer flexible endoscopy in the setting of penetrating trauma given its usefulness in both the ED and operating room as well in intubated patients or those who are unable to cooperate with oral contrast studies. Flexible endoscopy has a sensitivity of 100% and a specificity of 83% and should follow an equivocal contrast esophagography study or a CTA (deep surgical emphysema).[54] The combination of contrast studies and flexible endoscopy has an accuracy of essentially 100%.[55]

Blunt Injury

For PE injuries, CTA is typically the first study performed. Endoscopy can complement this with a sensitivity of 50% to 60% for perforation. A swallow study should be performed if there is subcutaneous air noted on CTA, but no clear injury identified.[4] Endoscopy is a reasonable option in equivocal cases as well. Alone, endoscopy has a sensitivity of 50% to 60% for perforation. However, it can be a useful adjunct when other studies are equivocal or when a negative study is obtained in a patient with a high pre-test probability of injury.

Laryngotracheal Injuries

Similar to the approach of any penetrating or blunt neck injury, the initial studies for a stable patient include laboratory testing, screening radiographs of the chest and neck, and CTA of the neck (see diagnostic vascular section).

The epiglottis, arytenoid vocal processes, and the cuneiform and corniculate cartilages never ossify because of their elastin fibrocartilage composition. The remaining airway cartilages are hyaline and will begin ossifying at 18 years and conclude by 65 years of age. When using CTA, thin cuts (1 to 2mm) are recommended to avoid missing subtle injury. There is controversy as to whether IV contrast further enhances visualization of these injuries.[56] MRI can provide additional information and is better for visualizing the airways of younger patients that lack calcification if a fracture is suspected but absent on CT scan. MRI does not have a role in the acute setting.[57]

Penetrating injury

CT plays a significant role in detecting LT injuries following penetrating injury; however, other diagnostic options exist in the setting of an inconclusive CTA. Direct laryngoscopy or flexible nasopharyngoscopy can be used initially not only for intubation, but also to directly visualize the airway. These procedures may be unsuccessful if significant airway edema, blood or debris is present. When CTA is nondiagnostic, rigid laryngoscopy can be performed in the operating room to glean further information about airway integrity.

Penetrating LT trauma can lead to acute complications including airway obstruction and death or long-term complications such as vocal cord dysfunction, voice changes, laryngeal or tracheal stenosis, chronic aspiration and tracheoesophageal fistulas.[41] Timely diagnosis and treatment are warranted in an attempt to mitigate these possibilities.

Blunt Injury

CTA is particularly useful when airway edema precludes passage of a laryngoscope.[4] However, some studies have shown a false negative CTA rate of up to 30%[28], therefore a high index of suspicion and a combination of laryngoscopy and CTA may be helpful in higher risk cases.

Hanging

CTA is adequate for the evaluation of the neck in hangings. However, cerebral anoxia or pulmonary edema may be the more significant pathology supporting additional imaging, specifically, brain MRI, chest imaging, and echocardiography, to detect the stress-induced characteristics of Takotsubo cardiomyopathy.

MANAGEMENT

Vascular Injuries

Penetrating injury

Vascular injury can present with life-threatening exsanguination. Direct manual pressure is the first line approach when a patient arrives with active bleeding, but in refractory instances, a 16- or 18-French Foley catheter placed and inflated in the wound may be required to tamponade the bleeding.[58] This is more likely in zone 3 injuries because the carotid artery lies deep into the mandible potentially precluding direct digital compression.[56]

Surgical access to vascular injury is dependent on the location with zone 2 wounds being the most accessible. Adequate surgical access to zone 3 may be partially obscured by the mandible and zone 1 by the sternum. Distal ICA injury at the base of the skull (zone 3) poses a unique challenge when attempting to gain vascular access for repair. Endovascular repair is the gold standard in this region. Open surgical options include primary surgical repair (such as end-to-end anastomosis, direct repair of defect, vein grafting, polytetrafluoroethylene patching, and transposition of the external carotid artery with the ICA) or ligation of the vessel.[11]

Primary repair or endovascular stent grafting are common approaches used for most penetrating carotid artery injuries with open repair being the gold standard.[11] Vertebral artery injuries are managed by surgical ligation, angiographic embolization, combined procedures or observation.[10,12] Unlike blunt carotid artery trauma where

TABLE 36.5 Biffl Scale Grading and Treatment of Blunt Cerebrovascular Injury

	Injuries	Management
Grade 1	Intimal injury or irregular intima	Anticoagulation or antiplatelet therapy (endovascular repair if not candidate)
Grade 2	Dissection with an intimal flap causing luminal narrowing of less than 25%	Endovascular repair if sx; o/w antiplatelet or anticoagulant
Grade 3	Pseudoaneurysm formation	Endovascular repair if symptoms; otherwise antiplatelet or anticoagulant
Grade 4	Vessel occlusion or thrombosis	Difficult to manage, as the injured vessel often thromboses and cannot be recanalized, endovascular repair if sx; o/w antiplatelet or anticoagulant
Grade 5	Vessel transection	Typically, lethal if left untreated; requires immediate endovascular intervention or surgical repair

antithrombotic therapy is widely accepted, data is lacking as to whether anticoagulation is warranted in penetrating carotid wounds.[59]

Blunt injury

Table 36.5 discusses decision making for medical versus surgical management. The Biffl scale dictates lesion grading, and largely management for BCVI. This is weighed against other injuries and risk of anti-thrombotic therapy.

Medical management of BCVI: Antithrombotic therapy is indicated in all grade I to IV injuries. For anticoagulation, the standard regimen includes a heparin infusion started at 10 units/kg/h and titrated to a PTT of 40 to 50 seconds. No heparin bolus is administered. If antiplatelet therapy is selected, 75 to 325 mg/day of aspirin (or 3 to 5 mg/kg in children) is recommended with some studies showing fewer bleeding-related complications and equivalency in stroke prevention in comparison to patients who are anticoagulated.[60] The Western Trauma association guidelines favor heparin in the acute phase, due to its short duration of action and the ability for it to be reversed,[61] while other guidelines support either therapy as reasonable. Typically, 3 to 6 months of antithrombotic treatment is recommended.[61] Treatment with either an anticoagulant or antiplatelet agent reduces stroke risk to somewhere between 1% and 7%.[39,62,63]

Surgical management of BCVI spans the spectrum from stenting to vessel sacrifice. One retrospective study indicated increased mortality with earlier intervention; however, this may have been biased toward sicker patients in the early intervention group.[64] Vascular occlusion of the external carotid does not usually necessitate treatment.[4]

Pharyngoesophageal Injuries

Regardless of the mechanism of injury, when esophageal injury is suspected, broad-spectrum antibiotics with anaerobic coverage (e.g., piperacillin and tazobactam IV or high-dose fluconazole IV) should be administered, and the patient made nil per os (NPO). Preoperative placement of an nasogastric tube (NGT) under endoscopic guidance may reduce the spillage of gastric contents into the wound.

Penetrating injury

Nonoperative management has been shown to be safe for hemodynamically stable patients with penetrating esophageal injuries, with no competing indications for exploration and no established sepsis. This approach is reinforced with a water-soluble swallow study showing either contained extravasation or none. Any uncontained perforation of the esophagus, signs of sepsis, or widespread contamination requires prompt surgery, whereas small, contained perforations may be candidates for observation and reimaging based on institution protocols.[65] Pharyngeal injuries if not recognized early and managed appropriately carry risks similar to esophageal injuries including sepsis. Most injuries to the caudal part of the cervical digestive tract mandate urgent exploration.[19] If the time to definitive repair is not excessively delayed, obtaining preoperative evaluation and diagnostic work-up of penetrating esophageal injury is associated with fewer hospital days as opposed to those patients who are taken directly to the operating room without preoperative definitive studies.[22]

Blunt Injury

About one quarter of those with blunt PE injury require surgical management. Some experts recommend repair of any injury greater than 2 cm in length. Observation, nothing per os, and prophylactic antibiotics are usually sufficient for smaller lesions.

Laryngotracheal Injuries

Early airway management can be challenging in LT injury. Up to 10% of neck wounds have associated respiratory compromise.[63] When approaching any neck injury, both airway integrity and the presence of active exsanguination will dictate early management. Assurance of a stable airway is the earliest priority and often represents a challenge. Airway integrity can be rendered unstable by several mechanisms including airway obstruction via blood or debris, partial or complete transection of the larynx or trachea, fractures of the cartilages, airway edema or compression secondary to a large hematoma or massive subcutaneous air.[66] Because these injuries are relatively uncommon, practice patterns vary regarding airway management, but most advocate for aggressive airway stabilization.[41]

Airway collapse in the setting of penetrating neck trauma can happen insidiously or in a delayed fashion, necessitating serial exams in the nonintubated patient. A pass at orotracheal intubation initially is warranted in an emergent situation. A one size smaller than anticipated endotracheal tube (ETT) in the setting of airway edema is prudent. A double set-up with a surgical airway option should be available during any intubation attempt.[42] In a semi-elective airway, fiberoptic intubation or an awake tracheostomy in the operating room are preferred. If such resources are not available, cricothyroidotomy in adults or needle cricothyroidotomy with jet ventilation in children under 12 years of age are reasonable back-up options. In the setting of a penetrating large partial or complete airway transection, localization of the distal airway with tracheal hooks and direct intubation through the wound may be required. Blind nasotracheal intubation or use of positive pressure supraglottic ventilation (e.g., bag-mask or laryngeal mask airway) is contraindicated in these injuries. Early intubation offers additional benefits including stenting a partially collapsed trachea as well air leak tamponade.[42] In a stable patient who appears to have a preserved airway, bedside laryngoscopy or fiberoptic nasopharyngoscopy can afford visualization of the upper airway proximal to the vocal cords. This quick look can help clarify the decision of whether intubation appears necessary in unclear cases. Both of these procedures can be challenging when significant amounts of blood, debris or airway edema are present. The majority of experts favor video laryngoscopy over direct laryngoscopy with these types of difficult airway trauma scenarios.

Definitive management for LT trauma is driven primarily by the grade of injury as defined by the Schaefer-Fuhrman classification. This grading system applies to both penetrating and blunt trauma. Table 36.6 lists the grades of injury according to this classification and typical treatment for each grade.[4] For mucosal lacerations less than 2 to 3

TABLE 36.6 Schaefer-Fuhrman Classification of Laryngeal Injury

	Injuries	Management
Grade 1	Endolaryngeal hematoma or laceration without detectable fracture; no airway compromise	Generally, medically managed and do not require surgical intervention. Helpful adjunctive medical treatments include steroids, antibiotics, humidification, voice rest
Grade 2	Moderately severe edema, hematoma, or laceration without exposed cartilage or nondisplaced fracture; partial airway compromise with varying degrees of severity	Serial examinations, since the injuries may worsen over time. These injuries infrequently require a tracheostomy. Helpful adjunctive medical treatments as described above
Grade 3	Massive laryngeal edema, large mucosal lacerations, exposed cartilage, displaced fracture, or vocal cord immobility, with associated airway compromise	Tracheostomy and surgical repair are often required. The following injuries of the larynx require surgical repair: disruption of the anterior commissure, major endolaryngeal lacerations, vocal cord tear, immobile vocal cord, cartilage exposure, displaced cartilage fractures
Grade 4	Grade III findings with more severe anterior laryngeal disruption, unstable fracture, two or more fracture lines, or severe mucosal injuries	Tracheostomy is always required Surgical repair requires stent placement to maintain the integrity of the larynx
Grade 5	Complete laryngotracheal separation	Disruption of the airway usually occurs above or below the cricoid cartilage, either at the cricothyroid membrane or cricotracheal junction. The airway is usually temporarily established using an endotracheal tube inserted through the neck directly into trachea distal to the site of transection. A complex laryngotracheal repair is then performed through a low cervical incision

Moonsamy P, Sachdeva U, Morse C. Management of laryngotracheal trauma. *Ann Cardiothorac Surg.* 2018;7(2):210–216.

cm in length, conservative management with analgesia, humidified air, elevation of the head of the bed, antibiotics, steroids, antireflux medications, vocal rest, and a clear diet is reasonable. For surgical lesions, prompt repair within 24 hours is important to minimize long-term disability from scar tissue and stenosis.[26] Long-term, about 20% will have a hoarse or breathy voice.[67] Aspiration, infection, air embolism, and recurrent laryngeal nerve injury can also complicate the course of these injuries.[42]

Hanging

Definitive studies providing guidelines for the management of hypoxic brain injury specifically related to near-hanging or strangulation injuries are lacking. Case series indicate a potential role for induced mild hypothermia in comatose survivors of strangulation. One study demonstrated a 43% rate of survival to discharge and 6% return of neurological function in hanging patients treated with hypothermia protocols after arrest. Case reports have suggested the use of thrombolysis for carotid injury-related stroke in survivors of near-hanging although confirmatory studies have not been conducted. Currently, there is insufficient data to recommend either for clinical practice.

Miscellaneous

Immediate surgical exploration is indicated when bony fragments are found in the facial canal or if facial paralysis is identified to prevent permanent loss of nerve function. Facial paralysis can result from direct nerve transection or from neuropraxia. In these settings, neuropraxia is often a result from a pressure effect related to local edema, hematoma or adjacent bone fragments.[4] For thyroid rupture, parenchymal hematoma should be observed for 24 hours in the intensive care unit (ICU) due to the risk of airway compression and thyroid storm.[43]

DISPOSITION

Penetrating Injury

Most penetrating injuries to the neck with platysma violation will be admitted to the hospital for ongoing definitive studies, management or observation. In the case of a penetrating wound in an asymptomatic or minimally symptomatic patient with no evidence of a viscerovascular injury and a negative CTA, serial examinations every 6 to 8 hours for 24 to 36 hours are recommended.[63]

Blunt Injury

BCVIs are high-risk injuries. For patients with CTA demonstrating vascular trauma not requiring surgery, admission is warranted.[68] Even grade 1 injuries have a risk of progression, with 5% converting to grade 3 while on heparin.[7] Upon discharge, patients should be asked to limit contact sports, neck manipulation, and estrogen-containing medications. Hypertension should be avoided, which may require additional prescriptions at discharge, or a discussion on the importance of compliance with prior prescriptions. In patients with stent placement, thrombosis of the stent has been reported and some providers discharge with anticoagulation, even in the face of a surgically managed lesion.

Since false positives can occur, a repeat CTA at 7 days to confirm diagnosis and at 3 months to confirm resolution is often prescribed.[61] If the injury is not seen at day 7, then antithrombotic therapy can be stopped. For patients at high risk but with a negative CTA, observation for 24 to 48 hours is recommended.[69]

Because CTA does not have perfect sensitivity for identifying LT fractures, a period of observation of 48 to 72 hours is recommended for patients suspected to have blunt LT injuries with a negative CTA who cannot also undergo laryngoscopy.[28] Patients with no identifiable injury beyond laryngeal tenderness, but who had a significant mechanism of injury can be observed for 12 hours in the ED or an observation unit. They can be subsequently discharged home if no additional symptoms or signs develop, voice and swallowing are normal, and discomfort is minimal and abating.

Since the mortality for PE injuries is up to 20%, these patients require admission.

Patients recovering from hanging with no identified injuries and no development of pulmonary edema after several hours of observation may be candidates for transfer to psychiatric care, as this most often represents an attempt at self-harm or suicide.

CHAPTER 36: QUESTIONS AND ANSWERS

1. The presence of which of the following signs after penetrating neck trauma would indicate a likely benefit from surgical intervention?
   - **a.** Decreased or absent radial pulse
   - **b.** Small degree of hemoptysis
   - **c.** Horner syndrome
   - **d.** Muffled voice
   - **e.** Stable hematoma

Answer: a. "Hard" signs of penetrating neck trauma are the presence of an expanding hematoma, severe active bleeding, shock not responding to fluids, decreased/absent radial pulse, vascular bruit/thrill, cerebral ischemia, and airway obstruction. Most patients with hard signs benefit from surgical intervention.

2. Which of the following is true regarding pharyngoesophageal injuries?
   - **a.** Esophageal barium swallow is the best initial x-ray modality for evaluating esophageal injuries.
   - **b.** Gastrografin has greater sensitivity than barium and is therefore the preferred contrast agent in the initial evaluation of esophageal injuries.
   - **c.** Confirmatory barium study is not necessary after a negative Gastrografin swallow study.
   - **d.** Computed tomography angiogram (CTA) is the initial study of choice in evaluating pharyngoesophageal injuries and never requires additional confirmatory studies
   - **e.** None of the above is true.

Answer: e. CTA is a reasonable exam with which to begin evaluation of a patient suspected to have PE injury but confirmatory studies in the setting of an equivocal CTA are often required. Esophageal barium swallow has greater sensitivity than Gastrografin but is associated with risk of delayed mediastinal fibrosis in the event of contrast extravasation. Most literature supports a confirmatory barium study in the setting of negative water-soluble imaging.

3. The pathophysiology and sequelae of hanging include all of the following except
   - **a.** Pulmonary edema
   - **b.** Hypoxic –ischemic brain injury
   - **c.** Cardiogenic pulmonary edema as a result of Takotsubo cardiomyopathy
   - **d.** Neurogenic pulmonary edema from massive parasympathetic discharge
   - **e.** Presence of Tardieu spots

Answer: d. Pulmonary edema can occur from several mechanisms: neurogenic pulmonary edema from centrally mediated, massive *sympathetic* discharge; post-obstructive from relief of the marked negative intrapleural pressure generated by forceful inspiratory effort against an extrathoracic obstruction; and cardiogenic pulmonary edema, which is increasingly recognized as a result of hanging-associated Takotsubo cardiomyopathy.

4. Which of the following statements is true regarding zonal injuries to the neck?
   - **a.** Zone 2 is the most commonly injured, has the highest mortality and is most amenable to surgical exploration
   - **b.** Zone 1 extends from the sternal notch to the cricoid cartilage

c. Penetrating trauma injuries to the neck often span multiple zones, and the most significant injury may lie in a different zone than the point of entry
d. Current consensus supports a "no-zone" approach which uses clinical examination coupled with computed tomography angiogram (CTA) to arrive at the best diagnostic and therapeutic pathways
e. All of the above are true.

Answer: e. Despite decades of relying on a zone-based selective algorithm, current consensus supports a "no-zone" approach which uses clinical examination coupled with CTA, not the zone of injury, to arrive at the best diagnostic and therapeutic pathways

5. Which of the following statements regarding airway management after penetrating neck trauma is true?
a. Awake fiberoptic intubation is the first-line technique.
b. Bag-valve-mask ventilation should be high tidal volume, low rate.
c. Cervical spine immobilization is typically unnecessary.
d. Nasotracheal intubation is relatively contraindicated in neck trauma.
e. Preintubation nasogastric tube (NGT) placement may be lifesaving.

Answer: c. Unless there is concomitant blunt injury or evidence of spinal cord injury, cervical immobilization is not needed. Oral intubation after rapid sequence intubation (RSI) is the technique of choice and is successful in almost all cases. Although rarely a first line choice, nasotracheal intubation has been used successfully in these trauma patients. Gentle bag-valve-mask technique with low pressure is indicated to avoid venous air embolism (VAE) and subcutaneous emphysema. NGT placement, if done at all, should be gentle and placed after intubation.

Thoracic Trauma

Ali S. Raja

KEY CONCEPTS

- Even relatively minor chest wall injuries, such as rib fractures, may result in serious complications in elderly patients and patients with preexisting pulmonary disease if adequate analgesia and close follow-up care are not provided.
- Unless there are abnormalities on the electrocardiogram (ECG) or an elevated serum troponin level, there is no need to pursue the diagnosis of myocardial contusion with more sophisticated testing.
- Many patients with myocardial rupture or traumatic aortic rupture survive to reach the hospital and can be salvaged with rapid diagnosis and intervention.
- Pericardial tamponade can be diagnosed accurately before hemodynamic decompensation occurs by standard cardiac ultrasound performed by emergency clinicians.
- Chest computed tomography (CT) scan is the diagnostic test of choice for blunt aortic injury even in the presence of normal chest radiographs.
- The NEXUS-Chest CT criteria can be used to determine the need for chest CT in patients with blunt trauma.

Many causes of early deaths (within the first 30 to 180 minutes) resulting from thoracic trauma are preventable and include tension pneumothorax, cardiac tamponade, airway obstruction, and uncontrolled hemorrhage.

Approximately 75% of patients with thoracic trauma require only simple tube thoracostomy and volume resuscitation, and the initial care and disposition of these patients is usually performed by emergency clinicians. Care of severe thoracic trauma is multidisciplinary in nature, involving trauma surgeons, cardiothoracic surgeons, and intensivists. Improved understanding of underlying physiologic mechanisms, newer imaging modalities, minimally invasive approaches, and pharmacologic therapies have contributed to decreasing morbidity and mortality in patients with thoracic injuries.

Injury location and type dictates both assessment and management. This chapter is organized into sections highlighting chest wall, pulmonary, tracheobronchial, diaphragmatic, cardiovascular, and esophageal injuries.

CHEST WALL INJURY

RIB FRACTURE

Foundations

Background and Importance

The susceptibility to rib fracture increases with age. These injuries can be exquisitely painful, but their importance lies not in the fracture itself, which generally is self-limiting and will heal, but rather with associated complications, particularly pneumothorax, hemothorax, pulmonary contusions, and post-traumatic pneumonia. Rib fractures in children are discussed in Chapter 160.

Anatomy and Physiology

An intact chest wall, protected by its rib cage, is necessary for normal ventilation. Outward expansion of the thorax by the respiratory muscles with descent of the diaphragm creates negative intrathoracic pressure. This allows passive air entry into the lungs during inspiration. Chest trauma, particularly blunt trauma, can severely disturb the physiology of respiration. Fortunately, most individuals have substantial respiratory reserve and can tolerate chest wall injuries with adequate support.

Flail chest results when three or more adjacent ribs are fractured at two points, allowing a free segment of the chest wall to move in paradoxical motion (Fig. 37.1), with the flail segment moving inward with inspiration and outward with expiration. It can also occur with costochondral separation or vertical sternal fracture in combination with rib fractures. Underlying pulmonary contusion is considered to be the major cause of respiratory insufficiency with flail chest, and it is therefore one of the most serious chest wall injuries (Fig. 37.2). In addition, flail chest can be associated with a variety of other injuries, including hemopneumothorax, liver or spleen lacerations, and mediastinal injury.

Pathophysiology

Ribs usually break at the point of impact or at the posterior angle or posterolateral area, which is structurally the weakest area. Ribs 4 to 9 are the most commonly involved. Ribs 1 to 3 are short and relatively protected, and ribs 9 to 12 are longer and more mobile at the anterior end. This confers the relative resistance to fracture of the "high" and "low" ribs. Fractures occur more easily in older adults than younger adults or in children, due to the progressive inelasticity of the chest wall that develops through aging.

The true danger of rib fracture involves not the rib itself but the potential for penetrating injury to the pleura, lung, liver, or spleen. Fractures of ribs 9 to 11 are also associated with intra-abdominal injury. Right-sided rib fractures are associated with hepatic injury and left-sided rib fractures with splenic injury. Injury severity is indicated by the number of rib fractures. The presence of two or more rib fractures at any level is associated with a higher incidence of internal injuries than with a single, isolated fracture. Patients over 65 years old with multiple rib fractures have a greater incidence of pneumonia and a higher mortality compared their younger counterparts.

Clinical Features

Rib fracture is often a clinical diagnosis, with severe point tenderness, bony crepitus, ecchymosis, and muscle spasm over the rib being the

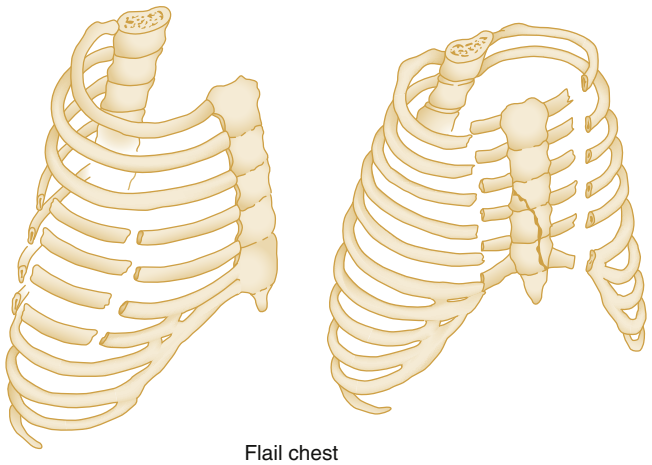

Fig. 37.1 Flail Chest. Fracture of several adjacent ribs in two places with lateral flail or central flail segments.

most common findings. Also, bimanual compression of the thoracic cage remote from the site of injury (barrel compression test) usually produces pain at the site of fracture. Injury to the parenchyma may be detected by assessing the respiratory rate, oxyhemoglobin saturation, respiratory effort, effectiveness of ventilation, and pulmonary breath sounds.

Flail chest is characterized by paradoxical motion of a portion of the chest wall during respiration and is usually obvious on physical examination. Unless the patient is unconscious, there will be severe pain, splinting, tenderness, and crepitus. Paradoxical chest wall motion is a product of negative intrathoracic pressure and is obscured if the patient has been intubated or is receiving positive-pressure ventilation. For such patients, the diagnosis is usually evident on examination of the integrity of the chest wall (compression and crepitus).

Differential Diagnoses

Patients with suspected rib fracture have always sustained trauma, thus focusing the evaluation. Patients with significant, potentially multisystem trauma require a thorough trauma evaluation (see Chapter 32). Rib fracture, costochondral separation, and rib contusion may present in similar fashion, and it is not critical to identify a single, isolated rib fracture. Patients with multiple suspected fractures are at higher risk for intrathoracic injury and also for later decompensation and complications. Important diagnoses to consider include chest wall or clavicle fracture (especially sternal fracture), pulmonary injuries (pulmonary contusion, laceration, pneumothorax, or hemothorax), tracheobronchial injury, diaphragmatic injury, cardiovascular injury (cardiac contusion or aortic injury), or esophageal injury. These broad differential diagnoses hold true for most patients with thoracic trauma, given the close proximity of the organs involved and the similar mechanisms behind most of the injuries described in this chapter.

Diagnostic Testing

Many patients with relatively minor thoracic trauma are evaluated and managed exclusively based on physical findings, and they do not require imaging. When the injury is significant enough to raise concern for underlying pulmonary injury, imaging is required. Because rib fractures are managed expectantly, imaging should be reserved for patients in whom multiple rib fractures, underlying pulmonary injury, or comorbid pulmonary status (e.g., chronic obstructive pulmonary disease [COPD]) is a concern. A plain chest radiograph will identify only about 50% of single-rib fractures; its greatest value is in identifying or excluding significant intrathoracic and mediastinal injuries. Rib series and expiratory, oblique, and cone-down views should not

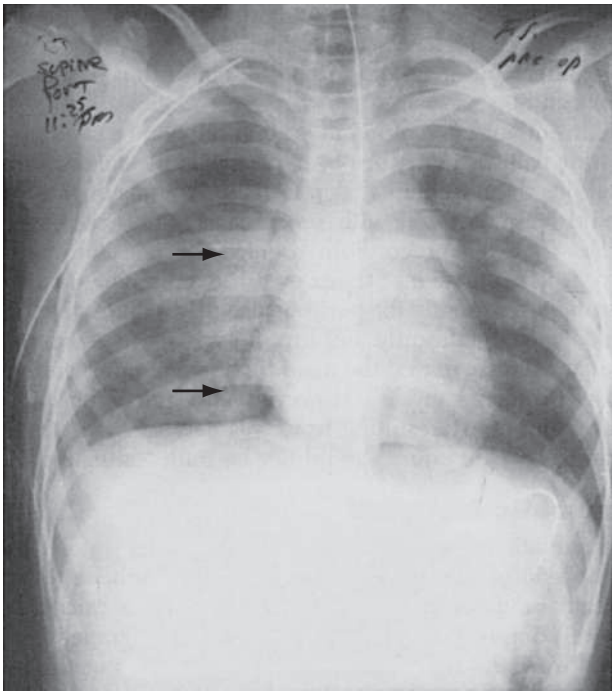

Fig. 37.2 Bilateral alveolar infiltrates *(arrows)* suggesting pulmonary contusion. Pneumopericardium and pneumomediastinum are also present.

Fig. 37.3 Multiple rib fractures seen on chest computed tomography (CT) scan. (Also note presence of bilateral hemothoraces.)

be used routinely. If additional imaging is required beyond a standard upright posteroanterior and lateral chest x-ray, a computed tomography (CT) scan of the chest should be obtained (Fig. 37.3). A CT scan is not indicated to confirm suspected isolated rib fracture, but it will identify multiple-level fractures and associated pulmonary injury, such as pneumothorax or hemothorax, with much greater accuracy than additional chest x-ray views.

In an attempt to limit unnecessary use of diagnostic ionizing radiation, the National Emergency X-Radiography Utilization Study (NEXUS) group derived and validated a decision instrument to guide the use of chest CT in patients with blunt trauma.[1] The NEXUS-Chest CT derivation and validation studies, performed at eight trauma centers in the United States, enrolled 11,477 patients. In the validation phase, the decision instrument had a sensitivity of 95.4%, a negative predictive value of 93.9%, and a specificity of 25.5% for all thoracic

BOX 37.1 NEXUS-Chest CT Criteria for Chest Computed Tomography After Blunt Trauma

- Abnormal chest x-ray
- Rapid deceleration mechanism (defined as fall >20 feet or motor vehicle collision >40 mph)
- Distracting painful injury
- Chest wall tenderness
- Sternal tenderness
- Thoracic spine tenderness
- Scapular tenderness

From Rodriguez RM, Langdorf MI, Nishijima D, et al: Derivation and validation of two decision instruments for selective chest CT in blunt trauma: a multicenter prospective observational study (NEXUS Chest CT). *PLoS Med*. 2015;12(10):e1001883.

injuries. The results were even more impressive for major clinical injuries, with both sensitivity and negative predictive value approaching 100% (99.2% and 99.8%, respectively). We recommend that CT scan not be obtained for patients sustaining blunt trauma who do not meet any of the seven NEXUS-Chest CT criteria (Box 37.1).[1–3]

Management

Respiratory decompensation is the primary indication for endotracheal intubation and mechanical ventilation for patients with multiple rib fractures. Obvious problems, such as hemopneumothorax or severe pain, should be corrected before intubation and ventilation are presumed necessary. In the awake and cooperative patient, noninvasive continuous positive airway pressure (CPAP) by mask may obviate the need for intubation.[3] In general, the most conservative methods for maintaining adequate oxygenation and preventing complications should be used. Adequate analgesia is of paramount importance in patient recovery and may contribute to the return of normal respiratory mechanics.

Treatment of acute rib fractures is based on adequate pain relief and the maintenance of pulmonary function. Outdated management techniques involving stabilization of the flail segment by positioning the person with the injured side down or placing sandbags on the affected segments have been discredited. These interventions actually inhibit expansion of the chest and produce increased atelectasis of the injured lung. Instead, oxygen should be administered, cardiac and oximetry monitors applied, and the patient observed for signs of an associated injury, such as tension pneumothorax.

Otherwise well patients with single rib fractures are managed with opioid and non-opioid analgesia. These injuries can be severely painful, and regular opioid medication along with transdermal lidocaine patches (particularly at bedtime) is usually necessary for up to a week. Thereafter, simple analgesia with acetaminophen or a nonsteroidal anti-inflammatory analgesic generally will suffice. Continuing daily activities and deep breathing should be stressed to ensure ventilation and prevent atelectasis. It is helpful to advise patients to wait 30 to 45 minutes after taking their pain medications before performing deep breathing exercises, ideally with an incentive spirometer.

The greater the number of fractured ribs, the higher the mortality and morbidity rates. Hospitalization should be considered for patients with three or more fractured ribs, despite the lack of other identified injuries, to receive pulmonary therapy, repeated evaluation, and appropriate effective analgesia. Elderly patients with six or more fractured ribs should be treated in an intensive care unit owing to high morbidity and mortality.

Multiple rib fractures in trauma patients are associated with significant morbidity and mortality. Intercostal nerve blocks with a long-acting anesthetic, such as bupivacaine with epinephrine, may relieve symptoms up to 12 hours. Other alternatives for hospitalized patients include patient-controlled analgesia, parenteral opioids, and thoracic epidural analgesia.

For flail segments, consultation with a trauma or thoracic surgeon is essential to plan for surgical intervention. Early operative internal fixation of the flail segment results in a speedier recovery, decreased complications, and better cosmetic and functional results, and it is cost-effective.[4] Indications for open fixation for flail chest include patients who are unable to be weaned from the ventilator secondary to the mechanics of flail chest, persistent pain, severe chest wall instability, or a progressive decline in pulmonary function.

The patient with flail chest should be treated in the emergency department (ED) as if pulmonary contusion exists regardless of whether mechanical ventilation is used.

Disposition

Most rib fractures heal uneventfully within 3 to 6 weeks, and patients should expect a gradual decrease in their discomfort during this period. However, in addition to the complications of hemopneumothorax, atelectasis, pulmonary contusion, and pneumonia, rib fractures can result in post-traumatic neuroma, empyema, nonunion, or costochondral separation.[5] These rare complications are painful and heal slowly. Patients with blunt trauma and multiple rib fractures should be observed for 12 to 24 hours to ensure that occult vascular or intrapulmonary injuries are not present and then considered for discharge, with the full understanding that the rib fractures themselves will require a prolonged recovery period and close outpatient follow-up.

The outcome of flail chest is a function of associated injuries. Because many different physiologic mechanisms have been implicated in flail chest, there is no consensus about hospital treatment. The cornerstones of therapy include pulmonary physiotherapy, effective analgesia, selective use of endotracheal intubation and mechanical ventilation, and close observation for respiratory compromise.

STERNAL FRACTURE

Foundations

Background and Importance

Sternal fractures and dislocations are caused primarily by anterior blunt chest trauma (e.g., motor vehicle collisions [MVCs] or bicycle accidents when the chest strikes the steering wheel or handlebars). Risk factors for sternal fracture from blunt trauma include types of vehicular passenger restraint systems and patient age. Restrained passengers are more likely than unrestrained passengers to sustain sternal fracture, likely related to the central location of the shoulder portion of the restraint. Cardiac complications, such as myocardial contusion, occur rarely, and there is no association between sternal fracture and aortic rupture. Although sternal fractures may occur in the context of major blunt chest trauma, the presence of a sternal fracture itself does not imply other major life-threatening conditions.

Pathophysiology

During rapid deceleration from a frontal impact, the forward thrust of the body against the fixed seat belt across the sternum can result in a fracture. The location of the sternal fracture varies depending on the position of the belt, patient size, the magnitude of the impact, and the vector of the forces.

Clinical Features

Patients with sternal fractures typically present with a history compatible with the injury, and anterior chest pain, point tenderness over the sternum, ecchymosis, soft tissue swelling, or palpable deformity.

Diagnostic Testing

When sternal fracture is suspected after a relatively minor mechanism of injury (e.g., ground level fall or blow to the chest), posteroanterior and lateral chest radiography is sufficient to establish the diagnosis and for evaluation of the pulmonary structures. However, when more significant traumatic signs or symptoms are present (as per the NEXUS-Chest CT criteria)[1] or when plain radiography shows a displaced fracture or possible evidence of intrathoracic injury, we recommend obtaining a chest CT scan. Results will guide management of the sternal fracture and any associated mediastinal or other intrathoracic injuries.[6,7] Notably, there are also specific ultrasound views during evaluation by extended focused assessment with sonography in trauma (e-FAST) that may be more sensitive than plain radiography for sternal fracture.

Management

Treatment consists of providing adequate analgesia, as for rib fractures. In the absence of associated injuries, most patients with isolated sternal fractures who can achieve adequate pain control with oral medications can be safely discharged home. A small subset of patients with more severe sternal fractures may have severe pain and develop respiratory compromise or nonunion. These patients are best referred for operative fixation.

NONPENETRATING BALLISTIC INJURY

Foundations

Background and Importance

Injury caused by low-velocity projectiles against protective vests or the use of rubber bullets or beanbag shotgun shells represent high-frequency examples of nonpenetrating ballistic injuries. Composed of many different combinations of synthetic fibers such as Kevlar®, lightweight synthetic body armor is often used by law enforcement officers, emergency medical services personnel, and private security guards to protect against gunshot injury. These vests are "bullet resistant" rather than "bulletproof," depending on the weapon being used against them. Therefore, wearers who are shot often suffer nonpenetrating ballistic injuries rather than gunshot wounds. Rubber bullets have been used for many years by police agencies throughout the world for crowd dispersal and for nonlethal use of force. Beanbag shotgun shells are nylon bags filled with pellets, which are fired from a standard shotgun. Both of these projectiles have the potential to cause serious injury despite their classification of "nonmetal" or "less-than-lethal" use of force.

Pathophysiology

Bullet-resistant vests are usually capable of stopping penetration by the low-velocity projectiles from most handguns, but the kinetic energy of a bullet can be transmitted through the layers of protective cloth or armor and produce significant injury without penetration. The heart, liver, spleen, lung, and spinal cord are vulnerable to nonpenetrating ballistic injury that may occur despite benign-appearing skin lesions.

Clinical Features

Patients who have been shot with "less-than-lethal projectiles" or with standard bullets while wearing bullet-resistant vests usually have erythema, ecchymosis, and marked tenderness to palpation over the affected area. There may be a projectile, such as a beanbag, still located in the wound. The area of tenderness and surrounding structures should be carefully palpated to identify any subcutaneous emphysema, crepitus, or bony step-offs.

Diagnostic Testing

Most patients with nonpenetrating ballistic injury do not require testing beyond a thorough physical examination. Those in whom there is concern for retained foreign body or underlying injury may need ultrasound examination, chest x-ray, or CT scan (as they might with other blunt trauma). However, patients with only superficial ecchymoses without clinical signs or symptoms of rib fracture, pneumothorax, hemothorax, intrapleural or peritoneal penetration frequently require no additional testing.

Management

In patients in whom underlying injury has been excluded or determined to be of low clinical probability, management of nonpenetrating ballistic injury focuses on wound care, either of the ecchymotic area or of the superficial abrasion or laceration. Underlying injuries, when present, should be managed as noted elsewhere in this chapter.

Disposition

It is recommended that patients with all but the most superficial nonpenetrating ballistic injuries to the chest be observed for 4 to 6 hours to detect internal injuries that may manifest in a delayed manner.

PULMONARY INJURIES

PULMONARY CONTUSION AND LACERATION

Foundations

Background and Importance

Pulmonary contusion is present in up to 75% of patients with significant blunt chest trauma, most often from MVCs with rapid deceleration.[8] Pulmonary contusions can also be caused by high-velocity missile wounds and the high-energy shock waves of an explosion in air or water.

In addition to contusions, the lungs can also sustain lacerations. Although they are most often lacerated from penetrating injury, they may also be injured by the inward projection of a fractured rib or avulsion of a pleural adhesion.[4,8]

Pathophysiology

Pulmonary contusion is caused by an impact to the lung parenchyma followed by alveolar edema and hemorrhage but without an accompanying pulmonary laceration. The early diagnosis of pulmonary contusion is important if treatment is to be successful. Since its onset may be insidious, it should be suspected from a history of a high mechanism of injury (e.g., a fall from height, an MVC, and other forms of significant trauma) rather than the initial chest radiograph.

Clinical Features

The clinical manifestations include dyspnea, tachypnea, cyanosis, tachycardia, hypotension, and chest wall bruising. There are no specific signs for pulmonary contusion or laceration, but hemoptysis may be seen. Moist rales or absent breath sounds may be heard on auscultation. Palpation of the chest wall commonly reveals fractured ribs. If flail chest is discovered, pulmonary contusion is also likely present.

Of note, many of the worst contusions occur in patients without rib fractures. It has been theorized that the more elastic chest wall in younger individuals transmits increased force to the thorax. Although isolated pulmonary contusions can exist, they are associated with extrathoracic injuries in the majority of patients.

Diagnostic Testing

Laboratory

Hypoxemia frequently occurs with pulmonary contusions and is often detected by a decreasing pulse oximetry reading. In patients with thoracic injury and hypoxemia in whom other, more severe injuries (e.g., pneumothorax) have been excluded, a pulmonary contusion should be suspected. In these patients, arterial blood gas assessment is helpful in making the diagnosis, because a widening alveolar-arterial oxygen difference indicates a decreasing pulmonary diffusion capacity of the patient's contused lung, and it is one of the earliest and most accurate means of assessing the current status, progress, and prognosis.

Radiology

Typical radiographic findings can begin to appear within minutes of injury and range from patchy, irregular alveolar infiltrate to frank consolidation (Fig. 37.4). Although these changes may be present on the initial examination, they are almost always present within 6 hours. The rapidity of changes on chest x-ray visualization usually correlates with the severity of the contusion or laceration. Pulmonary contusion should be differentiated from acute respiratory distress syndrome (ARDS) because the radiographic appearance of the two conditions may be similar. Contusion usually manifests within minutes of the initial injury, is usually localized to a segment or a lobe, is often apparent on the initial chest study, and tends to last 48 to 72 hours. ARDS is diffuse, and its development is usually delayed, with onset typically between 24 and 72 hours after injury.

The increased frequency of CT scans for blunt trauma patients has resulted in a corresponding increase in the diagnosis of pulmonary contusions and lacerations. CT scans have been shown to detect at least twice as many pulmonary contusions as plain radiographs, and one recent study found that isolated pulmonary contusions seen on CT had a mortality of only 2.6% (compared to 4.7% for all patients with pulmonary contusion detected by plain radiography).[8]

Chest CT scan is particularly valuable to identify a pulmonary contusion in the acute phase after injury because plain chest x-ray films have a low sensitivity. Although CT scan may not be necessary to make the diagnosis of a pulmonary contusion that is evident on plain chest radiography, it may be helpful to further define the extent of the contusion and to identify other thoracic injuries. Occult pulmonary contusions are those that are initially visible only on CT scan, not plain radiographs, and usually involve less than 20% of the lung volume. These occult pulmonary contusions are not associated with a worse clinical outcome as compared with blunt trauma patients without pulmonary contusion.[8]

Management

Treatment for pulmonary contusions is primarily supportive. As with flail chest, intubation and mechanical ventilation should be avoided if possible, because they are associated with an increase in morbidity, including pneumonia, sepsis, pneumothorax, hypercoagulability, and longer hospitalization. In the rare case in which one lung has been severely contused and is causing significant hypoxemia, consideration should be given to intubating and ventilating each lung separately with a dual-lumen endotracheal tube and two ventilators. This allows for the difference in compliance between the injured and the normal lung and prevents hyperexpansion of one lung and gradual collapse of the other.

Management of patients with pulmonary contusions should include the restriction of intravenous (IV) fluids (to maintain intravascular volume within strict limits) and comprehensive supportive care consisting of tracheobronchial toilet, suctioning, and pain relief. These maneuvers may preclude the need for ventilator support and allow a more selective approach to both flail chest and pulmonary contusion.

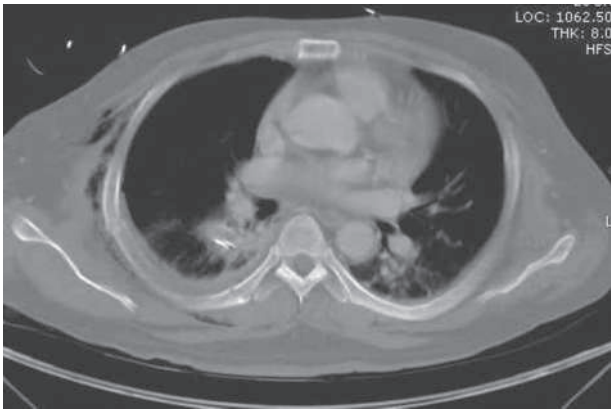

Fig. 37.4 Chest computed tomography (CT) scan showing bilateral alveolar infiltrates suggesting pulmonary contusion. There are also multiple rib fractures and subcutaneous emphysema.

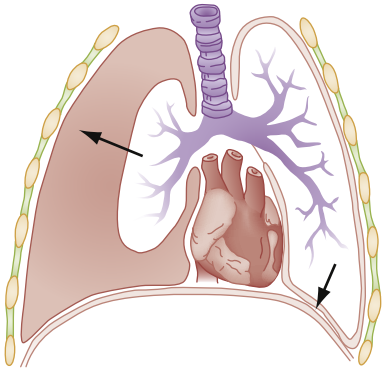

Fig. 37.5 **Closed Pneumothorax.** Simple pneumothorax is present in the right lung with air in the pleural cavity *(left arrow)* and collapse of the right lung *(right arrow)*.

Patients sustaining the force necessary to inflict a pulmonary contusion may also have pulmonary lacerations. Most of these are minor and rarely life-threatening, and they can usually be treated with continuous oxygen therapy, observation, or tube thoracostomy. Severe lacerations are associated with hemopneumothorax, multiple displaced rib fractures, and hemoptysis. Often, these life-threatening lacerations require thoracotomy with resection or tractotomy to control bleeding.

PNEUMOTHORAX

Foundations

Background and Importance

Pneumothorax, which is the accumulation of air in the pleural space, is a common complication of chest trauma. It is reported to be present in 15% to 50% of patients who sustain significant chest trauma and is invariably present in those with transpleural penetrating injuries.

Pathophysiology

Pneumothorax can be divided into three types depending on whether air has direct access to the pleural cavity: (1) simple, (2) communicating, and (3) tension.

Simple pneumothorax. A pneumothorax is considered simple or closed (Fig. 37.5) when there is no communication with the atmosphere or any shift of the mediastinum or hemidiaphragm resulting from the accumulation of air. Traumatic simple pneumothorax is most often caused by a fractured rib that is driven inward, lacerating the pleura. It may also occur without a fracture when the impact is delivered at full

inspiration with the glottis closed, leading to a tremendous increase in intra-alveolar pressure and the subsequent rupture of the alveoli. A penetrating injury, such as a gunshot or stab wound, may also produce a simple pneumothorax if there is no free communication with the atmosphere (Fig. 37.6).

Communicating pneumothorax. A communicating pneumothorax (Fig. 37.7) is associated with a defect in the chest wall and most commonly occurs in combat injuries. In the civilian sector, this injury is typically secondary to gunshot wounds. Air can sometimes be heard flowing sonorously in and out of the defect, prompting the term "sucking chest wound." The loss of chest wall integrity causes the involved lung to paradoxically collapse on inspiration and expand slightly on expiration, forcing air in and out of the wound. This results in a large functional dead space for the normal lung and, together with the loss of ventilation of the involved lung, produces a severe ventilatory disturbance.

Tension pneumothorax. The progressive accumulation of air under pressure within the pleural cavity, with shift of the mediastinum to the opposite hemithorax and compression of the contralateral lung and great vessels, is the constellations of findings in tension pneumothorax (Figs. 37.8 and 37.9). It occurs when the injury acts like a one-way valve, prevents free bilateral communication with the atmosphere, and leads to a progressive increase of intrapleural pressure. Air enters on inspiration but cannot exit with expiration. The resulting shift of mediastinal contents compresses the vena cava and distorts the cavoatrial junction, leading to decreased diastolic filling of the heart and subsequent decreased cardiac output. These changes result in the rapid onset of hypoxia, acidosis, and shock.

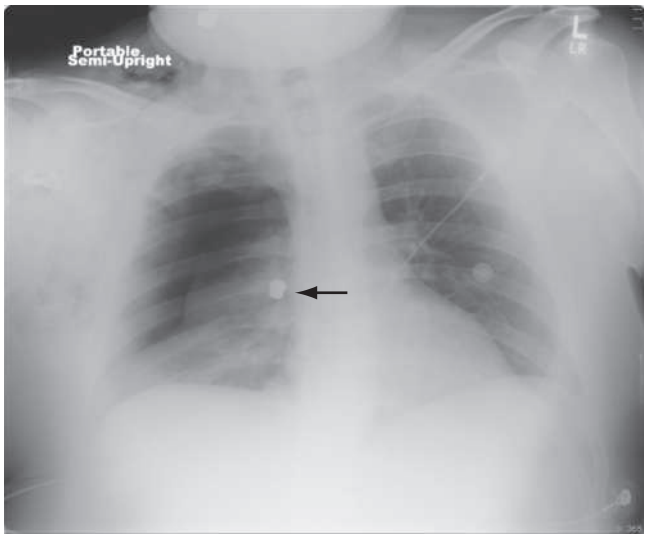

Fig. 37.6 Chest radiograph showing a moderate-sized right pneumothorax. A bullet *(arrow)* can be seen near the right mediastinum.

Clinical Features

Shortness of breath and chest pain are the most common presenting complaints of pneumothorax. The patient's appearance is highly variable, ranging from acutely ill with cyanosis and tachypnea to misleadingly healthy appearance. The signs and symptoms are not always correlated with the degree of pneumothorax. The physical examination may reveal decreased or absent breath sounds and hyper-resonance over the involved side as well as subcutaneous emphysema, but small pneumothoraces may not be detectable on physical examination.

Patients with tension pneumothorax become acutely ill within minutes and develop severe cardiovascular and respiratory distress. They are dyspneic, agitated, restless, cyanotic, tachycardic, and hypotensive and display altered mental status. The cardinal signs of tension pneumothorax are tachycardia, hypotension, oxyhemoglobin desaturation, jugular venous distention (JVD), and absent breath sounds on the ipsilateral side. However, JVD may not reliably be present with massive blood loss.

Diagnostic Testing

Because intrapleural air tends to collect at the apex of the lung, the initial chest radiograph should be an upright full inspiratory film if the patient's condition permits. An upright film will often reveal small pleural effusions that are not visible on supine films, and it also allows better visualization of the mediastinum. Although the chest radiograph has traditionally been the preferred initial study for diagnosing a simple pneumothorax, several studies have found that ultrasound has greater sensitivity for pneumothorax than chest radiography.[9,10] During the e-FAST examination, pneumothorax will be detected well before chest radiography is performed. This may be particularly critical in the hypotensive poly-trauma patient with oxyhemoglobin desaturation for whom tension pneumothorax is one of the considerations as

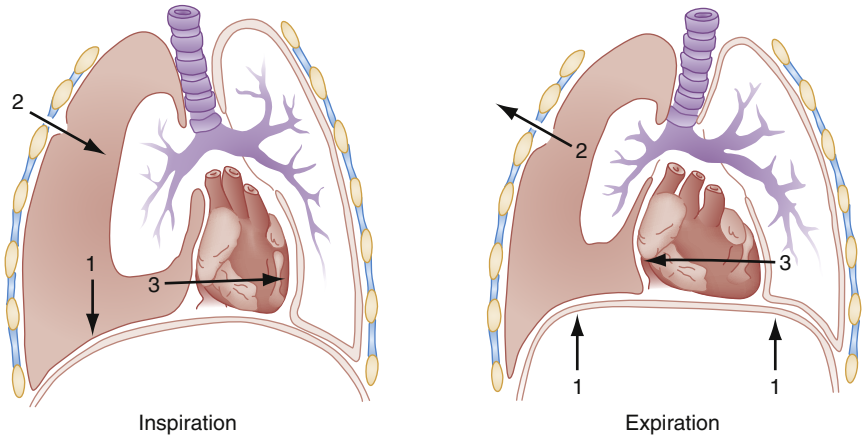

Fig. 37.7 Inspiration *(left):* The diaphragm contracts causing negative intrathoracic pressure *(arrow 1)* that draws air through the sucking chest wound in the pleural cavity *(arrow 2)* and causing the mediastinal structures to shift to the patient's left *(arrow 3)*. Expiration *(right):* The diaphragm recoils *(arrow 1)* causing air to exit the chest *(arrow 2)* and allowing the mediastinum to shift back to normal position *(arrow 3)*. The collapsed lung paradoxically shrinks on inspiration and expands on expiration.

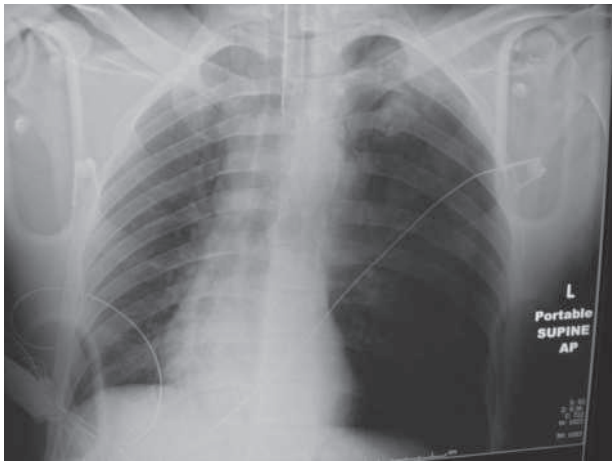

Fig. 37.8 Tension pneumothorax seen in intubated patient.

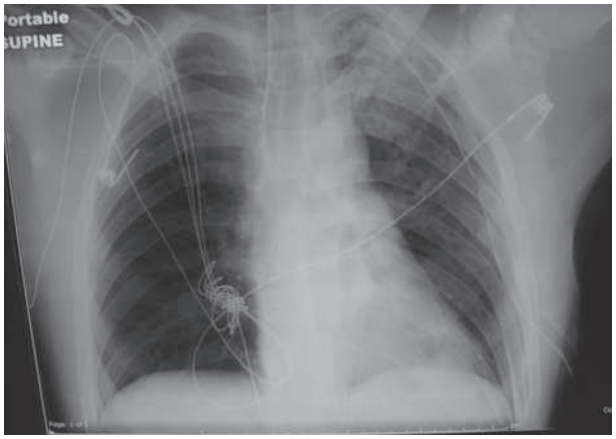

Fig. 37.9 Resolution of the tension pneumothorax shown in Fig. 37.8 with placement of a left-sided tube thoracostomy.

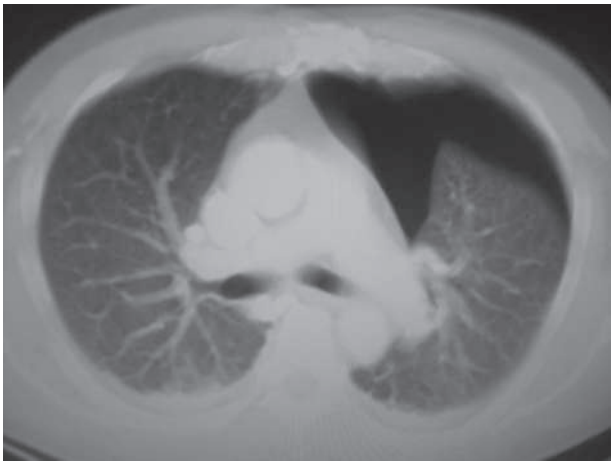

Fig. 37.10 Occult Pneumothorax. Large left-sided pneumothorax visible on chest computed tomography (CT) scan, which was not visible on chest x-ray film.

BOX 37.2 Indications for Tube Thoracostomy

- Traumatic cause of pneumothorax (except asymptomatic, apical pneumothorax)
- Moderate to large pneumothorax
- Respiratory symptoms regardless of size of pneumothorax
- Increasing size of pneumothorax after initial conservative therapy
- Recurrence of pneumothorax after removal of an initial chest tube
- Patient requires ventilator support
- Patient requires general anesthesia
- Associated hemothorax
- Bilateral pneumothorax regardless of size
- Tension pneumothorax

From Dougall AM, Paul ME, Finely RJ, et al. Chest trauma—current morbidity and mortality. *J Trauma* 1977;17:547.

the cause of the unstable state. Suspicion of tension pneumothorax on the basis of clinical findings is indication for immediate tube thoracostomy. Treatment should not be delayed pending a confirmatory chest radiograph. Ultrasound can confirm the presence of a pneumothorax within the first minutes of the patient's arrival, and identification of a pneumothorax in a patient with pulmonary and hemodynamic compromise is also considered confirmatory empirical evidence of tension pneumothorax requiring thoracostomy. Even without ultrasound confirmation, clinical suspicion of tension pneumothorax is justification for emergent tube thoracostomy, because delay can be detrimental.

Occult Pneumothorax

A pneumothorax that is absent on the initial chest radiograph but is identified on subsequent chest or abdominal CT is called an *occult pneumothorax.* Occult pneumothorax is being diagnosed more frequently given the increased use of CT scanning (Fig. 37.10).[11]

Management

An asymptomatic patient who suffers a low-velocity penetrating trauma (typically a stab wound) and who has negative initial imaging can be safely observed, typically for 6 hours. If the initial imaging was a CT scan, the patient may be safely discharged after the period of observation. If the initial imaging was via plain radiograph, a delayed chest x-ray should be performed prior to discharge.

Simple Pneumothorax

Treatment of a simple pneumothorax depends on its cause and size. Small, isolated apical pneumothoraces due to stab wounds may be observed without intervention. However, this conservative method seldom has application in multisystem trauma, and a chest tube should be inserted immediately upon any sign of deterioration.

Similarly, small occult pneumothoraces found only on CT scan in hemodynamically stable patients without symptoms can be managed with observation and do not need intervention, even if the patient is placed on positive-pressure ventilation.[11]

Any moderate to large pneumothorax should be treated with a chest tube. The indications for tube thoracostomy (chest tube insertion) are listed in Box 37.2. The preferred site for insertion is the fourth or fifth intercostal space at the midaxillary line. This lateral placement of the tube is preferred not only because it is more efficient, but also because it does not produce an easily visible cosmetic defect, compared to the anterior site at the second interspace at the midclavicular line. With multisystem trauma in which hemothorax is likely, a large chest tube (36-F to 40-F in adults and 16-F to 32-F in children) should be used. Conversely, spontaneous pneumothoraces or those due to minor or isolated injuries can be treated with smaller caliber chest tubes.

Care is taken to be certain the vent holes along the side of the tube are all inside the chest cavity. A radiopaque line along the side of the tube with interruptions at these drainage holes helps in radiographically

interpreting tube position. The tube should be attached to a water seal drainage system that allows re-expansion of the pneumothorax. If there is significant air leak or a large hemothorax, the tube may be connected to a source of constant vacuum at 20 to 30 cm H_2O for more rapid re-expansion.

Tube thoracostomy does have some potentially serious complications, including the formation of a hemothorax, pulmonary edema, bronchopleural fistula, pleural leaks, empyema, subcutaneous emphysema, infection, intercostal artery laceration, contralateral pneumothorax, and parenchymal injury.[12] A recent meta-analysis did not find sufficient evidence for or against the use of empirical antibiotics with all tube thoracostomy placements to prevent empyema or pneumonia, especially those needed for spontaneous pneumothoraces. However, for patients with multisystem trauma or hemothorax, the data was suggestive of a clinical benefit. We recommend routine intravenous antibiotic administration in these patients, specifically cefazolin 1 to 2 g given prior to, or within 1 hour of chest tube insertion. Vancomycin (1 g) or clindamycin (600 mg) are appropriate alternatives in patients with cephalosporin allergies.[13]

Communicating Pneumothorax

For a patient with a communicating pneumothorax in the out-of-hospital setting, the defect should be covered immediately, which helps convert the condition to a closed pneumothorax, eliminating the major physiologic abnormality. Either a partially occlusive dressing or a commercial vented chest seal can be applied; care should be taken to continually assess for conversion of the injury to a tension pneumothorax, especially in patients who are intubated and undergoing positive-pressure ventilation. The wound should never be packed, because the negative pressure during inspiration can suck the dressing into the chest cavity. These considerations are not as critical once the patient is in the ED, where formal tube thoracostomy can be performed. Positive-pressure ventilation can then be initiated, if needed, without the fear of producing a tension pneumothorax, and the patient can be prepared for definitive surgical repair.

Tension Pneumothorax

When the diagnosis of tension pneumothorax is suspected clinically, the pressure should be relieved immediately with needle thoracostomy, which is performed by inserting a large-bore (14-gauge or larger) catheter, at least 5 cm in length, through the fourth or fifth interspace laterally or the second or third interspace anteriorly on the involved side. However, some catheters may not be of sufficient length to penetrate the pleural space.[14] Therefore, we recommend the lateral approach if it is accessible. This method can be easily performed in the field, allowing vital signs to improve during transport or preparation for a tube thoracostomy.[15]

In the ED, it may be just as expeditious to insert a chest tube (or even perform a "finger thoracostomy," without actually inserting the chest tube) as it is to perform a needle thoracostomy, depending on the availability of equipment. Regardless, even if a needle thoracostomy is performed on a patient with suspected tension pneumothorax in the ED, a chest tube should emergently follow.

The intubated patient in the ED who is receiving positive-pressure ventilation and external cardiac compressions is at particular risk for developing tension pneumothorax. Fractured ribs from cardiopulmonary resuscitation (CPR) can penetrate lung parenchyma and cause pneumothorax. Positive-pressure ventilation then increases intrapleural pressure and produces a tension pneumothorax. The earliest sign of this complication is an increase in resistance to ventilation. If the patient has detectable vital signs, the blood pressure will fall and the central venous pressure (CVP) will rise. Misplacement of an endotracheal tube does not result in tension pneumothorax but, rather, asymmetry of breath sounds. If tension pneumothorax is suggested, the clinician should proceed with empirical emergent therapy.

HEMOTHORAX

Foundations

Background and Importance

Hemothorax, which is the accumulation of blood in the pleural space after blunt or penetrating chest trauma, is a common complication that may produce hypovolemic shock and rapidly reduce vital capacity. It is commonly associated with pneumothorax and extrathoracic injuries.

Pathophysiology

Hemorrhage from injured lung parenchyma is the most common cause of hemothorax, but this tends to be self-limited unless there is a major laceration. Specific vessels are less often the source of hemorrhage, with intercostal and internal mammary arteries causing hemothorax more often than hilar or great vessels. Bleeding from the intercostal arteries may be brisk, however, because they branch directly from the aorta.

Clinical Features

Depending on the rate and quantity of hemorrhage, varying degrees of hypovolemic shock will be manifested. Patients may present in respiratory distress and be tachycardic and hypoxemic. Breath sounds may be diminished. The diagnosis should also be recognized as a potential complication of central line placement and considered—along with pneumothorax—in patients who present with these symptoms after the procedure.

Diagnostic Testing

The *upright* chest radiograph remains the primary diagnostic study in the acute evaluation of hemothorax. A hemothorax is noted as meniscus of fluid blunting the costophrenic angle and tracking up the pleural margins of the chest wall when viewed on the upright chest x-ray film. Blunting of the costophrenic angles on upright chest radiograph requires at least 200 to 300 mL of fluid. The supine view chest film is less accurate but is often the only film available because of the patient's unstable condition. In the supine patient, blood layers posteriorly, creating a diffuse haziness that can be rather subtle (or appear to be a pulmonary contusion), depending on the volume of the hemothorax (Fig. 37.11). With massive hemothorax, the large volume of blood can create a tension hemothorax, with signs and symptoms of both obstructive and hemorrhagic shock (Fig. 37.12).

As is the case with pneumothoraces, ultrasound has greater sensitivity than supine chest radiography in the detection of hemothoraces.[10,16] Given this, early bedside ultrasonography should routinely be performed in patients with thoracic trauma, regardless of findings on supine radiography. Additional imaging via chest CT scan (Fig. 37.13) should be performed if indicated by the NEXUS-Chest CT criteria as discussed earlier,[1] because it may detect hemothorax or other associated injuries (Fig. 37.14).

Management

Treatment of hemothorax consists of restoring the circulating blood volume, controlling the airway as necessary, and evacuating the accumulated blood. Tube thoracostomy allows constant monitoring of the blood loss, and serial chest radiographs help monitor lung reexpansion.

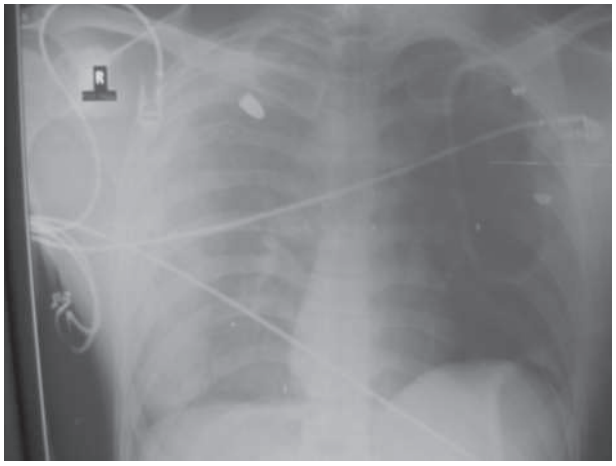

Fig. 37.11 Hemothorax Secondary to Gunshot Wound. Note haziness over right hemithorax with bullet seen in right upper lobe.

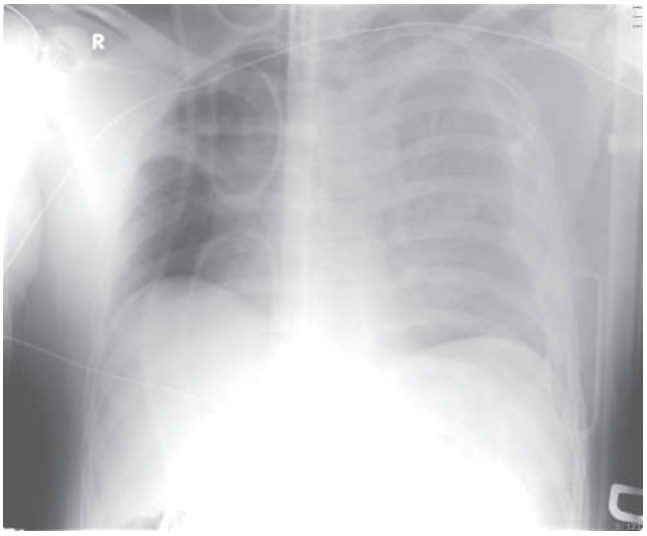

Fig. 37.12 Tension Hemothorax.

A large-bore tube (36-F to 40-F) should be inserted in the fifth interspace at the anterior axillary line and connected to underwater seal drainage and suction (20 to 30 mL H_2O).

Although small hemothoraces may be observed in stable patients, a moderate hemothorax or any hemothorax in an unstable or symptomatic patient requires tube thoracostomy. Severe or persistent hemorrhage requires thoracostomy or open thoracotomy. Further studies are required to better delineate the size of a hemothorax detected on CT scan that requires tube thoracostomy drainage.

Autotransfusion has been successfully used in tube thoracostomy. Autotransfusion also eliminates the risk of incompatibility reactions and transmission of certain diseases, such as hepatitis C. Because the majority of blood loss occurs immediately after tube thoracostomy placement, an autotransfusion apparatus should be immediately available in the ED.

Close monitoring of the initial and ongoing rate of blood loss should be performed. Immediate drainage of more than 1500 mL of blood from the pleural cavity is considered an indication for urgent thoracotomy, as is a continued output of at least 200 mL/h for 3 hours. General considerations for urgent thoracotomy are outlined in Box 37.3.

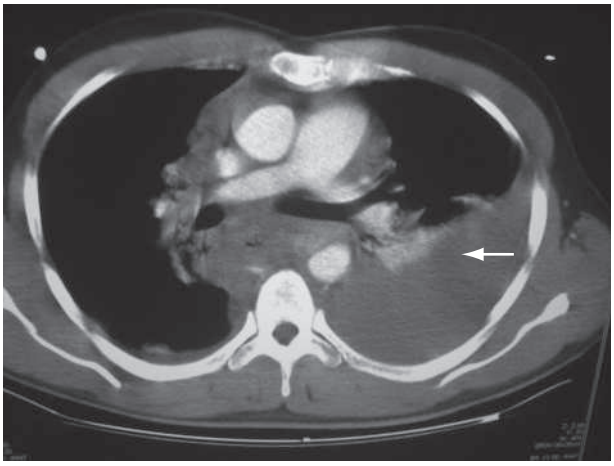

Fig. 37.13 Left-sided hemothorax visible on chest computed tomography (CT) scan *(arrow)*.

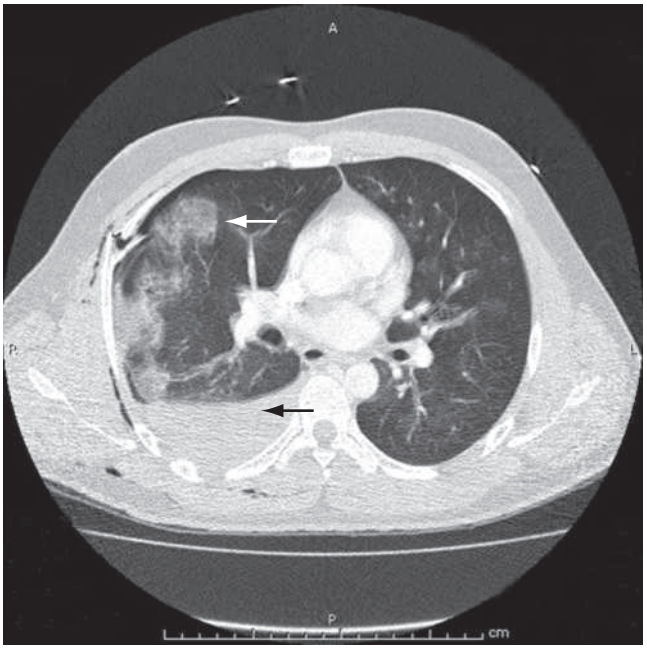

Fig. 37.14 Rib fracture resulting in pneumothorax, with associated hemothorax *(bottom arrow)* and pulmonary contusion *(top arrow)* seen on chest computed tomography (CT) scan.

BOX 37.3 Indications for Urgent Thoracotomy

- Initial thoracostomy tube drainage is more than 20 mL of blood per kilogram
- Persistent bleeding at a rate greater than 7 mL/kg/h is present
- Increasing hemothorax seen on chest x-ray films
- Patient remains hypotensive despite adequate blood replacement, and other sites of blood loss have been ruled out
- Patient decompensates after initial response to resuscitation

TRACHEOBRONCHIAL INJURY

Foundations

Background and Importance

Tracheobronchial injuries may occur with either blunt or penetrating injuries of the neck or chest. MVCs are the most frequent mechanism

causing tracheobronchial injury, accounting for more than half of all cases.

Although there has been an increase in the occurrence of tracheobronchial disruption, it is still a relatively rare injury, occurring in fewer than 3% of patients with significant chest injury. Its associated mortality rate is reported to be approximately 10%, although mortality rates are significantly affected by associated injuries and the timing of diagnosis and surgical repair.

Pathophysiology

Tracheobronchial injuries caused by knife wounds develop almost exclusively from wounds in the cervical trachea (see Chapter 36), whereas gunshot wounds may damage the tracheobronchial tree at any point. Intrathoracic injury to the tracheobronchial tree occurs most commonly from blunt trauma. These injuries may result from direct blows, shearing stresses, or burst injury. A direct blow to the neck may crush the cervical trachea against the vertebral bodies and transect the tracheal rings or cricoid cartilage. Shear forces on the trachea will produce injury at the carina and the cricoid cartilage, which are its relatively fixed points.

Sudden deceleration of the thoracic cage pulls the lungs away from the mediastinum, producing traction on the trachea at the carina. When the elasticity of the tracheobronchial tree is exceeded, it ruptures. It has also been suggested that if the glottis is closed at the time of impact, the sudden increase in intrabronchial pressure will rupture the tracheobronchial tree. Regardless of the mechanism, more than 80% of these injuries occur within 2 cm of the carina.

Clinical Features

Massive air leak through a chest tube, hemoptysis, and dramatic or increasing subcutaneous emphysema should suggest the diagnosis of major airway damage. Subcutaneous emphysema is typically the most common physical exam finding. Auscultation of the heart may reveal *Hamman's crunch* if air tracks into the mediastinum. Hamman's crunch is a crunching, rasping sound that is synchronous with the pulse and is best heard over the precordium. It is the result of the heart beating against air-filled tissues. Patients with tracheobronchial disruption have one of two distinct clinical pictures. In the first group of patients, the wound opens into the pleural space, producing a large pneumothorax. A chest tube fails to evacuate the space and reexpand the lung, and there is continuous bubbling of air (indicating a persistent leak) in the underwater seal device (Fig. 37.15).

In the second group of patients, there is complete transection of the tracheobronchial tree but little or no communication with the pleural space. A pneumothorax is usually not present. The peribronchial tissues support the airway enough to maintain respiration, but within 3 weeks, granulation tissue will obstruct the lumen and produce atelectasis. These patients are relatively free of symptoms at the time of injury, but weeks later they have unexplained atelectasis or pneumonia. Radiographic signs in either group of patients are pneumomediastinum, extensive subcutaneous emphysema (Fig. 37.16), pneumothorax, fracture of the upper ribs (first through fifth), air surrounding the bronchus, and obstruction in the course of an air-filled bronchus.

Diagnostic Testing

When tracheobronchial injury is suspected, bronchoscopy should be performed. Flexible endoscopic bronchoscopy is the most preferred and reliable means of establishing the diagnosis and determining the site and extent of the injury. However, CT scan has been shown to have high sensitivity in detecting tracheobronchial injury. Bronchopleural fistula (a communication between a bronchus and the lung parenchyma) can occur as a complication of tracheobronchial disruption and in some cases has been treated successfully via the fiberoptic bronchoscope. A mediastinal fluid collection, evidence of mediastinitis, or both may be noted on chest CT.

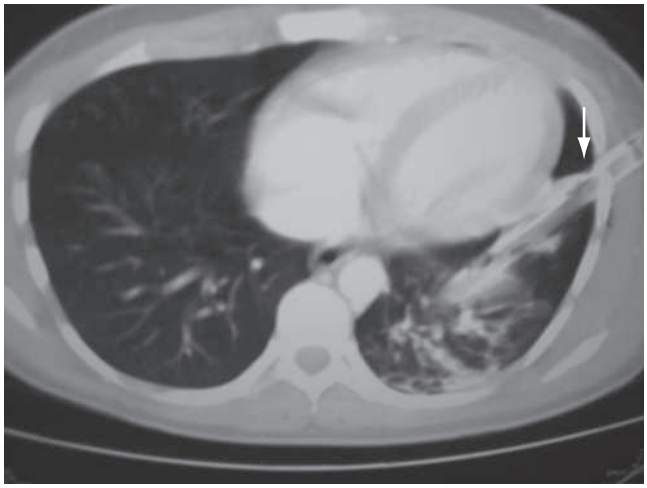

Fig. 37.15 Penetration of lung parenchyma by tube thoracostomy *(arrow)*, with large residual pneumothorax, visible on computed tomography (CT) scan.

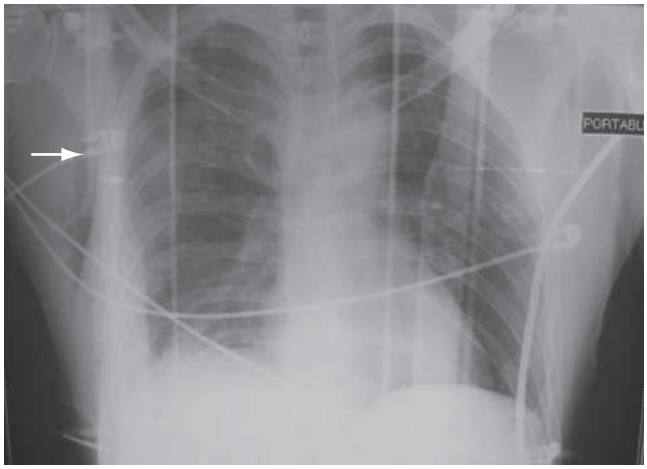

Fig. 37.16 Multiple rib fractures with extensive subcutaneous emphysema *(arrow)*, with no pneumothorax seen.

Management

If diagnostic bronchoscopy is performed, endotracheal intubation can be visualized over the bronchoscope to ensure that the tube passes safely beyond the site of injury. Blind intubation should not be attempted. If intubating using a video laryngoscope (or conventional laryngoscope), the tube is advanced slowly and gently to avoid creating a false passage or converting a partial tracheal tear to a complete tear.

The standard treatment for tracheobronchial injury has been thoracotomy with intraoperative tracheostomy and surgical repair of the disrupted airway. However, conservative medical treatment of such injuries can be considered for patients with tracheal tears less than 2 cm and without esophageal prolapse, mediastinitis, or massive air leakage.

DIAPHRAGMATIC INJURY

Foundations

Background and Importance

Diaphragmatic rupture is present in 1% to 6% of major thoracic injuries. Diaphragmatic rupture occurs most commonly after blunt

thoracoabdominal trauma, such as occurs in MVCs or falls from heights, but can also occur from penetrating trauma.

Pathophysiology

Diaphragmatic hernia is a herniation of abdominal structures into the thoracic cavity through a defect in the diaphragm, with a potential risk of strangulation of abdominal viscera, especially the small bowel. Signs and symptoms may not occur during the initial admission and may be delayed for as long as months to years, with a significant mortality rate.

Three-quarters of cases of diaphragmatic rupture secondary to blunt trauma occur on the left side, presumably due to the protective effect of the liver on the right side. Only about 5% of cases are bilateral. With penetrating injury, diaphragmatic injury occurs at the site of the penetration but may be occult.

In cases of blunt injury, the increased pressure within the abdominal cavity causes the diaphragmatic tear, and a pressure difference of generally 5 to 10 mm Hg forces the abdominal organs through the diaphragmatic defect. Because blunt trauma can cause multiple organ injuries, these coexisting injuries can mask the more silent diaphragmatic injuries, and diaphragmatic rupture may initially be overlooked. Over time, negative intrathoracic pressure generated by inspiration tends to draw abdominal contents into the thorax. This effect is minimized with the use of intubation and positive-pressure ventilation.

Clinical Features

Patients with diaphragmatic rupture can range from being completely asymptomatic to having vomiting; shortness of breath; abdominal, thoracic, or referred shoulder pain; or may have multiorgan failure that can result from visceral obstruction, strangulation, or perforation of hollow viscous. Delayed presentation up to years in patients with undiagnosed diaphragmatic tears without herniation can occur. As a result of the mechanism of injury and the force required to impart this injury, pelvic fractures as well as other significant intraabdominal and thoracic injuries are frequent, typically involving the lung, liver, and spleen. Rib and sternal fractures as well as cardiac contusions are also common.

Diagnostic Testing

Accurate diagnosis of traumatic diaphragmatic hernia is essential because prompt surgical repair is the treatment of choice. Plain chest radiography alone is poorly sensitive for diaphragm rupture. In patients with blunt trauma, CT examination of the abdomen and chest can be useful for the evaluation of diaphragmatic injury, although injury site and type affect its sensitivity. Nevertheless, CT can demonstrate findings consistent with diaphragmatic injury, including diaphragmatic discontinuity, intrathoracic herniation of abdominal contents, and waist-like constriction of abdominal viscera (known as the "collar sign").

In patients with penetrating left thoracoabdominal trauma, the incidence of herniation of abdominal contents is sufficiently high that thoracoscopy or laparoscopy is recommended for the diagnosis and repair of a diaphragmatic injury. Even in patients with right-sided penetrating lesions (which do not typically result in herniation because of the protective effect of the dome of the liver), evaluation of both sides of the diaphragm with laparoscopy or thoracoscopy is recommended.

Management

Diaphragmatic injuries may be markers of severity and predictors of serious associated injuries in trauma and should be surgically repaired. CT scan should identify the site and extent of herniation, herniated organs, complications, and damage to associated organs. Although they are not without complications, laparoscopy and thoracoscopy may be used for diaphragmatic hernia repair.

The incidence of diaphragmatic involvement after penetrating left sided thoracoabdominal injury is high, making nonoperative, expectant management of these patients potentially hazardous.

CARDIOVASCULAR TRAUMA

BLUNT CARDIAC TRAUMA

Blunt cardiac injury usually results from high-speed MVCs in which the chest wall strikes the steering wheel. Other causes, such as falls from heights, crushing injuries, blast injuries, and direct blows, are less common. The diagnosis of a blunt injury to the heart remains elusive because of the usual concomitant serious injuries to other body organs and, more important, because there is no accepted gold standard for making the diagnosis.

The importance of detecting blunt myocardial injury lies in the recognition of associated potentially fatal complications. Life-threatening dysrhythmias, conduction abnormalities, congestive heart failure, cardiogenic shock, hemopericardium with tamponade, cardiac rupture, valvular rupture, intraventricular thrombi, thromboembolic phenomena, coronary artery occlusion, ventricular aneurysms, and constrictive pericarditis have all been reported as complications.

Blunt cardiac trauma may be viewed as part of a continuous spectrum (i.e., myocardial concussion, contusion, infarction, and rupture). Myocardial concussion occurs when a blunt injury to the interior chest produces a "stun" response in the myocardium. No permanent cellular injury occurs, but transient clinical effects may result. Myocardial contusion is the least severe form of injury that can be demonstrated pathologically. Cellular injury occurs with extravasation of red blood cells into the muscle wall, along with localized myocardial cellular necrosis. Permanent myocardial damage is rare. Infarction typically occurs with traumatic occlusion or disruption of a coronary artery. Cardiac rupture is obviously the most severe form of blunt cardiac injury.

MYOCARDIAL CONCUSSION

Foundations

Background and Importance

The terms *myocardial concussion* or *commotio cordis* are used to describe an acute form of blunt cardiac trauma that is usually produced by a sharp, direct blow to the midanterior chest that stuns the myocardium and results in brief dysrhythmia, hypotension, and loss of consciousness. It is a rare event and primarily occurs in adolescents, especially those playing sports involving hard spherical objects (e.g., baseballs, hockey pucks).

Pathophysiology

Animal models of commotio cordis have determined that it is much more likely to occur if the impact occurs during early ventricular repolarization.[17] Additionally, flat objects and softer balls (e.g., tennis, soccer) are less likely to cause commotio cordis than other balls. Once this dysrhythmia occurs, it can result in a non-perfusing rhythm, such as asystole or ventricular fibrillation, and irreversible cardiac arrest. There are, however, a number of documented cases of successful resuscitation with both rapid provision of CPR and the use of an automated external defibrillator (AED).[18]

Clinical Features

Commotio cordis has a characteristic mechanism (blunt chest trauma) and presentation (sudden collapse). Notably, the condition itself is defined by a lack of structural cardiac damage, and so more severe

trauma (such as that necessary to cause cardiac contusion or rupture, as described later) is incongruent with the diagnosis.

Diagnostic Testing

Laboratory Tests and Electrocardiogram

Patients who present with the characteristic mechanism and presentation above and who have shockable rhythms on electrocardiogram (or who were defibrillated by an AED) can be presumed to have commotio cordis if there is no evidence of structural heart damage on echocardiography or CT. Laboratory evaluation of serum electrolyte and cardiac biomarker levels may identify additional contributors to their presentation, but these will typically be normal.

Management

The initial treatment of patients with commotio cordis should follow standard advanced cardiac life support (ACLS) algorithms, ideally with initiation of bystander CPR and early defibrillation (especially at sporting events). Barring any other more severe cardiac injuries (discussed later), commotion cordis does not require any specific interventions.

Disposition

In patients who survive the dysrhythmia of commotio cordis and are not found to have more severe traumatic cardiac injury, a short period of observation is appropriate. Although there is a paucity of evidence as to the duration of this observation period, we recommend 6 to 12 hours of telemetry monitoring. After this, patients may be discharged, although they should not return to sports play until additional outpatient cardiac testing (e.g., stress testing, cardiac magnetic resonance imaging [MRI], and pharmacologic testing for primary conductive disorders) is performed.[18]

MYOCARDIAL CONTUSION

Foundations

Background and Importance

Myocardial contusion is a very poorly understood and nebulous condition. Decades of research and widely varied clinical practice have failed to produce a consensus regarding its diagnosis, complication rate, and proper disposition.

Pathophysiology

Several mechanisms have been postulated by which the heart may be injured in cases of blunt trauma. A direct blow to the chest transmits energy through the ribs to the spine. When a large force is applied to the chest wall, the sternum is displaced posteriorly, and the heart is compressed between the sternum and vertebrae or an elevated diaphragm. Either can presumably result in cardiac injury. Increased intrathoracic pressure from a direct blow to the chest may contribute to the injury. In addition, compression of the abdomen and pelvis may displace abdominal viscera upward and result in cardiac injury.

Clinical Features

Myocardial contusion manifests clinically as a spectrum of injuries of varying severity. Although the majority of patients with myocardial contusion have external signs of thoracic trauma (e.g., contusions, abrasions, palpable crepitus, rib fractures, or visible flail segments), the absence of identifiable thoracic injury decreases the likelihood of myocardial contusion but does not exclude it. Virtually every known intrathoracic and chest wall injury has been associated with myocardial contusion. The most sensitive but least specific sign of myocardial contusion is sinus tachycardia, which is present in approximately 70% of patients with documented myocardial contusions. A reduction in cardiac output, which can be clinically insignificant or manifest as pronounced cardiogenic shock, may occur in patients with significant cardiac contusion.

Diagnostic Testing

There is no agreed upon gold standard diagnostic definition for myocardial contusion. Clinical evidence is often nonspecific, especially in the setting of multiple traumas. Many tests and definitions have been proposed over the years, but none has emerged as definitive.

Laboratory Tests and Electrocardiogram

Electrocardiogram. The right ventricle is far more likely to be injured than the left ventricle because of its anterior position in the thorax and proximity to the sternum. The standard 12-lead ECG is relatively insensitive to right ventricular damage, as demonstrated by pathologic evidence of cellular damage in patients with normal ECGs. A cardiac contusion usually results in moderate right ventricular damage with only minor electrical changes, which can easily be missed on ECG. Right-sided ECGs (the addition of V_4R) have not been found to be of diagnostic benefit.

The ECG for patients with myocardial contusion often shows evidence of dysrhythmia, conduction disturbance, or ischemia. Dysrhythmias or ECG changes also can be caused by significant hypoxia as a result of pulmonary injuries or blood loss, which resolve once the hypoxemia or blood loss has been corrected.

A few cases of delayed life-threatening dysrhythmia have been reported up to 12 hours after injury, and patients may develop less lethal dysrhythmias up to 72 hours after injury. The onset of ECG changes may be delayed up to 48 hours after injury, but all ECG changes usually resolve in 4 to 60 days. The presence of ECG abnormalities is neither specific enough to confirm the diagnosis of myocardial contusion nor reliable enough to predict subsequent complications, but a newly abnormal ECG (arrhythmia, heart block or ischemic changes) warrants admission for continuous ECG monitoring.[19]

Cardiac biomarkers. Creatine kinase (CK) is nonspecifically increased in trauma patients owing to associated skeletal muscle injury, and CK-MB levels have also been found to be falsely elevated in multitrauma patients. Therefore, the troponin assay is the preferred cardiac biomarker for testing.

The combination of a normal troponin level and a normal 12-lead ECG has a negative predictive value sufficient to "rule out" myocardial contusion, and these patients do not require any other evaluation or monitoring specific for myocardial contusion.[19]

Imaging

Although echocardiography provides a means to directly visualize cardiac structures and chambers and can be useful to rule out structurally significant myocardial injuries (e.g., wall motion or valvular abnormalities), it should not be routinely used as a primary screening modality for blunt cardiac injury. Rather, echocardiography should be reserved for patients in whom myocardial contusion is suspected (based on ECG or troponin level) and who have unexplained hypotension or arrhythmias.[19]

Management

Treatment of a suspected myocardial contusion is similar to that of a myocardial infarction (MI): cardiac monitoring, administration of oxygen if hypoxic, and analgesic agents. Dysrhythmias are typically transient and do not require treatment. Serious dysrhythmias, such as ventricular tachycardia or atrial flutter should be treated with appropriate medications as per current ACLS guidelines. No data exist to support prophylactic dysrhythmia suppression. Measures should be

taken to treat and prevent any conditions that increase myocardial irritability (e.g., metabolic acidosis). Thrombolytic agents and aspirin are contraindicated in the setting of acute trauma. In rare instances, there may be an acute MI associated with trauma, which can arise from lacerations or blunt injury to the coronary arteries. These cases should be managed by percutaneous coronary intervention (PCI), with cardiothoracic surgery for definitive repair as indicated.

In the setting of depressed cardiac output caused by suspected or confirmed myocardial contusion, judicious fluid administration to augment preload is warranted (e.g., 200 to 250 mL boluses every 15 minutes to a maximum of 1 to 2 L). A dobutamine infusion may be useful once preload has been optimized. While intra-aortic balloon counterpulsation has been used successfully in refractory cardiogenic shock, the priority is to ascertain that the decreased cardiac output is not the result of other undiagnosed traumatic injuries, particularly aortic rupture.

The prognosis of a patient with myocardial contusion depends on the character and magnitude of the initial trauma, the size and location of the contusion, the preexisting condition of the coronary arteries, and, most importantly, with the number of associated serious injuries. Recovery without complications is the usual course.

Disposition

Patients with suspected myocardial contusion who have normal serial troponin levels and a normal ECG do not have the diagnosis. Myocardial contusions resulting in ECG changes or troponin elevations necessitate telemetry observation or in-hospital monitoring, depending on the patients' other associated injuries. Markedly abnormal ECGs, troponin elevations, or hypotension warrant echocardiography and cardiology consultation.

MYOCARDIAL RUPTURE

Foundations

Background and Importance

High-speed MVCs are responsible for most cases of traumatic myocardial rupture, which is almost always fatal. Approximately one-third of these patients have multiple chamber rupture, and one-fourth have an associated ascending aortic rupture. Approximately 20% of patients survive at least 30 minutes, theoretically long enough to get them to operating room if the injury is recognized immediately and the center has the necessary cardiovascular surgical capabilities.

Anatomy and Physiology

Myocardial rupture refers to an acute traumatic perforation of the ventricles or atria, but it may also include a pericardial rupture or laceration or rupture of the interventricular septum, interatrial septum, chordae, papillary muscles, valves, and lacerated coronary arteries. A delayed rupture of the heart may also occur weeks after nonpenetrating trauma, most likely as a result of necrosis of a contused or infarcted area of myocardium.

The chambers most commonly involved in cardiac rupture are the ventricles, with right ventricular rupture being most common. Ruptures of the atria are less common, with right atrial rupture being more common than left. Multiple chamber involvement occurs in 20% of patients. Twenty percent of nonsurvivors have concomitant aortic rupture.

Pathophysiology

A rupture occurs during closure of the outflow tract when there is ventricular compression of blood-filled chambers by a pressure sufficient to tear the chamber wall, septum, or valve. This is the most likely mechanism for ventricular rupture when injury occurs in diastole or early systole concomitant with maximal ventricular distention. The atria are most susceptible to rupture by sudden compression in late systole when these chambers are maximally distended with venous blood and the atrial ventricular valves are closed. Other proposed mechanisms of rupture include: (1) deceleration shearing stresses acting on the "fixed" attachment of the inferior and superior vena cava at the right atrium; (2) upward displacement of blood and abdominal viscera from blunt abdominal injury that causes a sudden increase in intracardiac pressure; (3) direct compression of the heart between the sternum and vertebral bodies; (4) laceration from a fractured rib or sternum; and (5) complications of a myocardial contusion, necrosis, and subsequent cardiac rupture.

Because of the mechanisms involved in cardiac rupture, associated multisystem injuries are common. More than 70% of reported survivors of myocardial rupture have other major associated injuries, including pulmonary contusions, liver and spleen lacerations, closed head injuries, and major fractures.

The immediate ability of the patient to survive cardiac rupture depends on the integrity of the pericardium. Two-thirds of patients with cardiac rupture have an intact pericardium and are protected from immediate exsanguination. These patients may survive for a brief period but will then develop significant hemopericardium and pericardial tamponade. One-third of patients with cardiac rupture have associated pericardial tears and succumb promptly to exsanguination.

Clinical Features

The clinical presentation of a patient who has sustained a myocardial rupture is usually that of cardiac tamponade or severe hemorrhage. Rarely, a patient is seen with a large hemothorax, hypotension, and hypovolemia, obscuring the diagnosis by mimicking a serious pulmonary or other intrathoracic injury. A patient with an intact pericardial sac and developing tamponade displays physical findings of tamponade, usually with subsequent clinical deterioration. Initial inspection of the torso may reveal little more than a bruised area over the sternum or no external physical evidence. More often, however, signs of significant chest trauma or other associated injuries will be present, indicating a mechanism of injury that could result in myocardial rupture. Auscultation may reveal a harsh murmur, known as a *bruit de moulin,* which has been classically described as sounding like a "splashing mill wheel." This is caused by pneumopericardium.

Diagnostic Testing

Early use of ED ultrasound may facilitate the early diagnosis of cardiac rupture and pericardial tamponade. The combination of shock and JVD in a patient with blunt chest trauma should immediately suggest pericardial tamponade or tension pneumothorax, both conditions rapidly assessable by bedside ultrasound. In patients with coexistent hemorrhage from other injuries, JVD may be absent. Other considerations include myocardial contusion, superior vena cava obstruction, and ruptured tricuspid valve. Sonographic visualization of pericardial fluid in this setting should be followed by emergent thoracotomy (Fig. 37.17).

A portable chest radiograph may be helpful in patients suspected of having sustained trauma severe enough to cause myocardial rupture. Although this study usually does not help diagnose cases of myocardial rupture, it notes the presence of other intrathoracic injuries (e.g., hemothorax, pneumothorax, and signs of possible aortic dissection). An increase in the size of the cardiac silhouette more commonly reflects preexisting disease or valvular incompetence with chamber enlargement caused by increased filling pressures. ECG changes may occur with myocardial injury, but these are often nonspecific.

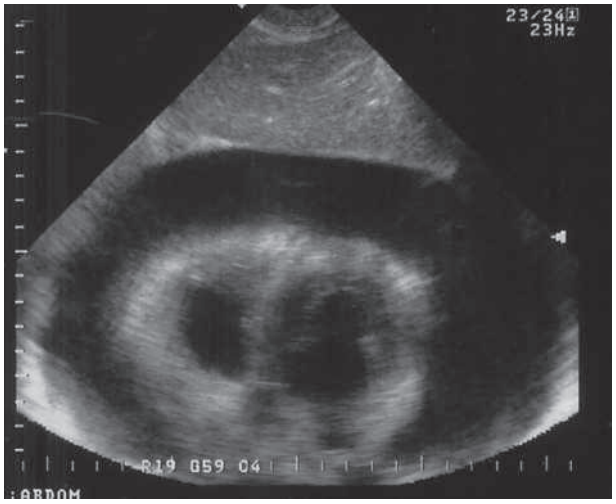

Fig. 37.17 Echocardiogram demonstrating pericardial fluid with cardiac tamponade.

Bedside echocardiography in the ED should be performed in any case of suspected cardiac rupture, pericardial tamponade, a previously undiagnosed murmur, or shock unexplained by other causes (e.g., exsanguination).

Management

When nonhospital medical personnel evaluate a patient who has sustained blunt chest trauma, they should concentrate on rapid transport and observe for any signs of pericardial tamponade. If examination is consistent with tension pneumothorax, this should be treated with needle decompression.

In the ED, treatment of patients with a myocardial rupture is directed toward immediate decompression of cardiac tamponade and control of hemorrhage. Pericardiocentesis may be effective in cases of a small rupture, but it is usually performed as a diagnostic or temporizing therapeutic procedure until surgical correction can be undertaken. Emergency thoracotomy and pericardiotomy may be required in the ED if the patient has rapidly deteriorating vital signs or a cardiac arrest. After emergency thoracotomy and pericardiotomy, the myocardial rupture should be controlled until the patient can be transported to the operating room for definitive repair. Hemorrhage from a ruptured atrium can often be controlled by finger occlusion or application of a vascular clamp. Insertion of a Foley catheter through the defect, followed by inflation of the balloon and traction on the catheter, may also help control the bleeding. Ventricular rupture can usually be controlled by direct digital pressure or by suturing with nonabsorbable vascular sutures.

Cardiopulmonary bypass is required in only 10% of successful repairs of myocardial rupture. Therefore, for patients with suspected myocardial rupture, it is appropriate to undertake emergency thoracotomy in institutions that have qualified surgeons but no immediate access to cardiopulmonary bypass.

PENETRATING CARDIAC TRAUMA

Penetrating cardiac injuries are one of the leading causes of death in the setting of urban violence. Improvements in emergency medical services, along with an emphasis on rapid transport, are responsible for an increasing number of cardiac injury patients arriving in impending or full cardiopulmonary arrest at high-volume urban trauma centers. The proportion of gunshot wounds versus stab wounds varies widely in reported case series, depending on the location of the trauma center.[20,21]

The right ventricle is affected more often than the left ventricle owing to its anterior anatomic location. One-third of penetrating cardiac wounds affect multiple chambers, and survival is much worse in these cases. In a minority of cases, a coronary artery is lacerated, although these injuries usually involve a distal segment of the artery and rarely produce significant acute MI when they are ligated. More proximal coronary artery lacerations require coronary bypass. Rarely, the interventricular septum, a valve, papillary muscle, or chordae tendineae are lacerated, producing an acute shunt or valvular insufficiency. These lesions are poorly tolerated and can quickly produce massive pulmonary edema and cardiogenic shock.

Two conditions may occur after penetrating heart injury: (1) exsanguinating hemorrhage if the cardiac lesion communicates freely with the pleural cavity, or (2) cardiac tamponade if the hemorrhage is contained within the pericardium. Patients with exsanguinating wounds frequently die before they reach medical attention, or they have rapidly progressive hemorrhagic shock on presentation, culminating in cardiac arrest. This presentation is most typically seen in patients sustaining gunshot wounds to the heart. Cardiac tamponade is a life-threatening condition but appears to offer some degree of protection and increased survival in patients with penetrating cardiac wounds. These patients often require immediate resuscitation by emergency department thoracotomy (EDT) if they meet those criteria listed in Box 37.4.

ACUTE PERICARDIAL TAMPONADE

Foundations

Background and Importance

The reported incidence of acute pericardial tamponade is approximately 2% in patients with penetrating trauma to the chest and upper abdomen; it is rarely seen after blunt chest trauma. It occurs more commonly with stab wounds than with gunshot wounds, and 60% to 80% of patients with stab wounds involving the heart develop tamponade. Patients with acute pericardial tamponade can deteriorate in minutes, but many can be saved if proper expediated steps are taken.

Pathophysiology

The primary feature of a pericardial tamponade is an increase in intrapericardial pressure and volume. As the volume of the pericardial fluid encroaches on the capacity of the atria and ventricles to fill adequately, ventricular filling is mechanically limited, and thus the stroke volume is reduced. This results in decreased cardiac output and ultimately diminished arterial systolic blood pressure and decreased pulse pressure. As little as 60 to 100 mL of pericardial blood may produce the clinical picture of tamponade. Concomitantly, CVP rises because of the mechanical backup of blood into the vena cava.

Several compensatory mechanisms then occur. The heart rate and total peripheral resistance rise in an attempt to maintain adequate cardiac output and blood pressure. A less effective compensatory response, resulting in a greater rise in CVP, is an increase in venomotor tone caused by contractions of the smooth muscles within the wall of the vena cava.

The diagnosis of pericardial tamponade should be suspected in any patient who has sustained a penetrating wound or blunt trauma to the thorax or upper abdomen. The trajectory of the bullet or the length, force, and direction of a knife thrust on initial evaluation may be difficult to ascertain. Wounds directly over the precordium and epigastrium are more likely to produce a cardiac injury resulting in tamponade than those in the posterior or lateral thorax. Nevertheless, it is assumed that a penetrating wound, particularly a gunshot wound, anywhere in the thorax or upper abdomen may have injured the heart. Rapid bedside echocardiography, performed as part of the standard e-FAST examination, easily detects a pericardial effusion causing cardiac tamponade.

BOX 37.4 Indications for Emergency Department Thoracotomy

Penetrating Traumatic Cardiac Arrest
Cardiac arrest at any point with initial signs of life in the field
Systolic blood pressure below 50 mm Hg after fluid resuscitation
Severe shock with clinical signs of cardiac tamponade

Blunt Trauma
Cardiac arrest in the emergency department (ED)

Clinical Features

Patients with cardiac tamponade may initially appear deceptively stable if the rate of bleeding into the pericardial space is slow or if the pericardial wound allows intermittent decompression. Some patients may complain primarily of difficulty breathing, which suggests pulmonary rather than cardiac pathology.

The physical findings of pericardial tamponade—hypotension, distended neck veins, and, rarely, distant or muffled heart tones (known as *Beck's triad*)—may be difficult to identify clinically, especially in the midst of a major resuscitation with concomitant hypovolemia, when the neck veins may be flat. Although the most reliable signs of pericardial tamponade are an elevated CVP (>15 cm H_2O) in association with hypotension and tachycardia, bedside echocardiography performed as part of the e-FAST examination rapidly diagnoses pericardial tamponade (by identifying pericardial fluid with concomitant tamponade physiology) and has largely replaced the use of CVP measurements to make the diagnosis. Echocardiography also distinguishes pericardial tamponade versus tension pneumothorax when the triad of elevated CVP, hypotension, and tachycardia is present.

Acute pericardial tamponade may be seen with three distinct clinical pictures. If the hemorrhage is confined to the pericardial space, the patient is initially normotensive but will have a tachycardia and elevated CVP. If untreated, most of these patients go on to develop hypotension. If significant hemorrhage has occurred outside the pericardial sac, either through a tear in the pericardium or from associated trauma, the clinical picture is that of hypovolemic shock with hypotension, tachycardia, and a low CVP. If the CVP rises to a level of 15 to 20 cm H_2O with volume replacement but hypotension and tachycardia persist, pericardial tamponade should be considered. The third clinical picture is that of an intermittently decompressing tamponade due to intermittent hemorrhage from the intrapericardial space, partially relieving the tamponade. The clinical picture may wax and wane depending on the intrapericardial pressure and volume and total blood loss. In general, this condition is compatible with a longer survival than are the first two clinical presentations.

Pulsus paradoxus is defined as an excessive drop in systolic blood pressure during the inspiratory phase of the normal respiratory cycle. This sign may be an additional clue to the presence of pericardial tamponade, but it is often difficult to measure during an intensive trauma resuscitation or in the presence of shock.

Diagnostic Testing

Radiology

Ultrasound. Ultrasound enables rapid, accurate, and noninvasive diagnosis of pericardial tamponade.[22] This study can be performed at the bedside in the ED during the initial resuscitation of the patient as part of the e-FAST examination. Although the sonographic definition of tamponade is the simultaneous presence of pericardial fluid and diastolic collapse of the right ventricle or atrium, the presence of pericardial fluid in a patient with chest trauma is highly suggestive of pericardial hemorrhage (see Fig. 37.17). An indirect sonographic sign of tamponade is the demonstration of a dilated inferior vena cava in a hypotensive patient. EDs in which cardiac ultrasonography is performed with subcostal and long parasternal views have reported a sensitivity and specificity of nearly 100% for the detection of pericardial effusion (see Chapter E3). Because ultrasound is noninvasive and extremely accurate, its immediate availability in the initial phase of major trauma resuscitation can help detect pericardial fluid before the patient deteriorates hemodynamically.

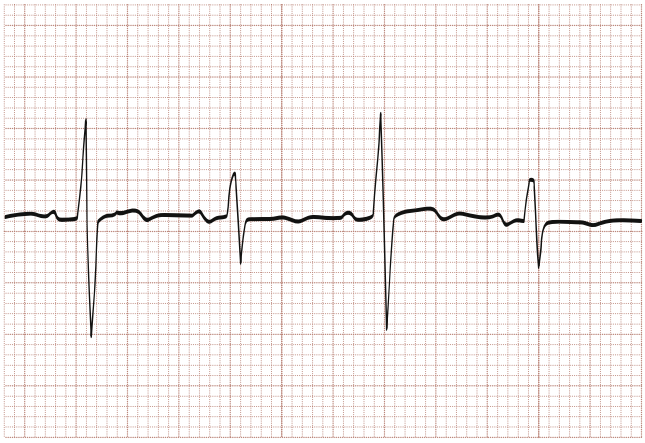

Fig. 37.18 Lewis (S5) lead electrocardiogram (ECG) revealing total electrical alternans of the QRS complexes. (From Sotolongo RP, Horton JD. Total electrical alternans in pericardial tamponade. *Am Heart J.* 101:853, 1981.)

Radiography. The radiographic evaluation of the cardiac silhouette in acute pericardial tamponade generally is not helpful, unless a traumatic pneumopericardium is present. Because small volumes of hemopericardium lead to tamponade in the acute setting, the heart will typically appear normal. This is in contrast to the "water-bottle" appearance of the heart with chronic pericardial effusion. Usually, the latter condition is tolerated for a long period of time.

Electrocardiography

Many ECG changes of pericardial tamponade have been described in the literature, but few are diagnostic, and each is more likely to be seen with chronic rather than acute tamponade. For example, electrical alternans (in which the morphology and amplitude of the P, QRS, and ST-T waves in any single lead alternate in every other beat [Fig. 37.18]) has been reported to be a highly specific marker of pericardial tamponade. The postulated cause is the mechanical oscillation of the heart in the pericardial fluid, which is called the *swinging heart phenomenon.* Echocardiographic studies have revealed that when fluid accumulates to a critical extent, the frequency of cardiac oscillation may abruptly decrease to half the heart rate. The cardiac position will alternate, with the heart returning to its original position with every other beat, and thus electrical alternans may be seen. Electrical alternans, when present, is pathognomonic for tamponade. However, it is much more common in chronic pericardial effusions that evolve into a tamponade, and it is rarely seen in acute pericardial tamponade. Notably, however, low amplitude of the QRS complexes may be seen as a result of the presence of pericardial effusion in both the acute and chronic settings.

Management

Field treatment for cases of pericardial tamponade is essentially the same as that outlined for any victim of major trauma. The diagnosis of tamponade should be suspected by the location of penetrating wounds or by the patient's poor response to vigorous volume resuscitation.

Tension pneumothorax, which is much more common, mimics certain aspects of acute pericardial tamponade. If the patient is in extremis or the clinical condition rapidly deteriorates, consideration should be given to performing a needle thoracostomy, which, if not therapeutic, suggests pericardial tamponade in the appropriate clinical presentation by virtue of a "diagnosis of exclusion." Expedient transport to the nearest trauma center should be paramount.

Upon ED arrival, volume expansion with crystalloid solution via two or three large-bore (14- or 16-gauge) catheters should be established immediately. The presence of a pneumothorax or hemothorax, which is often associated with penetrating cardiac trauma, is treated expeditiously with tube thoracostomy. Bedside echocardiography should be performed as quickly as possible to establish the diagnosis of pericardial tamponade, which then should be followed by emergent surgical repair.

There is increasing controversy regarding the role of pericardiocentesis. In the past, it was recommended that pericardiocentesis be performed for both diagnostic and therapeutic reasons. Aspiration of as little as 5 to 10 mL of blood may result in dramatic clinical improvement. However, it should be emphasized that pericardiocentesis is not a benign or invariably successful procedure. Blood in the pericardial space tends to be clotted, and aspiration may not be possible. Possible complications include the production of pericardial tamponade, the laceration of coronary artery or lung, and induction of cardiac dysrhythmias. Whenever possible, pericardiocentesis should be performed under sonographic guidance, because this approach will increase the success rate and decrease the incidence of complications. A pigtail catheter may be introduced into the pericardial space for repeated aspirations while preparations are underway to quickly transport the patient to the operating room for definitive management. If pericardiocentesis is unsuccessful or the clinical status deteriorates, and if acute pericardial tamponade remains important in the differential diagnosis, thoracotomy should be performed as quickly as possible.[23] Patients with penetrating cardiac injury invariably require surgical repair. The location (operating room vs. ED) and timing (immediate vs. urgent) depends on the patient's clinical status.

Emergency Department Thoracotomy

EDT is a drastic, dramatic, and potentially lifesaving procedure in which emergency clinicians should be proficient. Although the procedure is not described in detail here, a few technical points merit further description (see Chapter 32). A left lateral incision is preferred because it is rapidly accomplished; allows the best exposure of the heart, aorta, and left hilum; and facilitates open cardiac massage and internal defibrillation (Fig. 37.19). With right-sided or multiple injuries, it may be necessary to extend the incision across the sternum and right chest wall, creating a "clamshell" incision. The internal mammary arteries need to be ligated if this maneuver restores effective perfusion. After the heart is sufficiently exposed, the pericardium is vertically incised anterior to the phrenic nerve. Release of a tamponade may rapidly restore cardiac output. The heart is then delivered through the pericardium, and penetrating wounds are identified.

There are several alternatives for repairing cardiac wounds. Small wounds can be compressed by digital pressure to control bleeding en route to the operating room. If the injury is large, balloon tamponade can be achieved by applying gentle traction on a Foley catheter inserted into the wound with the balloon inflated with saline. This can temporarily stop the hemorrhage to allow suture repair of the injury (cardiorrhaphy) or to gain time while the patient is transferred to the operating room for a more definitive surgical procedure. Lacerations of the atria can be temporarily controlled with a vascular clamp.

Suture of cardiac wounds over pledgets is the time-honored and effective technique but is technically more difficult and time-consuming. The use of a monofilament suture, such as 2-0 Prolene, is recommended. Some trauma surgeons recommend stapling cardiac wounds with standard skin staplers because this technique may be much quicker and equally effective in closing these wounds.

Fig. 37.19 Emergency Department Thoracotomy.

Care is taken to avoid ligating coronary arteries during the repair. Direct insertion of a large-bore catheter (e.g., a 5-French catheter) into the left atrial appendage provides a route for rapid infusion of fluids. If the heart is empty or the patient fails to respond to rapid fluid administration, the aorta is then cross-clamped to divert cardiac output to the brain and heart. Prolonged ischemia and severe acidosis often result in post-resuscitation myocardial depression with ineffective contraction and diminished cardiac output. Thus, the cross-clamp should be temporarily released every 30 to 45 minutes to minimize ischemic complications.

Indications for emergency department thoracotomy. Although it is tempting to perform "life-saving" EDT on all traumatic arrest victims in the ED, there are many cases in which patients have virtually no chance of survival. In addition, EDT is costly; requires the undivided attention of all personnel in the ED, diverting care from other, more salvageable patients in critical condition; and poses a risk to ED personnel for injury from needle sticks and other blood-contaminated exposures.

Evidence-based guidelines from the Eastern Association for the Surgery of Trauma recommend that EDT be performed on patients who lose pulses but who initially presented to the ED with signs of life after *penetrating* thoracic trauma (see Box 37.4). They conditionally recommend EDT for both patients who present to the ED without signs of life after *penetrating* thoracic trauma and patients who present to the ED with signs of life after *blunt* injury, and recommend against EDT in patients who sustain *blunt* injury and present to the ED pulseless.[23] It is worth emphasizing that EDT is a temporizing measure and should only be performed if definitive operative treatment is a viable option in the setting to which the patient presents.

BLUNT AORTIC INJURY

Foundation

Background and Importance

Blunt aortic injury is a life-threatening injury, usually resulting from sudden deceleration, frequently from MVCs. Other mechanisms of injury include high-velocity blunt trauma such as pedestrians struck by automobiles, motorcycle crashes, airplane crashes, and falls from heights. Despite the improvement in and increased use of restraint systems, the overall incidence of blunt aortic injury associated with fatal automobile crashes has remained unchanged over the past decade.

Blunt aortic injury includes a spectrum of lesions, ranging from a small intimal tear to frank rupture, which usually causes rapid lethal hemorrhage. The most common sites of injury are the aortic isthmus and the ascending aorta just proximal to the origin of the brachiocephalic vessels. Sixty percent to 90% of patients with blunt aortic injury die at the site of accident or within hours of hospital admission. However, an increasing number of patients arrive at a treatment facility because of improvements in out-of-hospital care, timely resuscitation in the field, and rapid transportation to a trauma center. The early survival rate of such patients depends on the initial resuscitation or the timeliness and correct choice of diagnostic procedures. A rapid and accurate diagnosis is thus mandatory to optimize treatment and maximize odds of survival.

Pathophysiology

The descending thoracic aorta is relatively fixed and immobile because of its tethering by intercostal arteries and the ligamentum arteriosum. With sudden deceleration, the more mobile aortic arch swings forward, producing a shearing force or "whiplash effect" on the aorta at the isthmus. A bending stress at the isthmus, created by sudden lateral oblique chest compression, may also result in rupture by causing flexion of the aortic arch on the left mainstem bronchus and the pulmonary artery. Forces created by the whiplash effect or lateral oblique compression may not be sufficient to provoke aortic tears. It is now postulated that those injuries may be caused by inferior and posterior rotation of anterior thoracic osseous structures (manubrium, first rib, and medial clavicles), pinching and shearing the interposed aorta as they strike the vertebral column.

Rupture of the ascending aorta just distal to the aortic valve likely occurs through a different mechanism. At the time of rapid deceleration and chest compression, the heart is displaced into the left posterior chest, which causes a shearing stress just above the aortic valve. A sudden increase in intra-aortic pressure, "the water hammer effect," may cause an explosive rupture of the aorta at this location. Involvement of the coronary ostia with coronary artery occlusion may occur in association with tears to the ascending arch. The intraluminal pressure tolerance of the aorta may be exceeded in a high-speed MVC.

A total of 80% to 90% of aortic tears occur in the descending aorta at the isthmus, just distal to the left subclavian artery (Fig. 37.20). Less common sites of involvement are the ascending aorta, the distal descending aorta at the level of the diaphragm, the midthoracic descending aorta, and the origin of the left subclavian artery. Although ruptures of the ascending aorta are much less common than those of the descending aorta, they have a 70% to 80% incidence of associated lethal cardiac injuries. This is in contrast to ruptures at the isthmus, which have a 25% incidence of associated cardiac injuries. Lethal cardiac injuries commonly include pericardial tamponade, aortic valve tears, myocardial contusion, or coronary artery injuries. Passenger ejection, pedestrian impact, severe falls, and crush injuries commonly result in ascending thoracic aortic ruptures. Survival long enough to be evaluated in the ED is rare among patients who sustain an ascending aortic rupture.

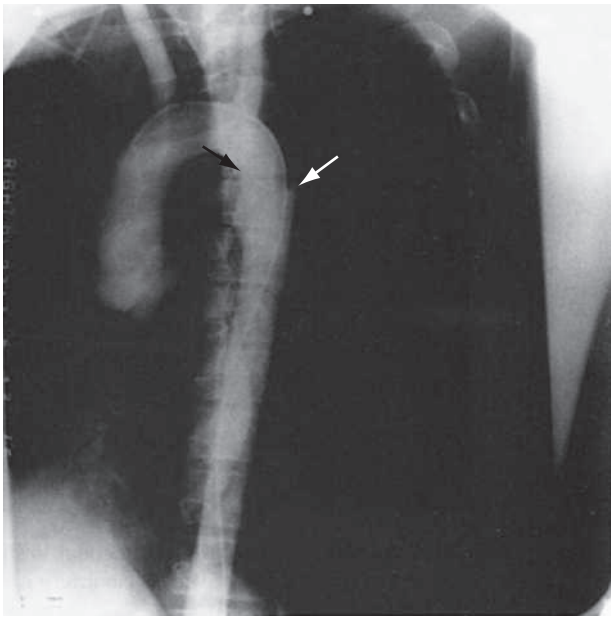

Fig. 37.20 Aortogram shows tear in aorta *(arrows)* at the most common location, at or just distal to takeoff point of left subclavian artery, which is not visualized.

Aortic rupture may occur from causes other than high-speed MVC deceleration. Rupture has been documented as a complication of external cardiac massage and has been known to occur after fracture-dislocations of the thoracic spine, presumably as a result of direct shearing force. Vertical deceleration injuries resulting from falls can cause a rupture of the ascending aorta by producing an acute lengthening of the ascending aorta. This is the likely mechanism responsible for aortic rupture in the setting of airplane and elevator accidents. Direct kicks by animals, crush injuries, sudden burial by landslide, and air bag deployment have also been reported as causes of aortic rupture. Direct compression of the compliant thorax has been postulated to contribute to aortic rupture in children. Displaced fractures of the sternum, ribs, and clavicle have also been shown to directly lacerate the aorta.

Clinical Features

The possibility of aortic disruption should be considered in every patient who sustains a severe deceleration injury, because approximately 30% of surviving patients with blunt aortic injury will die within the first 24 hours without treatment. This is especially true if the automobile was moving in excess of 45 mph or if there is evidence of severe blunt force to the chest (e.g., from a damaged steering wheel). In the case of any moderate- or high-speed MVC, it is imperative that paramedics carefully evaluate the extent of damage to the vehicle, the presentation of the victims, and the physical manifestations of blunt chest trauma. This information should be promptly relayed to the emergency clinician.

Despite the severe nature of the injury, the clinical manifestations of an aortic rupture are often subtle and deceptive. Associated pulmonary, neurologic, orthopedic, facial, and abdominal injuries are commonly present. Coexisting injuries can mask the signs and symptoms of an aortic injury or divert the clinician's attention away from the more lethal aortic rupture. The absence of any external evidence of a chest injury does not eliminate the possibility of an aortic tear. One-third to one-half of patients reported in the literature have no external signs of chest trauma.

The most common symptom is interscapular or retrosternal pain. It is often found in nontraumatic aortic dissection but is present in only

25% of patients with a traumatic aortic disruption. Other symptoms described in the literature but uncommonly present include dyspnea resulting from tracheal compression and deviation, stridor or hoarseness caused by compression of the laryngeal nerve, dysphagia caused by esophageal compression, and extremity pain caused by ischemia from decreased arterial flow.

Clinical signs are uncommon and nonspecific. Generalized hypertension, when present, may be an important clinical sign. Sympathetic afferent nerve fibers, located in the area of the aortic isthmus, are capable of causing reflex hypertension as a response to a stretching stimulus. The presence of a harsh systolic murmur over the precordium or posterior interscapular area may be auscultated in up to one-third of patients. The murmur is thought to result from the turbulent flow across the area of transection. A less commonly encountered physical finding is a swelling at the base of the neck caused by the extravasation of blood from the mediastinum, which results in an increased neck circumference or a pulsatile neck mass. Other clinical signs suggestive of aortic rupture include lower extremity pulse deficit and lower extremity paralysis. Initial chest tube placement output in excess of 750 mL is also suggestive of aortic rupture, especially if the hemothorax is left sided. However, the physical examination is neither sensitive nor specific for aortic injury.

Diagnostic Testing

Chest Radiography

Radiography of the chest can be a valuable tool when aortic rupture is suspected. An increase in the width of the superior mediastinum is the most sensitive sign and is found in the majority of aortic ruptures (Fig. 37.21).

However, specificity of this radiologic sign may be as low as 10%; mediastinal widening may be caused by venous bleeding from a clavicle, thoracic spine, or sternal fracture; or pulmonary contusions, a previous mediastinal mass, a misplaced CVP catheter, or magnification caused by the anteroposterior and supine position of a portable chest radiograph. Hence the sign is not pathognomonic for aortic rupture. Every effort should be made to obtain a standard upright inspiratory posteroanterior film, if clinically feasible, before a mediastinum is declared abnormal, to avoid false-positive interpretations. However, although mediastinal widening may be indicative of aortic rupture, its absence does not preclude the injury. Up to nearly half of patients with blunt aortic injury may have a normal mediastinum on chest radiography.[24] Given this, we recommend the use of chest CT scanning in patients with suspected aortic rupture, regardless of the chest x-ray findings.[24]

Chest Computed Tomography Scan

Chest CT scanning is the gold standard test for blunt aortic injury and has replaced aortography as the diagnostic test of choice. CT scans have almost 100% sensitivity and specificity for rapidly detecting aortic injury while requiring only IV contrast administration (Figs. 37.22 and 37.23). A normal aortic contour on CT, even in the presence of a mediastinal hematoma, has been shown to be highly accurate in excluding thoracic aortic disruption (Figs. 37.24 and 37.25).[24]

As a result of the improvements in CT scanning technology, more subtle aortic lesions are now being identified, which has led to the term "minimal aortic injury." A minimal aortic injury is defined as an aortic injury with an intimal flap less than 1 cm, and no or minimal periaortic mediastinal hematoma. Up to 10% of patients with blunt aortic injury diagnosed on CT scan may have a minimal aortic injury.[24] It is felt that minimal aortic injuries carry a relatively low risk of rupture, and we recommend following these patients with serial CT scans. If the injury is associated with significant thrombus, periaortic hematoma, lumen encroachment, or pseudoaneurysm, the patient can be treated via endograft.

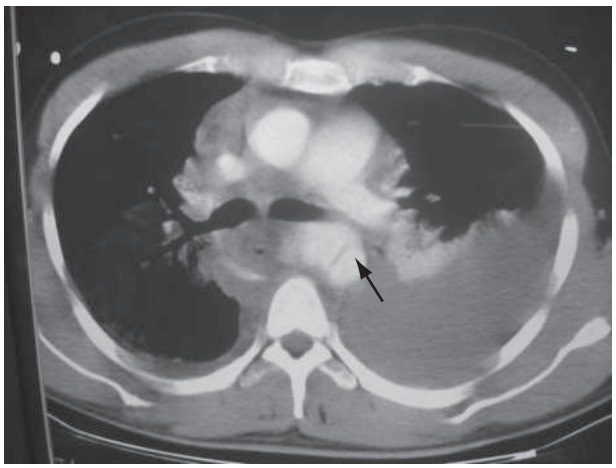

Fig. 37.23 Chest computed tomography (CT) scan demonstrating periaortic hemorrhage and an intimal flap *(arrow)*.

Management

Stabilization and Empirical Therapy

Due to the risk of sudden rupture and exsanguination, repair of the aortic injury should be performed as soon as the diagnosis is made. Management of the patient with multiple injuries who has documented

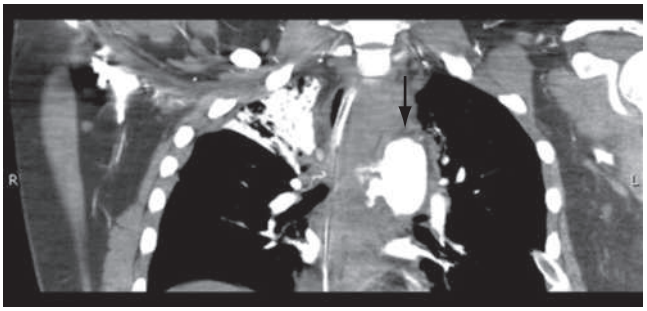

Fig. 37.24 Chest computed tomography (CT) scan showing aortic injury with active extravasation *(arrow).*

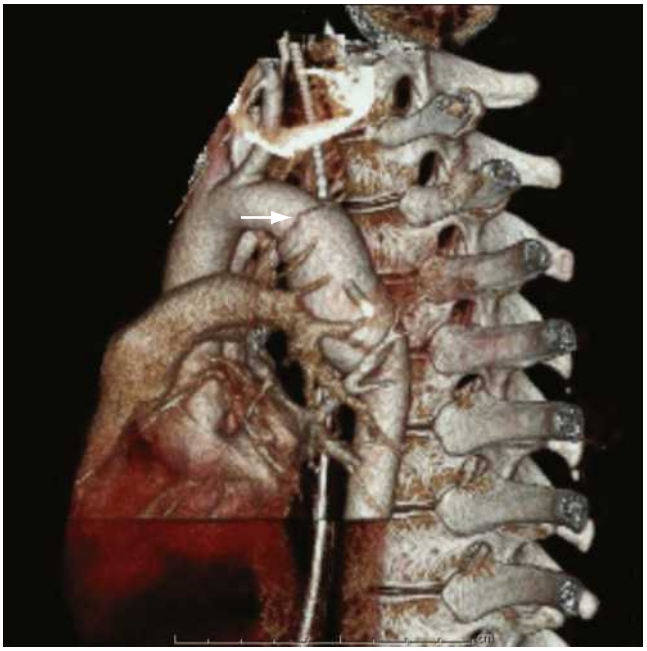

Fig. 37.25 Three-dimensional reconstruction of chest computed tomography (CT) scan showing aortic injury *(arrow).*

rupture of the thoracic aorta depends on the nature of associated injuries. Endovascular or surgical repair of the aortic rupture should be delayed in the presence of life-threatening intracranial or intra-abdominal injury or profuse retroperitoneal hemorrhage.[24] Consideration for delay of the procedure should be made for patients at high risk for infection (e.g., those who have extensive body surface burns, contaminated large open wounds, established sepsis, or severe respiratory insufficiency caused by thoracic trauma).

Careful regulation of blood pressure is mandatory until definitive surgical repair can be performed. If operative repair is delayed, the systolic blood pressure should be maintained between 100 and 120 mm Hg. The objective of lowering the blood pressure is to decrease the shearing jet effect of an elevated pulse pressure, thus decreasing the possibility of continued adventitial dissection and subsequent free rupture.

Esmolol, a short-acting titratable beta-blocker, is ideally suited for this purpose. Esmolol can be initiated with an intravenous bolus of 0.5 mg/kg over 1 minute, followed by an infusion of 0.05 mg/kg/min (titrated upward in 0.05 mg/kg/min increments to a maximum of 0.3 mg/kg/min). If blood pressure is not adequately controlled, nicardipine or clevidipine can be added as second agents.

Definitive Management

Many surgical techniques have been described since the first successful repair by Passaro and Pace in 1959. The pathologic condition found dictates the type of repair, and a synthetic graft is often required because of extensive tension on the vessel walls or jagged torn ends of the vessel. However, open repair can have associated complications of stroke, paraplegia, and renal failure due to aortic clamp time.

Endovascular repair. A number of studies indicate that success and complication rates are likely better than those of traditional open surgical repairs and that the risk of major surgery and subsequent paraplegia from prolonged aortic clamping is significantly reduced with endovascular repair. Current guidelines recommend endovascular treatment for patients without contraindications.[24]

ESOPHAGEAL PERFORATION

Foundations

Background and Importance

The classic description of esophageal perforation resulting from forceful vomiting was published in 1724 by Boerhaave, and from 1724 to 1941, the occurrence of Boerhaave syndrome was almost uniformly fatal. In 1941 the first successful surgical treatment, a drainage procedure, was reported, and in 1947 the first successful closure of a ruptured esophagus was described. Since then, improved surgical techniques, greater physician awareness leading to a prompt diagnosis, the availability of more effective antibiotics, and better supportive measures have reduced the mortality to approximately 20%. Mortality data cited for perforation are affected by several variables, such as location (with perforations of the thoracic segment having the highest mortality rate), mechanism of injury, time elapsed between injury and diagnosis, the presence of preexisting esophageal disease, and general health of the patient.

Pathophysiology

The anatomic feature responsible for the prolonged morbidity and high mortality associated with esophageal perforation is the lack of an esophageal serosal covering that allows perforation at any level with direct access to the mediastinum. Perforations in the upper or cervical esophagus enter the retropharyngeal space, where fascial planes extend from the base of the skull to the bifurcation of the trachea. Perforations in the midesophagus and lower esophagus enter directly into the mediastinum. Only the thin mediastinal pleura prevents free access to the entire pleural cavity, and this barrier is commonly overcome by continued drainage and the massive exudative inflammatory reaction induced by chemical and bacterial mediastinitis. When mediastinal pleura are penetrated, the negative pressure generated by respiratory efforts tends to increase contamination by promoting drainage from the gastrointestinal tract into the mediastinum and pleural space.

When esophageal rupture results from forceful emesis, as in cases of Boerhaave syndrome, the intrinsic weakness of the left posterior distal esophagus is important. Other areas (including cervical, midthoracic, and infradiaphragmatic sites) have been reported only rarely to rupture secondary to emesis. In addition, the esophagus has three areas of anatomic narrowing: (1) the cricopharyngeal muscle near the esophageal introitus, (2) the level at which the esophagus crosses the left mainstem bronchus and the aortic arch, and (3) the gastroesophageal junction. In the absence of a preexisting esophageal disease (such as carcinoma), it is unusual for a perforation caused by a foreign body to occur anywhere other than at these three sites. Foreign bodies may cause perforation by direct penetration, pressure, or chemical necrosis.

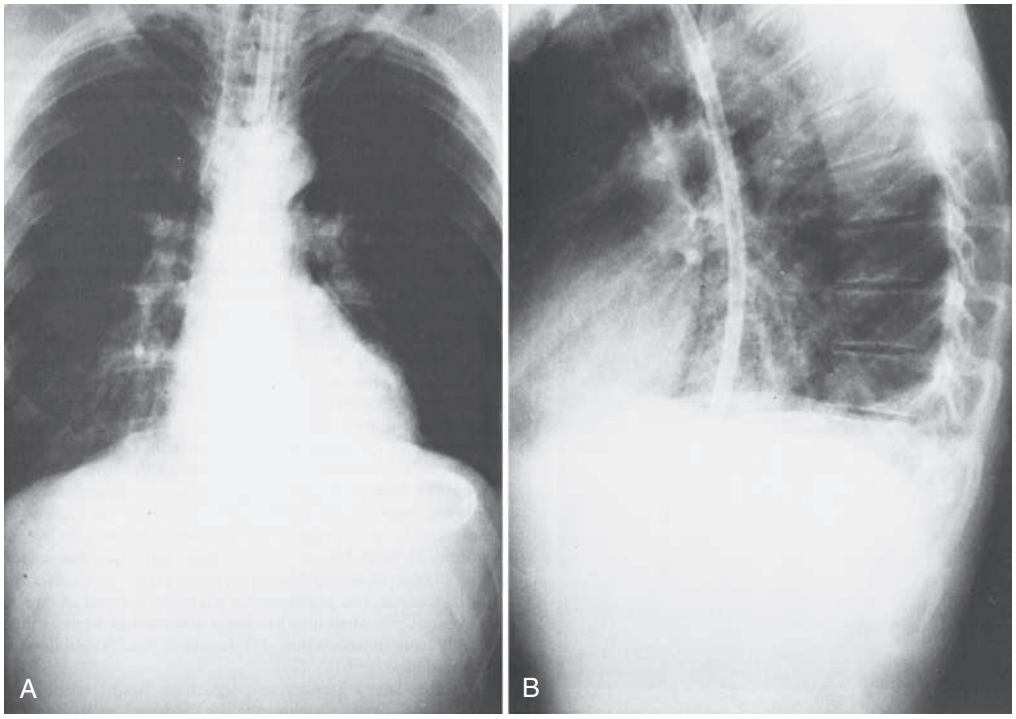

Fig. 37.26 (A) Chest radiograph of a 36-year-old man with acute onset of pleuritic chest pain after forceful vomiting. (B) Chest radiograph shows mediastinal and subcutaneous air typical of ruptured esophagus. Mediastinum is not yet widened, and there is no soilage of the pleural cavity.

Clinical Features

The most reliable symptom of an esophageal injury is pleuritic pain localized along the course of the esophagus that is exacerbated by swallowing or neck flexion (Fig. 37.26). Pain may be located in the epigastrium, substernal area, or back; usually worsens over time and tends to migrate from the upper abdomen to the chest. As the infectious process worsens, dyspnea usually ensues.

The early physical signs of an esophageal perforation are sparse. As air and caustic contaminated material move through the esophageal tear into the mediastinum and pleural space, and before any subcutaneous air is palpable at the root of the neck, the mediastinal air may impart a nasal quality to the voice. Mediastinal air may surround the heart and produce a systolic crunching sound (*Hamman's crunch*). As air and fluid move into the pleural space, signs of a hydropneumothorax or an empyema may develop. Eventually the air travels into the subcutaneous tissues, dissecting into the neck, where subcutaneous emphysema may first become evident. This classic sign is present in only approximately 60% of patients, however, and in the absence of a tracheal injury, it may occur in only 30%. The most common causes of an esophageal perforation are listed in Box 37.5.

Iatrogenic

Most esophageal perforations are iatrogenic, most commonly as a complication of instrumentation. The rigid endoscope is the most common offender, particularly when general anesthesia is used. Although use of the flexible endoscope has made this complication less likely, the total number of perforations has increased as more procedures are performed. Injuries tend to occur near the cervical esophagus as the endoscope is inserted. Endoscopic procedures that are too vigorous in the presence of a corrosive burn or carcinoma are also a common cause of iatrogenic esophageal injury. In the ED, nasotracheal or nasogastric intubations are the most common causes of iatrogenic perforation, with the perforation usually occurring in the pyriform sinus.

BOX 37.5 Most Common Causes of Esophageal Perforation

- Iatrogenic
- Foreign bodies
- Caustic burns
- Blunt or penetrating trauma
- Spontaneous rupture (post emetic or Boerhaave syndrome)
- Postoperative breakdown of anastomosis

Historically, the use of an esophageal obturator airway was also associated with occasional esophageal trauma, specifically midesophageal perforation. Use of newly designed esophageal obturator airways such as the laryngotracheal Combitube and the King airway, do not seem to be associated with trauma other than occasional esophageal abrasions or contusions.

Foreign Bodies

Foreign bodies can cause an esophageal injury by direct laceration, by pressure necrosis, or during endoscopic removal. Small perforations tend to seal without sequelae, but pressure necrosis or lacerating injuries provide ample access to the mediastinum. Foreign bodies usually lodge in the cervical esophagus. In children younger than 4 years old, the cricopharyngeal narrowing is the usual point of foreign body impaction. After 4 years old, most objects pass this region and traverse the remaining normal esophagus. In adults, a foreign body impaction, especially in cases of repeated episodes, raises the possibility of a stricture and warrants further diagnostic evaluation.

Caustic Burns

Caustic burns of the esophagus occur from intentional or accidental ingestion of acid or alkali. There are two peaks of incidence: (1) from 1 to 5 years old, which is when ingestion is accidental and with a small

amount of material, and (2) in the teens and 20s, when larger quantities are ingested during attempts of self-harm. Symptoms include hematemesis, respiratory distress, vomiting, drooling, or the presence of oropharyngeal lesions on physical examination.

The liquefaction necrosis classically resulting from strong alkali burns (pH >12) is more likely to cause esophageal perforation than the coagulation necrosis resulting from strong acid burns (pH <2). Individuals ingesting alkali substances with a pH less than 11.5 rarely sustain injuries more serious than superficial mucosal burns. Acid ingestions tend to cause damage more frequently in the stomach than in the esophagus.

Endoscopy within the first 6 to 18 hours may be used to determine the extent of the injury and guide therapy. Although admission after significant ingestion is the rule, some authors suggest that in the setting of accidental ingestion in children and in the absence of symptoms, endoscopy and admission may not be indicated. Esophagoscopy is commonly undertaken to ascertain the presence or absence of esophageal injury. Advancing the esophagoscope beyond the first burn in the esophagus increases the risk of perforation and is a common iatrogenic cause of esophageal perforation.

Penetrating and Blunt Trauma

Because of its well-protected position posteriorly, esophageal trauma is rare and usually not an isolated injury. Cervical esophageal injuries are the most common because of a lack of protection by the bony thorax, and the trachea is the most common associated site of injury. In some cases, the esophageal injury may be overlooked initially because of the dramatic presentation of a patient with a tracheal injury.

Typical symptoms seen in cervical esophageal injuries include neck pain, dysphagia, cough, voice changes, and hematemesis. Physical exam findings may include neck tenderness, resistance to flexion, crepitus, or stridor. In one large series, the most common life-threatening issue in the ED was compromise of the airway. Most of these cases were handled with rapid sequence intubation, but a significant number (12%) of patients required cricothyroidotomy.

If the patient's condition is stable, a preoperative esophagogram with a water-soluble agent should precede any endoscopy. Although chest and neck radiographs and CT scan also may be used to diagnose this injury, emergent bedside flexible endoscopy seems to be the diagnostic test of choice to confirm negative findings on esophagography (especially in the setting of penetrating trauma). Operative repair is indicated in most of these injuries (>90%) and should be done as quickly as possible to avoid the development of fistulae, mediastinitis, or abscess formation.

Spontaneous Rupture

Spontaneous esophageal rupture, post-emetic rupture, and Boerhaave syndrome are synonymous terms. This esophageal injury is associated with a poor prognosis because the forces required to rupture the esophagus result in almost instantaneous and massive mediastinal contamination. The distal esophagus is the usual site of injury, with a longitudinal tear occurring in the left posterolateral aspect. More than 80% of these injuries occur in middle-aged men who have ingested alcohol and large meals. Increases in intra-abdominal pressure resulting from blunt trauma, seizures, childbirth, laughing, straining at stool, and heavy lifting have also all been reported to cause this injury.

Diagnostic Testing

The diagnosis of esophageal perforation is aided by consideration of clinical circumstances. In patients with classic Boerhaave syndrome, emesis is followed by severe chest pain, subcutaneous emphysema, and cardiopulmonary collapse. Development of these signs and symptoms after instrumentation of the esophagus or removal of an esophageal foreign body is relatively straightforward. One-third of cases of perforated esophagus are atypical, however. A careful history and physical examination supplemented by appropriate imaging studies enable the clinician to diagnose a subtle case at an early stage. In considering any of the diagnoses listed in Box 37.6, a perforated esophagus should also be considered.

BOX 37.6 Clinical Conditions That May Mimic Esophageal Perforation

Spontaneous pneumomediastinum
Aortic aneurysm (thoracic)
Pulmonary embolus
Perforated peptic ulcer
Myocardial infarction (MI)
Pancreatitis
Mesenteric thrombosis
Cholecystitis
Pneumonia

Fig. 37.27 Lateral view of the cervical spine revealing air in the retropharyngeal area *(arrow)*.

Radiology

The radiographic examination usually suggests the diagnosis of an esophageal perforation. The classic chest radiograph findings are mediastinal air (with or without subcutaneous emphysema), left-sided pleural effusion, pneumothorax, and widened mediastinum. Lateral views of the cervical spine may reveal air or fluid in the retropharyngeal area that is characteristic of a cervical esophageal perforation but also is found when perforations in the lower parts of the esophagus release air or fluid that dissects superiorly (Fig. 37.27). Water soluble diatrizoate meglumine (Gastrografin) is preferred for visualization in cases of suspected esophageal perforation. It does not obscure visualization during

subsequent endoscopy, and it produces less mediastinal contamination than barium. Then, if no leak is found, this can be followed by a barium study to better define the mucosal detail.

Endoscopy

Endoscopy, similar to contrast studies, is not an infallible aid in establishing the presence or absence of an esophageal perforation. The size and location of the perforation and the skill of the endoscopist are important factors in the low incidence of false-negative studies. If the accuracy of the endoscopy is in doubt, an esophagogram should be performed. Helical CT with dilute oral contrast has been reported as a safer, faster, and less personnel-intensive diagnostic examination. Some of the abnormalities that may be seen on CT scan include extraluminal air, periesophageal fluid, esophageal thickening, and extraluminal contrast. These CT findings may be the first clue to establishing the diagnosis of esophageal perforation.

Management

Early diagnosis can best be accomplished if one is cognizant of the pathophysiology and clinical settings in which esophageal perforations occur. Time is crucial in minimizing the mortality and morbidity of this condition. If the diagnosis is strongly suggested or confirmed, management should include broad-spectrum antibiotics (covering oral flora, as well as antifungal coverage in certain immunocompromised patients), volume replacement, and airway maintenance. An emergency surgical consultation should be obtained because prognosis worsens as time passes, with mortality almost doubling in the first 12 hours.

Although operative therapy is standard, nonoperative therapy is an option for patients with well-contained perforations, with minimal mediastinal involvement, and without evidence of sepsis. In such cases, the patient is placed on *nil per os* (NPO) status for at least 72 hours, broad-spectrum antibiotics are initiated, along with total parenteral nutrition management as indicated. The use of nasogastric tubes should be discouraged because they may increase gastroesophageal reflux and worsen the contamination of the mediastinum.

CHAPTER 37: QUESTIONS AND ANSWERS

1. An 18-year-old man presents after a motor vehicle collision (MVC) in which he was ejected from the vehicle. The paramedics have been administering bag-valve-mask ventilation en route because of respiratory distress and now report increased resistance with ventilations. The patient has decreased breath sounds on the left. His blood pressure is 80/40 mm Hg, and his pulse is 145 beats per minute. His respirations are agonal, with a rate of 5 breaths per minute. Which of the following is the most appropriate next step in the management of this patient?

a. Anteroposterior chest radiograph
b. Emergency department thoracotomy (EDT)
c. Endotracheal intubation
d. Needle decompression
e. Tube thoracostomy

Answer: d. This clinical scenario depicts a patient with a tension pneumothorax. He has decreased blood pressure, decreased breath sounds, and, most important, an increased resistance to ventilation, which is the earliest sign of the development of a tension pneumothorax. Immediate decompression with a large-bore needle is the correct initial management in this condition.

2. Which of the following is the most sensitive electrocardiogram (ECG) manifestation of myocardial contusion?

a. Biphasic T wave
b. Left bundle branch block
c. Right bundle branch block
d. Sinus tachycardia
e. Transient ST segment elevation

Answer: d. Sinus tachycardia is present in approximately 70% of patients with documented myocardial contusion and is the most sensitive sign for this condition. It is, however, also the least specific.

3. A patient presenting with blunt thoracic trauma complains of shortness of breath and chest pain. On physical examination, he is tachypneic with chest wall bruising and moist rales on the right side on auscultation. Which of the following is the *least* likely finding?
- **a.** Consolidation within 6 hours of injury
- **b.** Diffuse patchy alveolar infiltrates on chest radiograph in 24 hours
- **c.** Low partial arterial pressure of oxygen (Pao_2) on arterial blood gas sampling
- **d.** Patchy alveolar infiltrate on chest radiograph within minutes of injury
- **e.** Rib fractures

Answer: b. This patient has physical findings consistent with pulmonary contusion. All answers are correct except B. Delayed onset of diffuse alveolar infiltrates is more consistent with acute respiratory disease syndrome (ARDS). The development of ARDS is diffuse and usually delayed, with onset typically between 24 and 72 hours after injury.

4. A 55-year-old man complains of chest wall pain after a high-speed motor vehicle collision (MVC). He has ecchymosis of the left lateral chest wall. You notice that there is outward movement of the left lateral chest wall on expiration. Which of the following statements regarding this patient's problem is *not true*?
- **a.** Chest radiograph likely demonstrates parenchymal contusions.
- **b.** Intubation splints the chest wall internally.
- **c.** Multiple rib fractures are likely.
- **d.** Positioning of patient with injured side down improves symptoms.
- **e.** The cornerstone of treatment is pulmonary physiotherapy.

Answer: d. This patient has a flail chest. Out-of-hospital or emergency department (ED) stabilization of the flail segment, by positioning the person with the injured side down or placing a sandbag on the affected segments, has been abandoned. Endotracheal intubation and positive-pressure ventilation will internally splint the chest wall, making the flail segment difficult to detect on physical examination. The cornerstones of therapy include pulmonary physiotherapy, effective analgesia, selective use of endotracheal intubation and mechanical ventilation, and close observation for respiratory compromise.

5. A 50-year-old woman is brought in by emergency medical services on a backboard after a motor vehicle collision (MVC), complaining of shortness of breath. She has decreased breath sounds on the right side of the chest. A chest tube is placed, with a return of 200 mL of blood in the first hour, 200 mL in the second hour, and 350 mL in the third hour. What is the next step in the management of this patient?
- **a.** Check coagulation profile
- **b.** Conservative management and transfusion as needed
- **c.** Emergency thoracotomy
- **d.** External fixation of rib fractures
- **e.** Insertion of a second thoracostomy tube

Answer: c. Immediate drainage of more than 1500 mL of blood from the pleural cavity is usually considered an indication for urgent thoracotomy. Perhaps even more predictive of the need for thoracotomy is a continued output of at least 200 mL/h for 3 hours.

6. A 37-year-old man presents with chest pain after a motor vehicle collision (MVC). He states that his chest hit the steering wheel. On initial evaluation, the patient is without fractures of the ribs or sternum, but there is a small chest wall contusion. The initial chest radiograph is negative, and the electrocardiogram (ECG) shows nonspecific ST-T wave changes. What is the next step in the emergency management of this patient?
- **a.** Admit to telemetry for 23-hour observation
- **b.** Discharge home after repeat ECG and troponin at 6 hours
- **c.** Discharge home after repeat ECG in 1 hour
- **d.** Discharge home if echocardiogram is negative
- **e.** Discharge home if initial troponin is negative

Answer: b. In patients who have minor injuries and are otherwise asymptomatic, elevated troponin levels and minor ECG abnormalities do not necessarily indicate a clinically significant myocardial contusion. Very few of these patients will develop complications. However, normal troponin level (4 to 6 hours after injury), along with normal (or unchanged) ECGs, correlate with minimal risk of cardiac complications. Echocardiography is rarely required in this low-risk subset of patients who have minor injuries and are otherwise asymptomatic.

7. A 30-year-old woman presents intubated by emergency medical services on a backboard with C-spine immobilization. She was found unresponsive and hypotensive after a front-end collision. She was the driver of the vehicle and unbelted. Despite fluid resuscitation, the patient continues to be tachycardic and hypotensive. On physical examination, you note jugular venous distention (JVD) and a harsh murmur that sounds like a splashing mill wheel. An electrocardiogram (ECG) reveals electrical alternans. Which of the following statements is true regarding the patient's underlying problem?
- **a.** Echocardiogram will reveal diastolic collapse of the right ventricle and fluid in the pericardium.
- **b.** Focused assessment with sonography in trauma (FAST) will demonstrate echogenicity in Morrison's pouch.
- **c.** Patchy consolidation will be seen on chest radiograph.
- **d.** Pericardiocentesis is not indicated.
- **e.** She will have a negative focused abdominal sonogram.

Answer: A. Early use of emergency department (ED) ultrasonography may facilitate the early diagnosis of cardiac rupture and pericardial tamponade. The combination of shock and JVD (or an elevated central venous pressure [CVP]) in a patient with blunt chest trauma should immediately suggest pericardial tamponade.

38

Abdominal Trauma

Megan L. Rischall and Michael A. Puskarich

KEY CONCEPTS

- The accuracy of a physical examination is limited in cases of abdominal trauma. It is rendered less reliable by distracting injury, altered sensorium (e.g., head trauma, alcohol or drug intoxication, developmental delay, psychiatric illness), and spinal cord injury.
- Stab and gunshot wounds frequently violate the lung parenchyma, diaphragm, mediastinum, intraperitoneal cavity, and retroperitoneum in some combination.
- Physical examination with extended focused assessment with sonography for trauma (e-FAST), followed by computed tomography (CT) scan when indicated, provides accurate diagnosis for the majority of blunt and penetrating abdominal trauma patients.
- Emergent laparotomy is indicated for patients sustaining a stab wound in the setting of hemodynamic compromise, peritoneal signs, evisceration, or left-sided diaphragmatic injury. Patients not meeting these criteria should undergo a combination of e-FAST, local wound exploration (LWE), CT scan, and serial examination, depending on the location of the wound
- Emergent laparotomy is indicated for patients sustaining a gunshot wound in the setting of hemodynamic compromise, peritoneal signs or evisceration. Patients not meeting these criteria should undergo a combination of e-FAST, CT scan, and serial examination, then proceed to laparotomy or admission for observation pending those results.
- The critical determinant in hemodynamically unstable patients with pelvic fracture is the existence of active intraperitoneal hemorrhage. Diagnosis of this by e-FAST, CT scan, or peritoneal aspiration is an indication for laparotomy, whereas its absence prompts diagnostic and potentially therapeutic angiography.

FOUNDATIONS

Background and Importance

The management of abdominal trauma relies on organization of key clinical features and the timely use of diagnostic procedures. Advancements in imaging have helped to decrease missed or delayed diagnoses, yet abdominal injuries can be notoriously occult, requiring vigilance to achieve the best clinical outcomes.

Penetrating Abdominal Trauma

Penetrating abdominal trauma is defined as any injury caused by an object that breaks the skin and enters the abdominal cavity. Whether by accident or intention, penetrating abdominal trauma can result from a wide variety of mechanisms of injury including weapons, sharp instruments, or other types of impalements. In general, the severity of injury is directly related to the velocity and depth of penetration, and approaches to management vary accordingly. Wounds from stabbing implements occur nearly as often as wounds from firearms, but the latter are responsible for approximately 90% of penetrating trauma mortality.[1] The small intestine, colon, and liver are the most likely organs to sustain injury after penetrating trauma.

The use of firearms in the United States contributes heavily to the morbidity and mortality of trauma. Firearm injuries are the third largest cause of trauma-related death in the United States, accounting for approximately 15% of trauma-related deaths. When compared with other mechanisms of trauma, firearm injuries have the highest case fatality rates across every age group.[1]

Blunt Abdominal Trauma

The majority of cases of blunt abdominal trauma are caused by motor vehicle collisions, whereas blows to the abdomen and falls from heights make up a minority of cases. Nevertheless, historical data may be incomplete, absent, or presumptive. The symptoms and signs can be unreliable and obfuscated by altered mental states due to trauma or other etiology or distracting injuries. The likelihood of extra-abdominal systems trauma adds further complexity, underscoring the need for a carefully organized diagnostic approach. Despite advances in imaging, blunt injuries can be difficult to diagnose and are commonly associated with severe trauma to multiple intraperitoneal organs and extra-abdominal systems.

The spleen is the organ most often injured; in nearly two-thirds of these cases, it is an isolated organ injury. The liver is the second most commonly injured intra-abdominal organ. Injury to any hollow viscus is uncommon by comparison, with the intestine the most likely hollow structure to be damaged.

Anatomy and Physiology

The abdominal cavity and its contents can be reached through the anterior abdominal wall and lower chest, as well as through the flank, back, and buttocks. Rarely, projectiles can lodge intraperitoneally after traversing the proximal extremities. The *anterior abdomen* is defined as that region between the anterior axillary lines from the costal margins to the groin creases. The *low chest* begins at the nipple line or fourth intercostal space anteriorly and the inferior scapular tip or seventh intercostal space posteriorly, and then extends down to the inferior costal margins. The *flank* is demarcated by the anterior and posterior axillary lines bilaterally from the inferior scapular tip to the iliac crest. The *back* is defined by the posterior axillary lines, beginning at the inferior scapular tip and extending down to the iliac crest. The intraperitoneal cavity is vulnerable to injury when penetration occurs as high as the fourth intercostal space anteriorly and the sixth laterally and posteriorly because the superior edge of the diaphragm can reach these levels during expiration. Simultaneous thoracic and abdominal penetration can be found in 20% to 40% of cases of abdominal thoracic trauma. Careful examination of entrance and exit sites, as well as wound tracts, is imperative.

Pathophysiology

Penetrating Abdominal Trauma

Penetrating abdominal injuries are predominantly caused by knives and firearms. Injuries caused by impalement from sharp objects such as fences, stakes, or similar objects should be treated as stab wounds. Projectiles from machinery or heavy equipment can be managed similarly to gunshot wounds, depending upon velocity of penetration. Fragmentation injuries produced by explosives are rare in the US civilian population, but industrial explosions can produce similar injuries, and blunt abdominal trauma from blast effect can coexist in this setting. Domestic terrorist acts may involve improvised bombs loaded with shrapnel, which can lead to penetrating abdominal trauma in the setting of more significant blast-related injuries.

The liver, followed by the small bowel, are most often injured from stab wounds, as a result of location and large surface area of these organs. Gunshot wounds typically result in multiple organ injuries, the greatest occurring in small bowel followed by the colon, and then the liver.

Stab wounds. Stab wounds occur most commonly in the upper quadrants and are caused by a variety of sharp implements besides knives. However, nearly one-quarter of cases have multiple wounds, and up to 10% of cases involve the chest. Most stab wounds do not cause an intraperitoneal injury, although the incidence varies with the implement used and the direction of entry. Anterior stab wounds penetrate the peritoneum in approximately 70% of cases but inflict a visceral injury in only half of these. Left lower chest wounds are associated with a 15% incidence of intraperitoneal damage in addition to the high rate of thoracic and diaphragmatic injuries, whereas right lower chest wounds have a much lower incidence of 0% to 5%. Abdominal entries from the flank and back have reported incidences of up to 45% and 15%, respectively. The liver and spleen are the viscera most commonly damaged in cases of back and flank stab wounds, but the injury pattern cannot be predicted by site of entry.

Gunshot wounds. The science of ballistics is complex, but a few basic principles are helpful in understanding the pathophysiologic processes. The magnitude of the injury is proportional to the amount of kinetic energy imparted by the bullet to the victim, according to the following equation:

$$E = \frac{7000\ mv^2}{2\ ga}$$

where E is the kinetic energy (in foot-pounds), m is the mass of the bullet, v is the velocity of the bullet (in ft/s), and ga is gravitational acceleration (in ft/s). The degree of injury depends on the mass of the bullet and the square of its velocity, although the resistance and viscoelastic properties of the tissue affect the resultant injury as well. Projectile velocities are categorized as low (slower than 1100 ft/s), medium (1100 to 2000 ft/s), and high (faster than 2000 to 2500 ft/s). Impact velocity is the most important determinant of extent of injury and depends on the distance between the firearm and the victim, the muzzle velocity, and characteristics of the projectile.

Although injury from low-velocity handguns occurs most often, injury due to higher-powered firearms is becoming more prevalent. At medium and high velocities, projectiles destroy tissue in its direct path; however, the shock wave of impact has an explosive effect and creates a temporary passage in the tissue along its course, directly proportional to the specific gravity of the penetrated tissue. The dissipating energy of impact displaces nearby organs and vascular structures, and bone and viscera may be fractured or torn without being directly struck by the projectile. Several cases of an intraperitoneal injury caused by a bullet that remained extraperitoneal throughout its entire course have been reported due to the secondary blast effect. Solid viscera, such as the liver and spleen, are more vulnerable to this effect. In addition, high-velocity missiles can drag external contaminants into the wound, fragment internally, and closure of the tract immediately after the bullet's passage may lead to an underestimation of tissue damage. A projectile at any velocity can fragment after contact with bone and cause additional multiple trajectories and injuries. Attempting to deduce the tracts of bullets in assessing patient injury is fraught with error and not recommended.

Shotgun wounds differ from other projectile injuries because the variation in tissue destruction is dependent upon type of shot (mass of pellets used), as well as distance of the victim from the firearm. Close-range, large buckshot wounds can be as lethal as high-velocity firearm injuries due to profound intra-abdominal tissue injury, whereas injuries sustained from greater distances or smaller pellets are associated with wider diameter clusters of injury, less tissue penetration (sometimes failing to penetrate the peritoneum), and lower mortality risk.

Blunt Abdominal Trauma

Sudden and pronounced rises in intra-abdominal pressures created by outward forces can cause rupture or burst injury of a hollow organ. Compression of abdominal viscera between the applied force to the anterior wall and the posterior thoracic cage or vertebral column produces a crushing effect. Liver and splenic injury are particularly susceptible to this type of injury. Individuals with reduced abdominal wall musculature are also more prone to these crush injuries. In addition, rapid acceleration and deceleration can cause a shearing affect, injuring organs and vascular pedicles by disruption of fixed points of attachment.

Seatbelt injuries. Unrestrained passengers are at an unequivocally greater risk of intra-abdominal injury than their restrained counterparts. The three-point shoulder-lap belt is the most effective restraining system in prevention of intra-abdominal injuries; however, abdominal injuries still occur with combined shoulder-lap belt systems. If seat belts are misused, particularly in the case of improper underarm use of the shoulder belt, the shoulder belt component can lead to rib fractures with potential for injury to underlying abdominal viscera. Injuries resulting from solitary lap belts are most often to the lower abdomen. The pathogenesis is usually the compression of bowel between the belt and the vertebral column, resulting in a contusion or perforation of the intestines or a tear of the mesentery. Approximately one-fourth of these patients develop evidence of a hemoperitoneum secondary to mesenteric lacerations. In the remainder, the intestinal injury most commonly involves the jejunum, and the initial signs and symptoms are often absent or considered insignificant. Subsequent delays in diagnosis of up to weeks later have rarely been reported. The "seatbelt sign," contusion or abrasion across the lower abdomen, is found in less than one-third of patients with abdominal injuries caused by lap belts. Its presence is highly correlated with intraperitoneal pathologic lesions. Rupture of the diaphragm can also occur in cases of high-speed frontal impact. Rare cases of acute abdominal aortic dissection with incomplete or complete occlusion have been described, and injuries to the lumbar spine are not uncommon. A patient with a seatbelt mark that suggests improper use of the restraint system (above the level of the iliac crests) is at particularly high risk of injury and clinical observation in addition to diagnostic imaging is recommended.[2]

Iatrogenic injuries. Abdominal injuries may be sequelae of various medical procedures. External cardiac compressions, manual chest thrusts to clear an airway obstruction, and the Heimlich maneuver can cause rib fractures and injury to abdominal viscera. Tube thoracostomy can cause injury to the liver or spleen because of unrecognized elevation of the diaphragm or improper technique or placement of the tube. Peritoneal lavage, paracentesis, and peritoneal dialysis can cause

vascular penetration or bowel perforation. A liver biopsy can lead to a hemoperitoneum or a biloma, whereas endoscopic procedures of the bowel may cause a hollow viscus perforation and peritonitis. Colonoscopy can cause splenic injury and hemoperitoneum, and although specific mechanisms and risk factors are less clear, it does not seem to be associated with the biopsy procedure.

Clinical Features

The patient's history may be unobtainable, elusive, or temporarily deferred while resuscitative measures are performed. The patient's ability to relate the course of events may be compromised by head or spinal cord injury, alcohol intoxication, developmental delay, psychiatric illness, and any number of toxins that will affect the clinician's assessment of the patient. In some cases, the trauma may have preceded the onset of symptoms by days or even weeks. When the situation permits and a reliable source is available, certain information such as the mechanism of injury, can prove valuable. Witnesses at the scene of injury, particularly paramedical personnel, often provide the most reliable data.

Appreciation of comorbid medical conditions, particularly cardiovascular disease and coagulopathies, will guide appropriate fluid and blood component therapy. When a prehospital care team or transferring hospital is involved, vital signs and physical exam assessment, prehospital course, and response to therapy should be obtained. Clinical records and laboratory and radiologic studies obtained at an outlying hospital should be carefully reviewed.

Abdominal pain is the most obvious symptom of abdominal trauma, as irritation of the peritoneum produces pain. The pain may be clearly present at the outset or delayed for hours to days. The communication of such pain may be impaired or ineffectual, or the perception of pain may be impaired by a spinal cord injury or underlying comorbidities. Occasionally, intense, competing pain at another body site dominates and distracts both the patient and clinician away from the abdomen. Abdominal pain can be localized (e.g., left upper quadrant with a splenic injury) or diffuse, such as in septic peritonitis secondary to bowel perforation.

Pain need not be localized to the abdomen, as irritation of the diaphragm by hemoperitoneum can cause referred pain to the right and left shoulder tips or neck, particularly when the patient has been in the Trendelenburg position. This most often is a marker of hepatic or splenic injury. Pain can also be referred to the inguinal region and testicles in the setting of retroperitoneal injury and is seen most commonly with urogenital and duodenal trauma.

A variety of other extra-abdominal symptoms may be present as well. If substantial enough, volume loss may cause dizziness, lightheadedness, confusion, and orthostasis. Nausea and vomiting can accompany peritoneal irritation or hypovolemia or can result from an obstruction, such as the development of a duodenal hematoma. Dyspnea sometimes occurs with gastric distention or diaphragmatic irritation or when abdominal contents herniate into the chest, impairing respiratory dynamics.

Specific Clinical Presentations

Penetrating Abdominal Trauma

Stab wounds. The number of stabs inflicted, type and size of the instrument, posture of the victim relative to the direction of assault, estimated blood loss at the scene, time of injury, and response to fluids help to gauge the nature and severity of injuries. Alteration in mental status due to any number of mechanisms, including drug or alcohol consumption, may make obtaining a useful history elusive and can compromise the clinical exam.

Gunshot wounds. Clinically helpful information for gunshot wound victims includes the weapon used, its distance from the victim when shot, the position of the victim in relationship to the weapon when fired, the suspected number of shots, the blood loss at the scene, the amount and type of field fluids administered, and vital signs assessment during the prehospital course.

Blunt Abdominal Trauma

Clinically relevant information for passengers in a motor vehicle crash includes the nature of the collision including the estimated velocity on impact, use of seatbelts, extent of damage to the car, presence or absence of intrusion, the victim's location within the car and evidence of internal impact such as steering wheel deformity, and airbag deployment. The magnitude of injury to pedestrians varies with the speed and size of the striking vehicle. A triad of injuries to the torso, cranium, and lower aspect of the lower extremity has been well described, and pathologic lesions discovered in two of these sites should prompt focused attention to the third. Motorcycle crashes can be placed in one of four categories: frontal, lateral, or angular ejection or "laying the bike down." Different pathologic lesions can be projected based on the mechanism of injury.

Physical Examination

Signs of abdominal trauma can range from subtle findings to severe shock and coma. Intraperitoneal injury can present as abdominal tenderness from peritoneal irritation, gastrointestinal hemorrhage, or hypovolemia not attributable to extra-abdominal causes. These signs may be initially absent or obscure but may emerge during serial examinations.

The physical examination of a hemodynamically unstable patient is performed coincident with resuscitation. When an obvious intracranial, thoracic, or orthopedic injury is present, abdominal symptoms or findings may remain undetected, and abdominal injury should be considered. Chest trauma is a risk factor for coincident intraperitoneal injury. This is particularly true in cases of suspected blunt trauma accompanied by a head injury, coma, or obtundation resulting from drugs or alcohol. An extended focused abdominal sonography for trauma (e-FAST) examination should be performed on all patients at the transition point from the primary to secondary survey (see Chapter 32). Acute hypotension resulting from hemorrhage is most often from a solid visceral or vascular injury. Traumatic pancreatitis may evolve to produce significant third-space fluid losses but is rarely the sole cause of acute shock. When unexplained hypotension accompanies significant blunt trauma, one should assume the presence of intraperitoneal hemorrhage until it is excluded. A known extra-abdominal source of hemorrhage does not mitigate the need to evaluate the peritoneal cavity. Solitary cranial or spinal injury should not be considered the sole cause of shock until an intra-peritoneal injury has been excluded.

In cases of penetrating trauma, inspecting the abdomen for entrance and exit wounds may help determine the path of injury. Distention can occur as a result of hemoperitoneum or pneumoperitoneum, gastric dilation, or ileus secondary to peritoneal irritation. An ecchymotic discoloration of the flanks *(Gray-Turner sign)* or umbilicus *(Cullen sign)* indicates retroperitoneal hemorrhage, but these findings can be delayed for 12 hours to several days. Abdominal contusions can result from several mechanisms; however, contusions from lap-seat belts result in intra-abdominal injuries in one-third of cases. Presence or absence of bowel sounds does not reliably identify or exclude the presence of intra-abdominal injury.

Although palpation elicits local or generalized tenderness in the vast majority of alert patients with an intra-abdominal visceral injury, it is less reliable in patients with an altered mental status. However, physical examination can be unreliable even in conscious and responsive patients. Local and generalized rebound tenderness and rigidity can be

signs of peritoneal irritation but occur less commonly. These signs lack specificity and can be found with lower rib fractures and contusions of the thoracoabdominal wall as well. Rarely, encapsulated bleeding into regions walled off by blood clots or adhesions can form palpable intra-abdominal masses, but these findings are usually delayed several hours after initial injury. Severe contusions of the abdominal wall can cause tenderness and voluntary guarding that is localized and usually exacerbated by use of the affected muscle. A palpable mass can represent a rectus ventral hernia or muscle hematoma, particularly in patients on anticoagulation therapy.

Rectal examination, once a routine part of the trauma assessment, rarely provides clinical useful information and is not indicated in the vast majority of trauma patients. This is particularly true in conscious patients of both sexes, for whom rectal examination is uncomfortable, unnecessary, and potentially humiliating. The sole remaining value of rectal examination is as part of the neurologic assessment (for anal sphincter tone) for patients with identified neurologic deficit believed to be caused by spinal cord injury.

Although the presence of physical findings makes intraperitoneal injury more likely, their absence does not preclude serious pathology. No finding is exclusively diagnostic of a specific injury. Extended observation, clinical imaging, and laboratory testing can reduce the chances of diagnostic error.

Penetrating Abdominal Trauma

Stab wounds. Serial physical examination performed by the same observer is useful in appropriately staffed and established trauma centers, particularly with patients who are alert, communicative, and neurologically intact. The presence of intoxicants does not necessarily preclude reliance on examination but may decrease its value until sobriety is regained. Even among patients with evidence of shock, peritonitis, or evisceration after penetrating trauma to the abdomen, exploratory laparotomy fails to reveal intraperitoneal organ injury in more than 10% of cases. In contrast, up to one-third of patients with significant intra-abdominal injuries have no suggestive physical signs, particularly when a retroperitoneal injury has occurred.

Gunshot wounds. As with blunt or other modes of penetrating trauma, there are limitations to physical examination of patients with abdominal gunshot wounds. Up to 20% of patients with a documented intraperitoneal injury have no peritoneal signs before exploration, whereas objective physical findings suggestive of intra-abdominal damage may be present in up to 15% of patients in whom laparotomy reveals no injury.

Blunt Abdominal Trauma

Overall, the accuracy of the physical examination in patients with blunt abdominal trauma is only 55% to 65% because the initial presentation may be deceptively benign. The most reliable symptoms and signs in alert patients are pain, tenderness, and peritoneal findings, particularly when risk factors for abdominal injury are present. When altered sensorium intercedes, the physical signs become less reliable. Frequent evaluations by the same examiner are indicated even in alert patients but especially in sensorium-altered patients, particularly as their mental status and sensorium normalize.

DIFFERENTIAL DIAGNOSES

The differential diagnosis in the setting of abdominal trauma is substantial and depends upon the mechanism of injury (blunt vs. penetrating) and the type of injuries that may occur. Both high-velocity blunt and penetrating abdominal trauma can cause lacerations or ruptures of intra-abdominal organs, whereas blunt injury can cause intra-abdominal solid or hollow viscous hematomas or isolated abdominal wall trauma and hematomas. The differential diagnosis includes solid or viscous organ injury, vascular injuries, intra-abdominal bleeding, abdominal compartment syndromes (ACSs) or retroperitoneal hematomas. Injury to the abdominal aorta can result in mortality up to 50% to 70%. Patients may present in profound shock and with altered mental status. Abdominal tenderness, although usually present, is largely unreliable depending upon presence of distracting injuries or altered mental status. Emergency clinicians should be vigilant for the effect of distracting injuries because isolated extremity injuries can, for instance, significantly suppress clinical signs of intra-abdominal injury.

Abdominal tenderness with rebound or guarding may suggest irritation of the peritoneum due to the presence of blood but will not detect the presence of a retroperitoneal injury. Rectal bleeding would suggest colonic laceration and the presence of blood at the urethral meatus would strongly suggest a genitourinal injury. "Open book" pelvic fractures and expanding hematomas can often present significant clinical challenges in combination with blunt abdominal trauma, resulting in extremely high rates of morbidity and mortality. The emergency clinician must be cognizant of the presence of this type of injury in the setting of high-velocity blunt force trauma (see Chapter 46). Traumatic diaphragmatic rupture, although present in less than 0.5% of all trauma cases, can be easily missed leading to high morbidity and mortality rates.

Medical and traumatic pathologic conditions can be coincident or can precipitate the other. The emergency clinician should be alert to instances in which medical conditions could portend traumatic events. For instance, hypoglycemia or a generalized convulsive seizure may precipitate a motor vehicle collision, and the patient's altered mental status may be incorrectly attributed to closed head injury, delaying the underlying diagnosis. Patients with infectious mononucleosis can experience splenic rupture after relatively trivial trauma, and the presentation of these injuries may be delayed. Patients with premorbid coagulopathy or who are on therapeutic anticoagulation may sustain serious intracranial or intra-abdominal hemorrhage from otherwise unimpressive traumatic injury (see Chapters 32 and 33).

DIAGNOSTIC TESTING

Ultrasonography

The e-FAST examination is indicated in all multiple-trauma patients and all patients with suspected abdominal injury, whether by blunt or penetrating mechanism. Ultrasonography's primary role is detecting free intraperitoneal blood after blunt trauma. This is accomplished by an examination of the *Morrison pouch*, splenorenal recess, and *pouch of Douglas*, which are dependent portions of the intraperitoneal cavity where blood is likely to accumulate (Fig 38.1). The thoracic portion of the examination detects pneumothorax, hemothorax, and pericardial effusion or tamponade (Fig. 38.2). Ultrasound applications in the trauma patient are discussed in Chapter e3. The e-FAST study is aimed precisely at the determinations described earlier and is most useful as a tool to rapidly rule-in the aforementioned conditions. The e-FAST exam is limited in the visualization of solid parenchymal damage, the retroperitoneum, or diaphragmatic defects and should not be used as a "rule-out" test for significant intra-abdominal trauma.[3,4]

Laboratory Testing

Metabolic and hematologic testing is of limited use in the initial management of the acutely traumatized patient and should be considered adjuncts to diagnosis and not substitutes for clinical assessment and

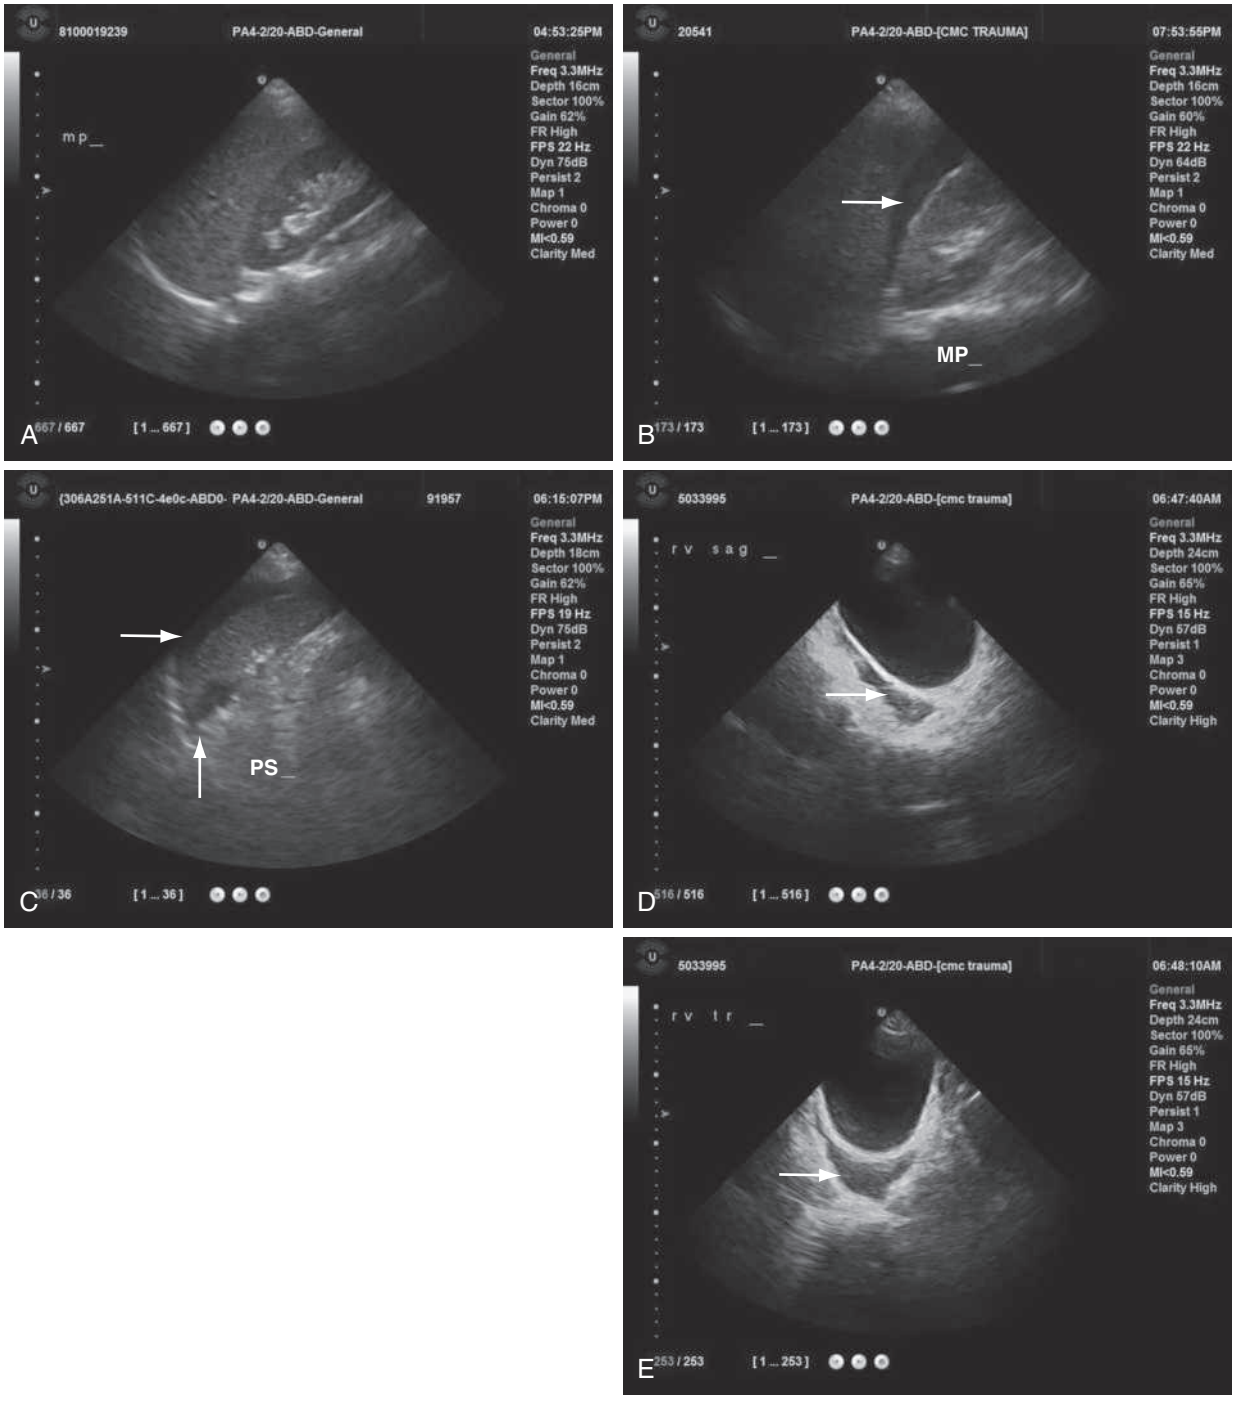

Fig. 38.1 (A) Normal Morrison pouch view. Note absence of an anechoic stripe, which would represent a fluid collection between the liver and kidney. (B) Positive Morrison pouch view. immediate interventions. However, targeted laboratory evaluation can provide significant guidance in the assessment and management of the traumatized patients that can be tailored to the severity of injury.

The hematocrit can represent a baseline value but is also a function of the extent of and time from hemorrhage, exogenous fluid administration, and endogenous plasma refill. Endogenous plasma refill is a physiologic compensatory shift of extracellular fluid into the intravascular space, the intent of which is to restore original blood volume. Based on a study of volunteers sustaining a 10% to 20% blood loss, this restoration can take more than 24 hours. Patients with hemorrhagic shock (at least 40%) demonstrate much faster plasma refill rates, with significant decreases in hematocrit within 90 minutes. Hematocrit values often represent a conundrum when viewed in isolation but are useful when measured serially.

The white blood cell (WBC) count has little discriminatory value in cases of abdominal trauma, particularly in its acute phase. The WBC

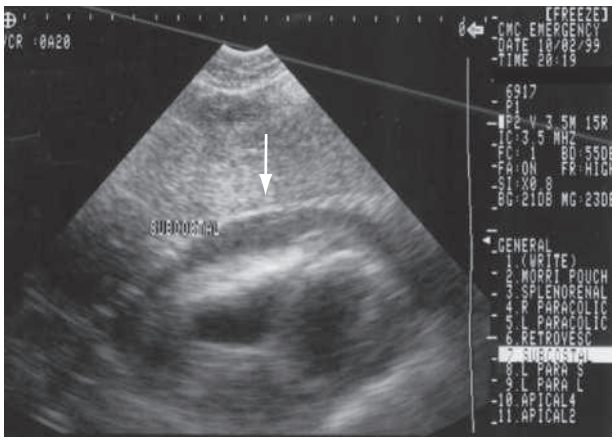

Fig. 38.2 Pericardial effusion seen on subcostal view *(arrow)*. The *white line* is the pericardium, and the anechoic space below represents a fluid collection in the pericardial space.

count may be normal or may show a modest leukocytosis (12,000 to 20,000/mm^3 with or without left shift), which can occur in the setting of multisystem trauma as a result of stress-induced demargination in the absence of any intra-abdominal process, or as a result of tissue injury, acute hemorrhage, or peritoneal irritation.

Metabolic acidosis in the setting of trauma can suggest the presence of hemorrhagic shock. This can be detected by a decreased serum bicarbonate level, increased base deficit, or elevated serum lactate level. Although normal values do not exclude abdominal injury, abnormalities, such as a base deficit greater than or equal to 6, elevated lactate greater than 4 mmol/L, or increase over time in either of these indices, suggest perfusion compromise or injury. These findings should be considered in clinical context because the cause of the abnormalities may be extra-abdominal and trending of laboratory findings may lag behind the clinical deterioration or stabilization of the patient.

Elevated serum transaminases can result from hepatic trauma but do not distinguish minor contusions from severe injury. Alternatively, these may be symptomatic of alcohol-induced liver damage. Elevated liver transaminase levels may be useful for screening pediatric patients for intentional trauma (see Chapter 172).

Screens for ethanol and drugs are often used in trauma centers. Their utility in the management of abdominal trauma has not been established, particularly in patients with a normal mental status. Positive study findings may prompt the emergency clinician to interdict and encourage the patient to decrease the use of ethanol or drugs, because physician intervention during these "teachable moments" has been shown to be effective. Although included in many "trauma panels," neither serum amylase nor lipase is useful in the evaluation of acute abdominal trauma. Normal levels do not exclude a major pancreatic injury, and elevated values may have other causes in addition to an injured pancreas, including chronic alcohol use or drug toxicity, systemic hypotension, and pancreatic hypoperfusion. Increasing levels may indicate but may not be conclusive of organ injury. In all cases, clinical examination, imaging, and vital signs assessment will direct further investigation.

Radiology

Resuscitation and initial stabilization measures precede abdominal radiographic studies. The purpose of diagnostic studies is twofold: to discern or eliminate the presence of hemoperitoneum in the patient whose condition is critical and unstable to properly sequence management and, in less urgent circumstances, to demonstrate organ injury that requires operative repair. Basic plain radiography of the abdomen in the trauma bay is not indicated, except for the location and identification of projectiles. Portable chest x-ray examination has been a staple to screen for significant hemothorax or pneumothorax before the patient is transferred to the computed tomography (CT) scanner, but this is largely being replaced by the chest portions of the e-FAST examination when equipment and sufficiently experienced personnel are available. The e-FAST is proven to be at least as sensitive and specific as a portable chest radiography for both conditions.

Hemodynamically stable patients who will undergo expedient abdominopelvic CT may forego portable pelvic radiographs during the initial trauma resuscitation. Indications for pelvic radiography are discussed in Chapters 32 and 46. In patients whose evaluation, including e-FAST results, demonstrates likely intra-peritoneal injury requiring laparotomy, delay in operative intervention to obtain further diagnostic radiology studies is permissible only when the patient has been stabilized and if these studies aid in determining management.

Plain Radiographs

The chest radiograph and anteroposterior pelvic films can be invaluable in some cases of penetrating and blunt trauma, depending on the presentation and results of initial evaluation. Chest radiographs can provide extra-peritoneal causes of hypotension in the unstable patient. Plain abdominal films can demonstrate the location or presumed track of projectiles in gunshot and shotgun injury but are of little value in blunt trauma or nonprojectile penetrating trauma, particularly if expedited CT imaging of the abdomen is anticipated. If plain radiography of the abdomen is obtained, the finding of rib, pelvic, vertebral body, or transverse spinous process fractures in the blunt trauma patient warrants special consideration for nearby visceral damage.

Although free intraperitoneal air can be detected on plain films, the small amounts and location of air associated with small bowel injuries are seen more readily on CT scan. Free intraperitoneal air uncommonly can be generated by mediastinal or pulmonary injury, as well as by barotrauma, and its presence is not pathognomonic of hollow viscus perforation. Intraperitoneal air is mobile; in upright x-rays, air is located under the diaphragm or the central tendon of the diaphragm anteriorly. In supine x-rays, air tracks under peritoneal attachments, such as the falciform ligament and urachus, up to the anterior abdominal wall. On radiographs in which the patient is in a lateral decubitus position, air is located in the superior flank and outlines the lateral liver edge. Extraperitoneal colonic perforations may extravasate air, which outlines the psoas muscle and perinephric region. All of these injuries are much more readily identified and localized on abdominal CT scan, which remains the imaging modality of choice.

Foreign bodies and projectiles are easily identified on abdominal images. Therefore their absence without a known exit wound warrants further search of other body cavities (e.g., the chest, upper thighs, buttocks). A ricochet off the spine or pelvis into the chest or proximal extremities can occur. An entry into the vascular system may carry the object toward and into the right side of the heart or peripherally into the arterial tree. It may also find migrate into the gastrointestinal tract and either produce obstruction or pass through unnoticed. Thus the location of a bullet and its fragments may provide its primary value in suggesting if extra-abdominal injuries are present.

Computed Tomography

CT scanning is the primary diagnostic imaging test for abdominal trauma because if its utility in defining the extent of intra-abdominal injury with detailed high-resolution images. It is most accurate for solid visceral lesions and discerns the presence, source, and approximate quantity of intraperitoneal hemorrhage (Fig 38.3). CT scanning can also demonstrate the presence or absence of active intra-abdominal

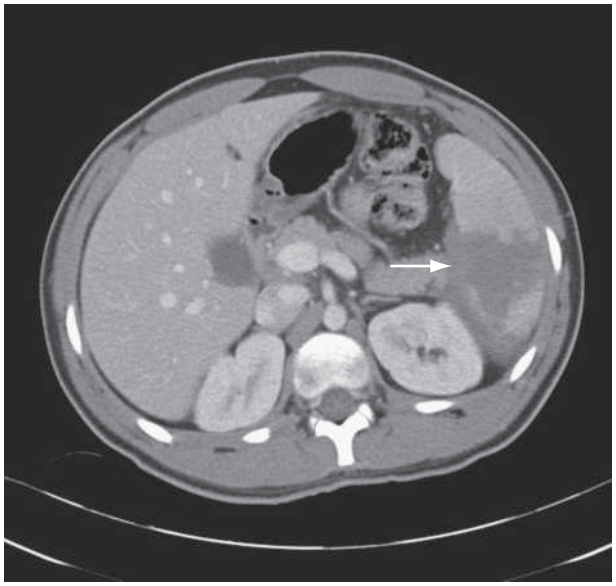

Fig. 38.3 Grade 4 splenic laceration *(arrow).*

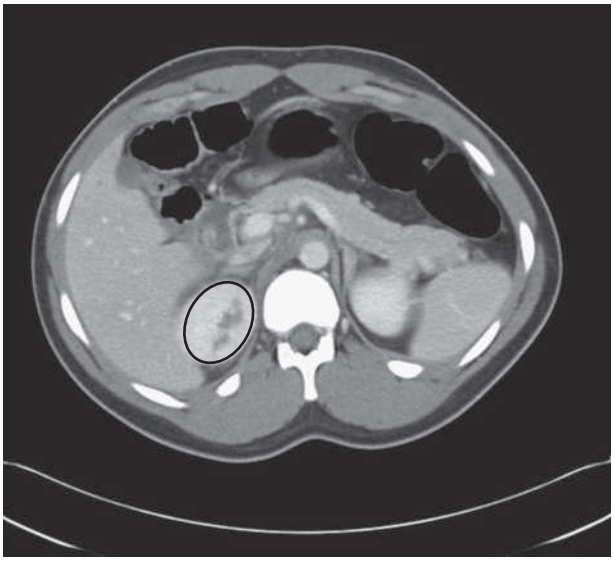

Fig. 38.4 Grade 3 right renal laceration *(encircled).*

bleeding and other vascular injury or hemorrhage, obviating the need for angiography in some patients. Imaging of the liver and spleen can support management decisions such as observation, therapeutic angiographic embolization, or open operative intervention. The minimization of nontherapeutic laparotomies for self-limited injury to the liver or spleen decreases morbidity and cost. CT scanning also can be used to definitively evaluate for genitourinary injury and can be used to evaluate the vertebral column and retroperitoneum (Fig. 38.4), areas not suitable for evaluation by ultrasound. The advantage of axial imaging is that the CT scanning and can be readily extended above or below the abdomen to visualize the thorax or pelvis for other associated injuries. The use of intravenous (IV) contrast alone is typically sufficient for most high-resolution imaging with little additional yield from the addition of oral contrast during initial scanning. When possible, protocols using high resolution (3 mm or less slice thickness values) with three-dimensional multiplanar reconstructions are ideal.[5]

CT imaging technology does have limitations. For example, injuries to the pancreas, diaphragm, small bowel, and mesentery can remain undetected, although higher-resolution technology is improving the diagnostic yield (Fig 38.5). Stab wounds can be particularly problematic. Sensitivity of detection of injury with axial imaging ranges from 50% to 100%, with 9% of patients with negative abdominal CT going on to require therapeutic laparotomy.[6,7] Given the risk of missed injuries, a negative CT scan should not be the sole determinant in the management and disposition of patients with abdominal stab wounds. In addition, coincidental hollow viscus injury in patients with blunt trauma is not rare, and increased morbidity and death can ensue if a diagnosis is missed or the condition goes undetected for a prolonged period. Findings on CT scans, such as suspected quantity of hemoperitoneum or the presence of isolated free fluid, are not sufficient to determine the need for operative intervention.

Use of CT scan is also not entirely risk free. Complications may result from IV contrast administration, including contrast-induced nephropathy, although recent data suggest the risk has been significantly overestimated.[8,9] In addition, there is increasing concern regarding the negative long-term effects from exposure to ionizing radiation resulting from medical imaging. Although direct evidence of increased cancer risk from CT scans has not yet been demonstrated, several techniques and parameters are used to reduce radiation exposure. These include patient positioning and scanning range, modulating the CT tube current and potential, reconstruction algorithms, and reconstructed slice thickness. Attempting to limit CT scanning only to a region of specific interest can be excessively insensitive for significant injury, and this practice is not recommended. Digital images should also accompany patients transferred between facilities, to avoid unnecessary repetition of the study and further radiation exposure.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is usually impractical and challenging to perform in the acute phase of patients with multiple blunt traumas. Currently, in acutely injured trauma patients, MRI should be reserved for the evaluation of spinal cord injuries and elusive diaphragmatic defects not amenable to laparoscopy or thoracoscopy in the fully stabilized patient.

MANAGEMENT

General principles: The field approach to multiple or serious trauma focuses on rapid transportation to a capable receiving emergency department (ED) and is discussed in Chapter 32. Although an emerging body of evidence has evolved around the concept of "permissive hypotension," in which a mild degree of hypotension (mean arterial pressure >50 mm Hg) is tolerated to decrease unnecessary fluid resuscitation during transport and initial stabilization, definitive clinical trial evidence mandating the practice is lacking, and current consensus recommend against this practice.[10]

Assessment of abdominal injury specifically is undertaken as part of the general management of the trauma patient (see Chapter 32). In patients who are intubated, have a massively distended abdomen, or in whom there is a high concern for stomach or duodenal injury, a nasogastric tube should be placed to decompress the abdomen, decrease the likelihood of aspiration, and determine whether blood is present, respectively. Placement of an orogastric tube is preferable in patients with midface or skull base fractures. Foley catheterization, once fairly routine, is reserved for unconscious patients, and those in shock, for whom urine output is an indicator of adequate end-organ perfusion. Thoracotomy and subsequent cross-clamping of the descending aorta have been used to stabilize patients with thoracoabdominal injuries and profound hypovolemic shock, but this is best undertaken as a temporizing rescue maneuver in the operating room when laparotomy identifies critical injuries not amenable to abdominal repair. In many

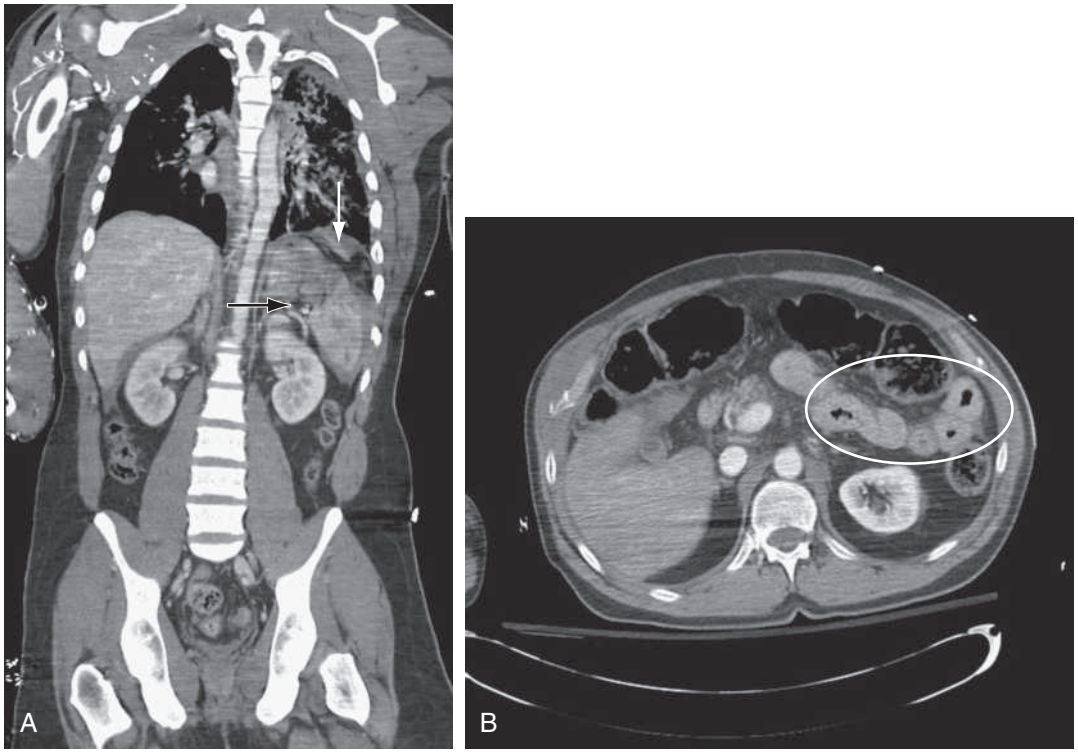

Fig. 38.5 (A) Grade 4 splenic laceration *(black arrow)* with diaphragmatic rupture *(white arrow).* (B) Small bowel edema concerning for hollow viscus injury *(encircled).*

trauma centers, resuscitative endovascular balloon occlusion of the aorta (REBOA) offers an emerging alternative to ED thoracotomy for management of exsanguinating intra-abdominal injuries in hypotensive patients who are not responding to initial resuscitation.[11]

Antibiotics, given prophylactically, are effective in decreasing the incidence of intra-abdominal sepsis. Intestinal perforation and soiling can occur with penetrating, and less commonly with blunt, trauma to the abdomen. A single preoperative dose of a broad-spectrum antibiotic or combination of antibiotics that covers both aerobic and anaerobic organisms, such as piperacillin-tazobactam 3.375 g intravenously, is recommended in the setting of perforated hollow viscus injuries.

Penetrating Abdominal Trauma

Stab Wounds

Selective management of abdominal stab wounds is currently well accepted because of the relatively low incidence of intraperitoneal injuries coupled with the success of various diagnostic strategies. This strategy is based on the site of penetration, the clinical status of the patient, and the experience of the hospital institution and its personnel. Compared with the former practice of mandatory laparotomy, selective management has resulted in a tremendous reduction in unnecessary laparotomies and associated morbidity, with minimal and acceptable loss in sensitivity for significant intraperitoneal injury. Overall, the nontherapeutic laparotomy rate should be less than 15%.

Anterior abdomen. In approaching the management of stab wounds to the anterior abdomen, the clinician is faced with three fundamental tasks. The first and most important is to determine whether clinical indications exist for emergent laparotomy. The presence of one or more of these indications, particularly in the context of an unstable patient, sets the course to expedited operative intervention. If none is found, the clinician may address the second issue of whether the peritoneal cavity has been violated. If it can be definitively demonstrated that it has not, no further diagnostic evaluation is required, and the patient can be discharged after appropriate wound care. If the cavity has been violated or if it cannot be determined whether the cavity has been violated, the third question is pursued: Does an intraperitoneal injury exist and, if so, is laparotomy required? One general approach to abdominal stab wounds founded on these three queries is summarized in Fig. 38.6. This algorithm is largely based on clinical indicators of injury, local wound exploration (LWE) as well as CT scanning, along with other radiologic modalities. Other strategies rely more heavily on other techniques, such as serial abdominal examinations or laparoscopy, and can be tailored to institutional expertise and resources.

Step I: Clinical indications for emergent laparotomy. Various clinical factors can be used to determine the need for emergent laparotomy (Table 38.1) based on the likelihood of associated intra-abdominal injuries requiring surgical repair. These clinical factors are summarized in the following list by reasons for immediate laparotomy, followed by clinical indications that require additional supportive evidence.

A: Emergent laparotomy immediately indicated

1. Hemodynamic compromise: This is the preeminent indication of the need for laparotomy in the setting of a stab wound and is the most likely reason that a patient will be taken urgently to the operating room without preliminary diagnostic studies.
2. Peritoneal signs: There is considerable debate over the reliability of peritoneal signs, particularly in the early postinjury period. Among physical examination findings, unequivocal peritoneal signs have the highest positive predictive value, whereas an entirely normal examination even in the presence of mild to moderate intoxication has the greatest negative predictive value for therapeutic laparotomy. In general, however, clear peritoneal signs indicate the need for laparotomy.
3. Evisceration: Patients with viscus evisceration sustain up to an 80% incidence of major intraperitoneal injury, and most trauma surgeons will take these patients for exploratory laparotomy. In rare cases, for isolated omental evisceration without

viscus evisceration and absence of free intraperitoneal blood on e-FAST examination, the surgeon may ligate, excise, and restore the omentum to the peritoneal cavity. This is done at the bedside in the ED trauma bay.

4. Left-sided diaphragmatic injury: Although rarely diagnosed acutely, left-sided diaphragmatic injury may be diagnosed through the observation of stomach or bowel in the left chest on bedside chest radiographs, and indicates the need for operative intervention.

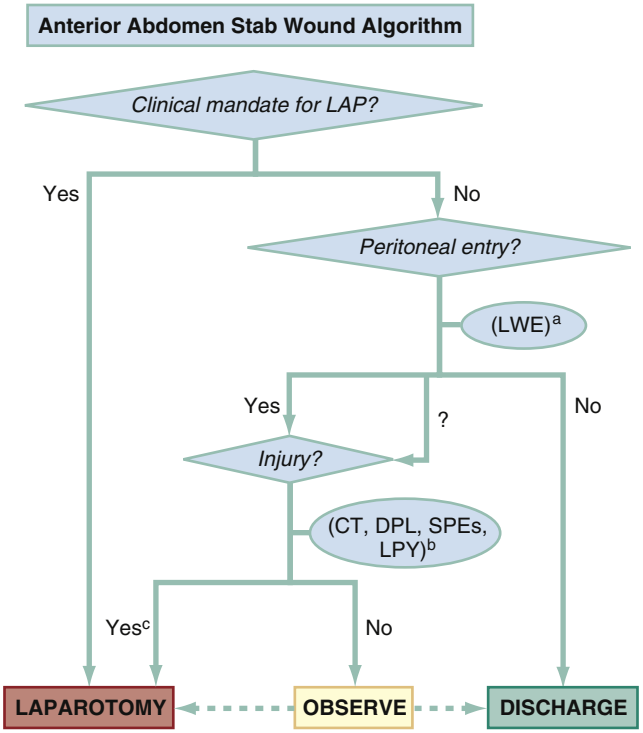

Fig. 38.6 Anterior Abdomen Stab Wound Algorithm. *LAP,* Laparotomy; *LWE,* local wound exploration. [a]Plain films, focused assessment with sonography for trauma, laparoscopy *(LPY),* and computed tomography *(CT)* can also assess peritoneal entry. [b]CT, diagnostic peritoneal lavage *(DPL),* serial physical examinations *(SPEs),* or LPY can be used in singular or complementary fashion, depending on the clinical scenario. [c]Expectant management of injuries is infrequently attempted.

B: Laparotomy only considered with additional clinical evidence

5. Gastrointestinal hemorrhage: Although rarely diagnosed because nasogastric tubes are rarely used in this clinical scenario, recovery of blood via a nasogastric tube or emesis may reflect a violation of the stomach or duodenum. However, blood without coincident peritoneal violation does not necessarily require surgical exploration.
6. Implements in situ: The conservative and widely held maxim is to remove implements in situ of the torso in the operating room. However, there is little evidence to support this practice and removal of such instruments in the ED under controlled circumstances and, in consultation with a surgeon, is reasonable.
7. Intraperitoneal air: See later.

Step II: Peritoneal violation. If clinical indications for laparotomy are absent, the logical next step is assessing the wound tract itself. The presence of peritoneal violation can be determined by a variety of means. There is great value in establishing that a wound tract is superficial to the peritoneal, retroperitoneal, intrathoracic, and pericardial cavities. In this event, the patient can be discharged from the ED after receiving appropriate wound care. If a study is inconclusive, it should be assumed that one or more of these cavities has been violated and further means of assessment are required. The five methods of assessing whether the peritoneum is intact are as follows:

1. Evisceration: Evisceration of bowel or omentum is clear evidence of peritoneal entry. Although typically mandating laparotomy, exceptions exist (see earlier).
2. Intraperitoneal air: Although a finding of intraperitoneal free air on an upright chest or a lateral decubitus abdominal radiograph may indicate bowel perforation, it may simply establish that the implement has entered the peritoneal cavity and drawn air in with it. Therefore, although intraperitoneal air is a strong indication of peritoneal violation, it does not necessarily imply bowel injury and is therefore should not determine the need for emergent laparotomy. Rarely, a false-positive determination of peritoneal entry can be made when the actual source of intraperitoneal free air is the pulmonary tract.
3. LWE: This has been demonstrated to be an effective tool in determining if the peritoneal cavity has been penetrated. Superficial wounds can be repaired if needed and the patient can be discharged from the ED. LWE is unreliable in small puncture type wounds, long tangential stab wound tracts, multiple stab wounds, or in obese

TABLE 38.1 Clinical Indications for Laparotomy Following Penetrating Trauma

Manifestation	Premise	Pitfall
Emergent Laparotomy Indicated		
Hemodynamic instability	Major solid visceral or vascular injury	Thorax, mediastinum, pelvic, or long bone sources; abdominal injuries causal or contributory
Peritoneal signs	Intraperitoneal injury	Unreliable, especially immediately post injury
Evisceration	Additional bowel or other injury	No injury in up to one third of stab wound cases
Diaphragmatic injury	Diaphragm	Rare clinical, radiographic findings unreliable
Laparotomy Requires Additional Clinical Evidence		
Gastrointestinal hemorrhage	Proximal gut	Uncommon, unknown accuracy
Implement in situ	Vascular impalement	Comorbid disease or pregnancy creates high operative risk
Intraperitoneal air	Hollow viscus perforation	Insensitive; may be caused by intraperitoneal entry only or may have cardiopulmonary source

Modified from Marx JA. Diagnostic peritoneal lavage. In Ivatury RR, Cayten CG, eds. *The textbook of penetrating trauma.* Baltimore: Williams & Wilkins; 1996.

patients with large subcutaneous fat layers.[5] In these cases, LWE alone should not be relied upon.

4. Ultrasonography: e-FAST examination demonstrating hemoperitoneum, pneumoperitoneum, or pericardial effusion (see Fig 38.2) identifies peritoneal penetration or injury. A negative e-FAST does not rule out peritoneal violation. Presence of intraperitoneal fluid on ultrasonography can preclude the need for LWE and suggests intra-abdominal injury.
5. Laparoscopy or thoracoscopy in the operating room: This has compared favorably with LWE in assessing the wound tract but requires a surgeon's expertise and carries a greater risk of iatrogenic complications. Benefits include the ability to detect organ injury (including diaphragmatic injury) and simultaneously repair some injuries, thus decreasing negative and nontherapeutic laparotomy rates. Thoracoscopy is primary used in evaluating for diaphragmatic violation in left anterior lower chest stab wounds.

Step III: Injury requiring laparotomy. In this algorithm, patients requiring an operation on clinical grounds have proceeded to laparotomy, and those in whom peritoneal violations have been excluded can be discharged home. The patients remaining have presumed or known peritoneal violation. The next consideration is whether injury exists that dictates operative repair, because organ injury is present in just over 60% of patients with peritoneal violation. In any case, patients who reach this stage of evaluation should be observed for 12 to 24 hours. Initial CT scanning coupled with serial e-FAST, and repeated physical examinations are used to identify significant wounds not initially obvious. Hollow viscus and occult diaphragmatic injuries remain the most frequently missed injuries on CT scan.

Historically, most patients with penetrating abdominal injuries and peritoneal violation underwent exploratory laparotomy, but selective nonoperative management (SNOM) of abdominal stab wounds is increasing. In examinable patients with no immediately identifiable operative injury, this approach includes close observation with serial vital signs, repeated abdominal examinations, and laboratory tests focused on identifying signs of new or ongoing hemorrhage or the development of peritonitis from hollow viscus injury. SNOM has been shown to decrease the incidence of nontherapeutic laparotomy, hospital length of stay, and cost without increasing morbidity or mortality.[12–14] Laparoscopy can also be performed when serial evaluation suggests possible, but not an obvious, need for laparotomy.

Thoracoabdominal penetration. Even a single stab wound to the low chest can violate the mediastinum, thoracic cavity, diaphragm, peritoneal cavity, and retroperitoneum. Nearly 20% of left thoracoabdominal stab wounds will be found to have diaphragmatic violation. When all thoracoabdominal wounds are considered, the risk of occult injury is 7%. Ultrasonography can be useful in permitting a quick assessment for hemopericardium and hemoperitoneum in the marginally stable patient, particularly if thoracotomy or laparotomy is not already clinically indicated. LWE of slash-type wounds may obviate the need for further evaluation, but the depth of investigation cannot be taken beyond the anterior rib margin to maximize safety and accuracy.

Diagnosis of diaphragmatic injury is particularly problematic in penetrating injuries, because many of the CT scan findings associated with blunt diaphragmatic injury are not present in penetrating injuries. Despite using multidetector CT, sensitivity for diaphragm injury in penetrating abdominal trauma can be as low as 47%. On retrospective review, the presence of a wound tract traversing the diaphragm is the most sensitive sign, occurring 92% of the time. Equivocal scans should be followed up with more definitive management, such as laparoscopy or thoracoscopy.[5]

Flank and back. The incidence of retroperitoneal injuries after stab wounds to the flank and back is greater than with injury to the anterior wall. However, risk of intraperitoneal organ injury also is significant, ranging up to 40%. LWE is less accurate than in anterior wounds because the paraspinal muscles are quite thick, so the procedure is only useful if the wound is obviously superficial (e.g., a slash wound). CT scanning with IV contrast is the method of choice for evaluating wounds not identified to be clearly superficial. A negative CT scan, followed by serial examination over a period of 24 hours, can effectively exclude the need for serious injury management of these patients.

Gunshot Wounds

Unlike stab wounds, almost all gunshot wounds penetrate the peritoneal cavity and typically produce multiple organ injuries and a high incidence of hollow visceral injury. Accordingly, the risk of mortality is significantly greater and increases with the velocity of the projectile. Penetration of the low chest commonly involves injuries to both intrathoracic and abdominal structures, including the diaphragm.

Anterior abdomen. Abdominal gunshot wounds enter the peritoneal cavity in approximately 80% of cases, and in more than 90% of those with penetration, there is intraperitoneal damage. If the patient is hemodynamically unstable, has peritonitis, or has an unreliable abdominal exam, the patient is taken for emergent laparotomy. In stable patients, a CT scan with IV contrast can be helpful in identifying the extent and severity of injuries and identifying active bleeding. If no peritoneal violation occurred or it is unclear, admission for serial examinations is indicated.

Previously, any patient with peritoneal violation from a gunshot wound was taken emergently to laparotomy, with very few exceptions. With advances in CT technology and increasing comfort with SNOM for other abdominal injuries, there is currently a growing trend towards SNOM of certain, isolated solid organ injuries secondary to gunshot wounds. This approach includes intensive monitoring and observation by an experienced trauma surgeon with or without adjunctive therapeutic angiography. Data from the National Trauma Data Bank suggest that SNOM is used in up to 35% of patients with renal injury and nearly 40% of patients with liver injury secondary to gunshot wound (GSW). Its use is independently associated with increased survival and decreased postoperative complications. Failure rate of SNOM is approximately 10% but use of SNOM is not associated with adverse outcomes. SNOM has been used across all grades of renal and liver injury.[15–18] Patient selection is critical, and a patient's hemodynamic status, mental status, abdominal exam, and CT scan findings should be considered. All patients not proceeding directly to the operating room should be admitted for monitoring and observation (Fig 38.7).

Thoracoabdominal. Fifty percent of patients with gunshot wounds to the low chest have intraperitoneal injuries. Clinical indications for emergent or urgent laparotomy are as for abdominal gunshot wounds. CT scanning is highly accurate for identification of both chest and abdominal injury and should be obtained before the patient is transferred to the operating room, unless the patient's instability will not allow this.

Flank and back. CT scan is highly accurate for identification of retroperitoneal injury and is the diagnostic test of choice in a stable patient. Most patients are then taken to the operating room. In some cases of low-velocity gunshot wounds to the flank, laparoscopy or observation alone can be used if the CT scan shows no evidence of injury and the bullet track does not traverse any anatomically important structures.

Blunt Abdominal Trauma

In cases of blunt trauma, laparotomy based on clinical findings alone is a rare exception. More typically, one or a complementary battery of diagnostic tests are performed. The choice of these tests is influenced

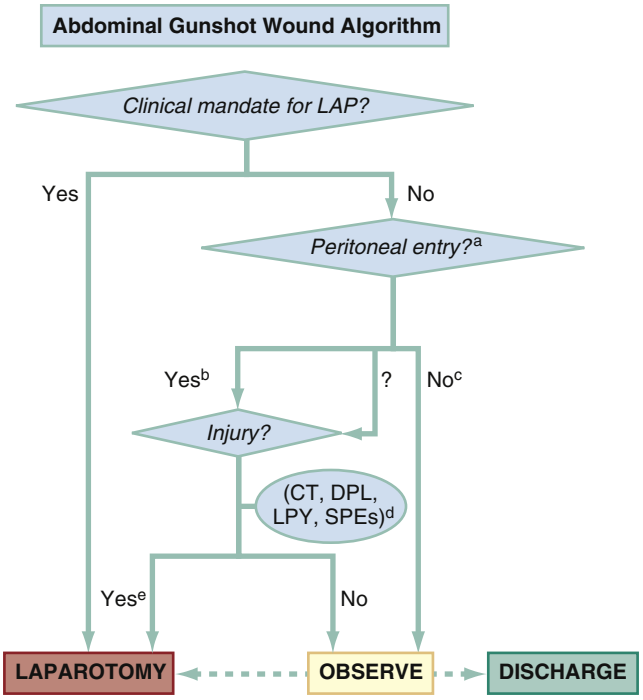

Fig. 38.7 Abdominal Gunshot Wound Algorithm. *LAP,* Laparotomy. [a]Can be assessed by missile path, plain films, local wound exploration, ultrasonography, and laparoscopy. [b]Most centers proceed to laparotomy if peritoneal entry is suspected. [c]Patients with documented superficial and low-velocity injuries can be discharged; unknown-depth or high-velocity injuries require further tests or observation. [d]Computed tomography *(CT),* diagnostic peritoneal lavage *(DPL),* laparoscopy *(LPY),* or serial physical examinations *(SPEs)* can be used in singular or complementary fashion, depending on the clinical scenario. [e]Expectant management of injuries caused by gunshot wounds is rarely attempted.

by the patient's hemodynamic status, the clinical scenario, and the institution's resources and preferences (Fig. 38.8).

The decision to perform immediate laparotomy after injury from a blunt mechanism is reserved for patients with the following findings (Table 38.2):

1. Refractory hypotension in a patient with positive e-FAST examination for hemoperitoneum and absence of an unstable pelvic fracture
2. Obvious peritonitis with positive e-FAST examination
3. Evidence on e-FAST of intra-abdominal injury in the context of other life-threatening injuries, such as uncontrollable chest hemorrhage, which require transfer to the operating room

In patients who are hemodynamically stable, CT scanning is the diagnostic modality of choice, as outlined earlier.

Operative Versus Nonoperative Management

Hemodynamically stable patients with solid organ injuries secondary to blunt trauma often can be managed without laparotomy. In patients with normal sensorium and without peritonitis or hemodynamic compromise, nonoperative management of blunt liver and spleen injuries has a success rate of 95%. [19–22] It is critical that an institution be adequately prepared to manage such patients, which includes having trauma surgeons, experienced nursing staff, adequate blood resources, and radiologists with the ability for rapid transfer to the OR for urgent laparotomy.

Several pitfalls in the expectant approach are noteworthy. First, hollow viscera injury, when present, requires operative management. The lack of sensitivity of CT scanning in the detection of hollow viscus injury is discussed earlier in this chapter. The patient with multisystem

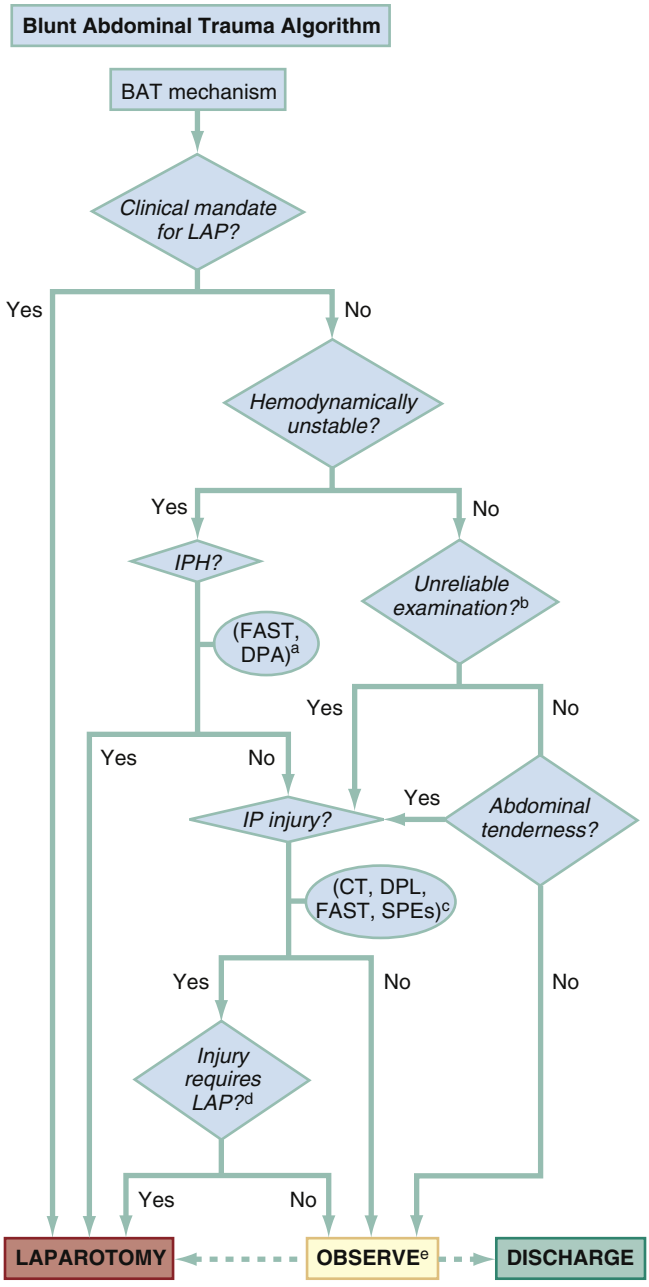

Fig. 38.8 Blunt Abdominal Trauma *(BAT)* Algorithm. *CT,* Computed tomography; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography for trauma; *IP,* intraperitoneal; *IPH,* intraperitoneal hemorrhage; *LAP,* laparotomy; *SPEs,* serial physical examinations. [a]Determined by unequivocal free intraperitoneal fluid on FAST or positive aspiration of blood on diagnostic peritoneal aspiration *(DPA).* [b]Can be unreliable because of closed head injury, intoxicants, distracting injury, or spinal cord injury. [c]One or more studies may be indicated. [d]Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources. [e]Duration of observation should be 6 to 24 hours depending on whether diagnostic tests have been performed, the results of the tests, and clinical circumstances, including the absence of factors rendering the examination unreliable.

injury and, specifically, closed head trauma is most vulnerable to having delayed diagnosis of perforated intestinal injury because of delayed development or impaired physical findings by abdominal examination. Second, expectant management may lead to increased use of blood products. Finally, this management approach will fail in those patients

TABLE 38.2 Clinical Indications for Laparotomy After Blunt Trauma

Manifestation	Pitfall
Unstable vital signs with strongly suspected abdominal injury	Alternate sources of shock
Unequivocal peritoneal irritation	Potentially unreliable
Pneumoperitoneum	Insensitive; may be caused by cardiopulmonary source or invasive procedures (diagnostic peritoneal lavage, laparoscopy)
Evidence of diaphragmatic injury	Nonspecific and insensitive, especially in penetrating trauma
Significant gastrointestinal bleeding	Uncommon, unknown accuracy

whose hemorrhage persists and is not amenable to therapeutic angiography and embolization. In such cases, the lag time from injury to an operative intervention may increase morbidity and mortality.

Pelvic Fracture

In the setting of pelvic fracture, the clinical triage determinant is the presence or absence of hemoperitoneum (Fig. 38.9). In a hemodynamically unstable patient with a pelvic fracture, the e-FAST exam is a reliable diagnostic bedside tool to identify clinically significant hemoperitoneum and guide further therapy.[23] If the e-FAST is negative and extra-abdominal sources of hypotension have been excluded, then the patient should proceed to therapeutic angiography with the presumed diagnosis of a life-threatening retroperitoneal bleed. In all patients, early mechanical pelvic stabilization is advised (see Chapter 46), and CT scan followed by pelvic angiography and embolization are undertaken as early as possible in the context of the multiple injuries.

Multiple System Injury

Complex trauma involving intraperitoneal hemorrhage in a patient with apparent closed head injury or suspected blunt aortic disruption or both is not uncommon. Operative intervention involving the abdomen usually takes precedence over that of the head and chest, given the key tenet that a patient with known hemoperitoneum whose vital signs cannot be stabilized should undergo laparotomy to avoid exsanguination. However, these situations are highly complex, and multispecialty decision making is influenced by numerous and dynamic variables. Approaches to two of these situations are summarized in Figs. 38.10 and 38.11.

Bedside Procedures

Diagnostic Peritoneal Lavage

Once the mainstay of evaluation of the abdominal trauma patient to determine the presence of injury and the need for laparotomy, diagnostic peritoneal lavage is currently largely of historic interest. Its remaining role in trauma is limited to centers where ultrasound equipment is not available or the clinician is not trained to perform ultrasound.

Local Wound Exploration

LWE is used to determine whether an anterior stab wound has penetrated into the peritoneal cavity in a nonobese patient. The wound is infiltrated with a local anesthetic containing epinephrine then carefully visualized through each successive layer of tissue. Blind probing with digits, instruments, or cotton-tipped swabs is unreliable, unless the peritoneal cavity is obviously freely entered. If LWE clearly indicates

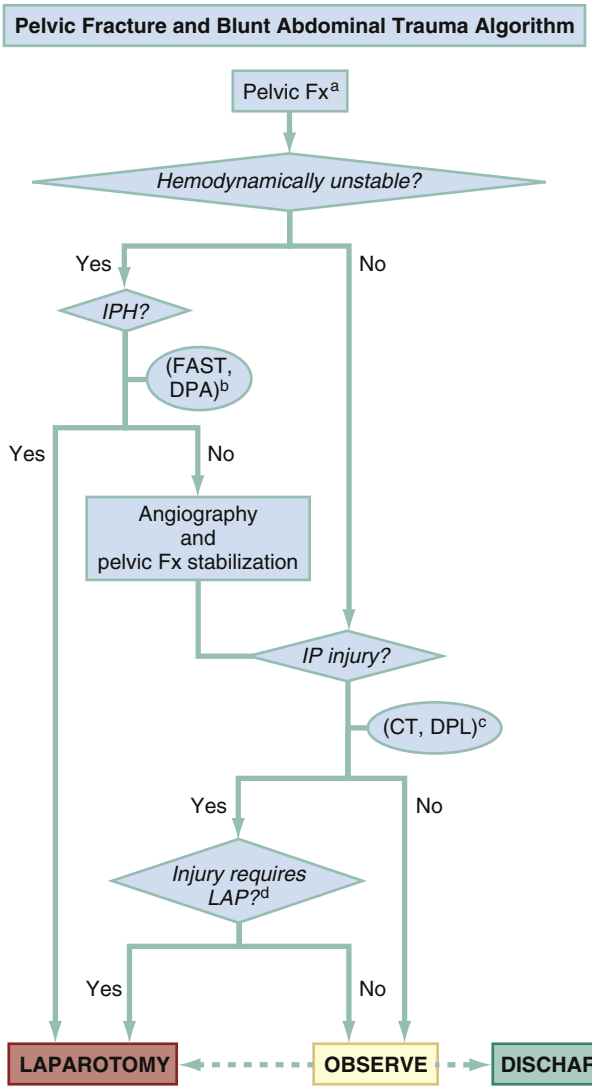

Fig. 38.9 Pelvic Fracture *(Fx)* and Blunt Abdominal Trauma Algorithm. *CT,* Computed tomography; *DPL,* diagnostic peritoneal lavage; *FAST,* focused assessment with sonography for trauma; *IP,* intraperitoneal; *IPH,* intraperitoneal hemorrhage; *LAP,* laparotomy. [a]Certain pelvic fractures are more likely to cause pelvic vascular disruption and subsequent retroperitoneal hemorrhage. [b]Determined by unequivocal free intraperitoneal fluid on extended e-FAST or positive peritoneal aspiration on diagnostic peritoneal aspiration *(DPA).* [c]One or more studies may be indicated. Serial physical examinations are generally considered unreliable owing to the presence of pelvic fracture. [d]Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources. [e]Discharge from the perspective of need for further consideration for laparotomy.

that the peritoneum is not violated, the e-FAST is negative, and the patient is otherwise uninjured, the injury can be treated as a local abdominal wall injury, and the patient is treated and discharged. Indication of entry into the peritoneal cavity or inability to locate the end of the wound tract is an indication for ongoing observation or abdominal CT scan (see Management section).

Wound exploration in patients with multiple entrances is impractical, requiring extensive effort, and it may be prudent to assume peritoneal penetration. Deep exploration over the thoracic cage is precluded by attendant complications to neurovascular structures and pleura. However, careful inspection of superficial chest wounds (e.g., slash wound) is safe and can provide diagnostic data.

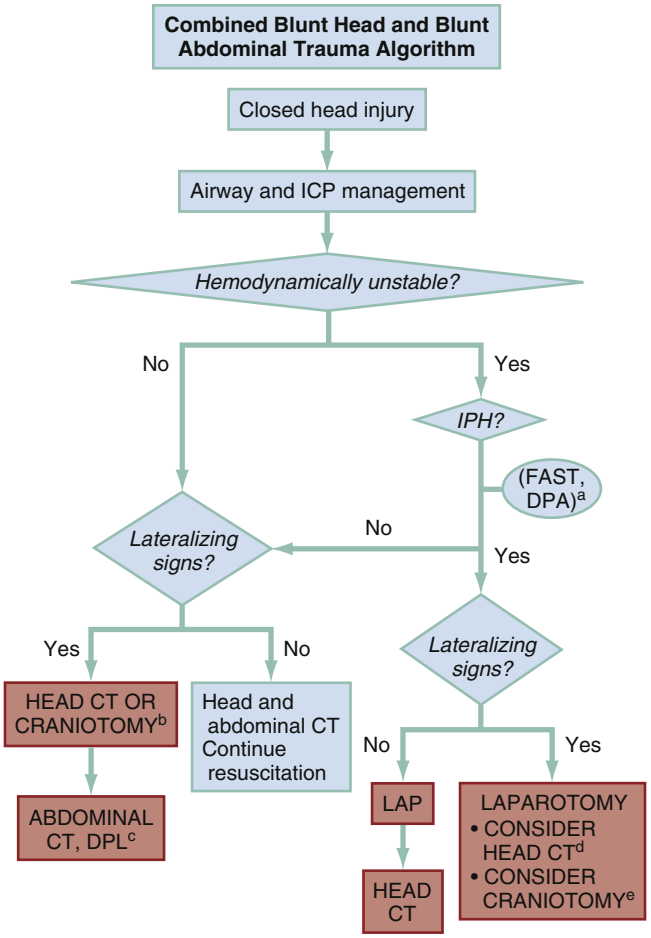

Fig. 38.10 Combined Blunt Head and Blunt Abdominal Trauma Algorithm. *CT,* Computed tomography; *ICP,* intracranial pressure; *IPH,* intraperitoneal hemorrhage. [a]Determined by unequivocal free intraperitoneal fluid on extended focused assessment with sonography for trauma *(e-FAST)* or positive peritoneal aspiration on diagnostic peritoneal aspiration *(DPA).* [b]Craniotomy or burr holes based on clinical picture and unavailability of computed tomography (CT). [c]Diagnostic peritoneal lavage *(DPL)* can be complementary to CT in determining hollow viscus injury. [d]Consider pre-laparotomy *(LAP)* head CT based on clinical picture and availability of CT. [e]Consider craniotomy or burr holes simultaneous with laparotomy.

[a]Preferably based on upright posteroanterior film and mechanism of injury; other radiographic signs or mechanism alone may signal need for evaluation. [b]Determined by unequivocal free intraperitoneal fluid on FAST or positive finding on diagnostic peritoneal aspiration *(DPA).* [c]Allows surgical access to majority of aortic disruption sites.

Resuscitative Endovascular Balloon Occlusion of the Aorta

REBOA is an endovascular procedure that can be performed at bedside to decrease ongoing intra-abdominal or pelvic exsanguination while increasing proximal (including cerebral) perfusion pressures. To place the device, access is obtained proximal to the bifurcation of the femoral artery, and the balloon is advanced and placed in the thorax distal to the subclavian for intra-abdominal bleeding or inferior to the renal arteries for pelvic bleeding. The balloon is partially inflated to increase proximal blood pressure while decreasing ongoing intra-abdominal bleeding. Indications for placement include life-threatening noncompressible hemorrhage unresponsive to resuscitation or traumatic arrest in place of resuscitative thoracotomy.[24,25] However, REBOA carries with it the risk of significant complications, including acute kidney injury, bowel ischemia, and lower extremity ischemia, particularly if the balloon is fully insufflated.[26] The optimal group to benefit from REBOA placement remains undefined. REBOA can be reliably learned within a formal training course and should be used only in the context of multidisciplinary protocols.[24] Should the device be placed, it should be considered a temporizing measure only as a bridge to definitive surgical management.

Therapeutic Angioembolization

Therapeutic angiography is usually reserved for the unstable patient with blunt trauma and pelvic fracture in whom it can be used to embolize bleeding vessels (Fig. 38.12). It can also be a means of stanching solid visceral hemorrhage from blunt trauma. Nonoperative management has become standard in management of splenic injuries but is associated with increasing failure rates in the setting of higher grades of injury. Successful nonoperative management increases significantly with the use of angioembolization. Angioembolization may have the added benefit over splenectomy of preserved splenic immunity, although further studies are needed. In both operative and nonoperative management of severe, isolated blunt liver injury, angiointervention is associated with increased survival despite increased systemic complications.[27] Angioembolization also has been used in rare cases for intraperitoneal and retroperitoneal hemorrhage after trauma by a penetrating mechanism.

DISPOSITION

Disposition will vary according to findings from the evaluation and the patient's clinical course. Stable patients without any identified injuries sustaining stab wounds (see Fig. 38.6) or blunt abdominal trauma (see Fig. 38.8) may be discharged home according to the algorithms provided. Patients sustaining penetrating wounds into the peritoneal cavity should

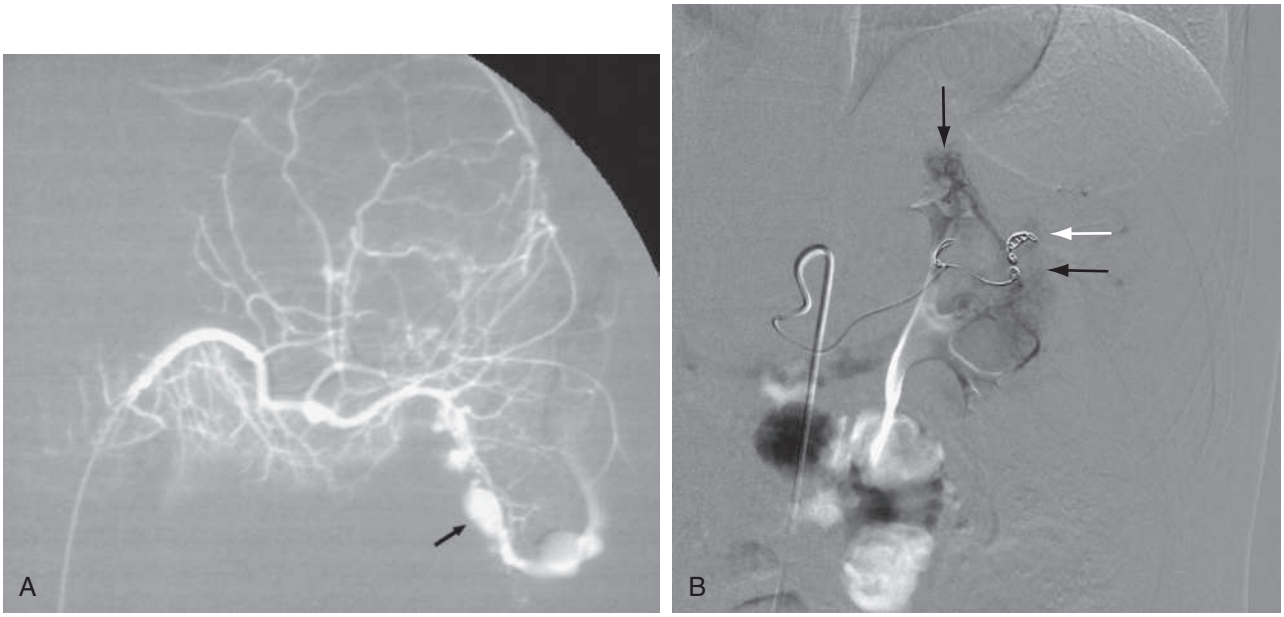

Fig. 38. 12 (A) Angiography of splenic laceration. Note the blush representing active hemorrhage *(arrow).* (B) Angioembolization of renal laceration. Note coil in the splenic artery *(white arrow)* and blush representing active hemorrhage stemming from two branches *(black arrows).* (A, From Mauro MA. *Image guided interventions.* Philadelphia: Elsevier; 2008:835)

either be admitted and followed with serial examinations or transferred immediately to the operating room (see Figs. 38.6 and 38.7). Patients sustaining blunt abdominal trauma should be taken to the operating room or angioembolization suite (see Figs 38.8, 38.9, 38.10 and 38.11), whereas stable patients with identified injuries can either be admitted for serial examinations or taken to the operating room, as necessary.

Consultation

Trauma is a multidisciplinary condition. Early consultation with a general or trauma surgeon or their involvement as part of a team response is a hallmark of an effective trauma center. Emergency clinicians provide care to the majority of abdominal trauma patients, but many injuries require operative intervention or prolonged observation on a surgical trauma service. Similarly, consultation with a radiologist may help to prioritize diagnostic studies, avoid unnecessary studies, or obtain the vital information with the minimum exposure of the patient to ionizing radiation or contrast material.

Transfer

Patients with significant abdominal trauma, whether blunt or penetrating, should be transferred to a trauma center as soon as possible after the threatening injury is identified and without delay for time-consuming imaging studies that will not alter the need for transfer. Trauma patients in nontrauma hospitals with significant transfer times may require a stabilizing "damage control" laparotomy by a general surgeon before being transferred to a trauma center for definitive care.

CHAPTER 38: QUESTIONS AND ANSWERS

1. The extended focused assessment with sonography for trauma (e-FAST) scan of a patient with blunt abdominal trauma shows a hypoechoic stripe in the pouch of Douglas. Which of the following is correct?

- **a.** In the presence of hemodynamic instability, this indicates a need for laparotomy.
- **b.** The patient needs to go for emergent laparotomy immediately.
- **c.** The patient requires repeat abdominal examinations and FAST examinations in the emergency department (ED).
- **d.** There is at least 500 mL free fluid in the abdomen.
- **e.** This indicates a ruptured bladder.

Answer: a. The pouch of Douglas is one of the areas of ultrasound inspection for an e-FAST examination. If free fluid is present and the patient is hemodynamically unstable, the patient should forego computed tomography (CT) scanning for the operating room. FAST examinations are effective in detecting as little as 100 mL of free fluid in the abdominal cavity.

2. An 18-year-old man presents after a high-velocity front-end vehicle collision. He has a blood pressure of 90/70 mm Hg, heart rate of 120 beats/min, respiratory rate of 17 breaths/min, and a Glasgow Coma Score (GCS) of 13. On physical examination, he has a tender abdomen and an unstable pelvis. An extended focused assessment with sonography for trauma (e-FAST) examination is positive for free fluid in the abdomen. What should be the patient's disposition?

- **a.** Admission to the trauma service for observation
- **b.** Emergency department (ED) observation for 12 hours with repeat FAST examinations
- **c.** Interventional radiology for pelvic angiography and embolization
- **d.** Operating room for emergency laparotomy

Answer: d. The e-FAST examination is an excellent bedside tool in guiding care in unstable patients with pelvic fractures. If the e-FAST exam shows intraperitoneal free fluid, the patient should be taken to the operating room emergently for laparotomy. If the e-FAST exam

CHAPTER 38: QUESTIONS AND ANSWERS—cont'd

is negative and no other readily identifiable source of hypotension is present, emergent pelvic angiography and embolization in interventional radiology (IR) is appropriate.

3. A 27-year-old male presents 4 hours after an isolated stab wound to the anterior abdomen. His vital signs are heart rate 84 beats/min and blood pressure 115/64, and the lactate level is 0.9 mg/dL. His extended focused assessment with sonography for trauma (e-FAST) examination is negative for free fluid. He denies alcohol and drug use and appears clinically sober. Which of the following statements regarding this patient's subsequent management is true?
   - **a.** A negative computed tomography (CT) scan rules out the need for further evaluation.
   - **b.** If local wound exploration (LWE) definitively demonstrates that the wound does not violate the peritoneum, the patient can be discharged from the emergency department (ED).
   - **c.** The negative e-FAST examination rules out intra-abdominal injury requiring operative intervention.
   - **d.** The patient meets criteria for emergent laparotomy.

Answer: b. Simple anterior abdominal stab wounds that do not violate the peritoneum can be discharged from the ED after appropriate wound care (see Fig. 38.6). CT scans poorly visualize both the small bowel and diaphragm and cannot be used in isolation to rule out injury in penetrating abdominal trauma. A negative e-FAST examination does not rule out significant intra-abdominal injury or even small-volume hemoperitoneum in either penetrating or blunt abdominal trauma. Not all anterior stab wounds meet indication for laparotomy, even in the presence of peritoneal penetration.

4. A 67-year-old female who is taking warfarin for atrial fibrillation presents after a high-mechanism motor vehicle collision. Her heart rate is 142 beats/min and blood pressure is 84/40 after 1 L of normal saline. Her Glasgow Coma Score (GCS) is 6, and her left pupil is 6 mm versus 3 mm on the right. Her physical examination is notable for a seat belt sign on the abdomen. Which of the following is *not* an acceptable approach to her initial assessment and treatment?
   - **a.** Perform an extended focused assessment with sonography for trauma (e-FAST) examination to evaluate for the presence of intra-abdominal fluid.
   - **b.** Perform chest and pelvic radiographs in the resuscitation bay.
   - **c.** Perform empirical craniotomy concurrently with laparotomy in the operating room after a positive diagnostic peritoneal aspiration.
   - **d.** Perform endotracheal intubation and begin mild hyperventilation.
   - **e.** Proceed to radiology for an emergent abdominal computed tomography (CT) scan.

Answer: e. The patient is hemodynamically unstable, with suspected intra-abdominal injuries in conjunction with signs of herniation. CT scanning of the abdomen would be inappropriate in this patient. Several concurrent management options to stabilize the patient and determine the source of her hypotension are desirable (see Fig. 38.10). Endotracheal intubation allows airway control and possible hyperventilation to delay impending herniation. Chest and pelvic radiographs rule out other sources of ongoing hemorrhage and may support emergent laparotomy. An e-FAST examination can confirm the presence of intra-abdominal free fluid, which in the setting of hemodynamic instability is an indication for laparotomy. Finally, after confirmation of intra-abdominal blood by e-FAST, proceeding to the operating room, with or without emergent CT scanning of the head, are management options. If the head CT is foregone because of instability, empirical craniotomy is an acceptable management option.

5. Which of the following statements regarding splenic injuries in blunt abdominal trauma is true?
   - **a.** A computed tomography (CT) scan with a grade IV splenic laceration indicates the need for laparotomy.
   - **b.** Angiographic embolization has no role in high-grade splenic lacerations.
   - **c.** Bedside extended focused assessment with sonography for trauma (e-FAST) can accurately rule-out splenic injury.
   - **d.** CT scanning followed by serial abdominal examinations and hematocrits is a reasonable management option for certain splenic injuries at experienced centers.
   - **e.** Mononucleosis increases the risk of splenic laceration from seemingly minor blunt abdominal trauma.

Answer: d. Serial abdominal examinations, laboratory tests, or repeat e-FAST examinations are reasonable management options at experienced centers. High-grade splenic lacerations, although having a higher rate of failed nonoperative or angiographic embolization management, do not represent a definitive indication for laparotomy. Angiographic embolization may preserve some of the immune function of the spleen, even in the setting of high-grade splenic lacerations. Bedside e-FAST, although sensitive for intra-abdominal fluid, is a relatively poor test for the evaluation of solid organ injury. Mononucleosis does increase the risk of splenic laceration. Trauma can be so minor that the patient may have little recollection of the remote trauma responsible.

Genitourinary Trauma

Spenser C. Lang and Sanjay N. Shewakramani

KEY CONCEPTS

- Microscopic or gross hematuria is suggestive of genitourinary trauma; however, the degree of hematuria does not correlate well with either the severity or anatomy location of injury.
- The kidney is the most frequently injured genitourinary organ, and imaging should be considered in patients with gross hematuria or microscopic hematuria with hemodynamic instability.
- Most noniatrogenic ureteral injuries are due to penetrating mechanisms and are unilateral; blunt ureteral trauma is rare. Delayed computed tomography (CT) images after intravenous (IV) contrast should be obtained in patients with mechanism or findings suggestive of ureteral trauma.
- CT scan with IV contrast is not sensitive for diagnosing bladder injury, and retrograde cystography should be obtained to allow proper distention of the bladder to allow for urinary extravasation.
- Pelvic fractures associated with hematuria strongly suggest bladder or urethral injury.
- Retrograde urethrography (RUG) should be performed in patients with pelvic fractures and hematuria, those with perineal ecchymosis or swelling, or those with blood at the urethral meatus, prior to attempting bladder catheterization, because blind passage of a Foley catheter in these scenarios can worsen a preexisting urethral injury.
- Genital injury is rarely life threatening but prompt diagnosis and evaluation are necessary to decrease the likelihood of future morbidity in these patients.

FOUNDATIONS

Background and Importance

Ten percent of trauma cases in the United States involve the genitourinary tract; however, most of these injuries are not life threatening. In fact, due to the anatomic protection of the kidneys, ureters, and bladder, as well as the mobile nature of the male external genitalia, isolated urologic injuries are uncommon in patients with major trauma. However, genitourinary trauma can cause significant, long-term morbidity, including renal insufficiency, chronic hypertension, incontinence, and sexual dysfunction. In addition, isolated traumatic renal injuries can be overlooked, due to the location of the kidneys and subtle presentation, with serious consequences for the patient.[1]

Approximately 5% of all trauma patients will have a concomitant renal injury, with a male predominance of 3:1.[2] Blunt mechanisms cause the vast majority of renal injuries. Although approximately half of all traumatic renal injuries are caused by motor vehicle collisions, it remains an uncommon injury that has continued to decrease with improvements in seat belts and airbags. Recent data show that less than 1% of all motor vehicle collisions result in any genitourinary trauma.[3] Although rare, 40% of patients with renal trauma also have a coexisting abdominal injury. Contrastingly, in urban or military settings, penetrating trauma accounts for 40% of renal injuries, and typically causes more tissue disruption and a higher severity of injury. Of the remaining blunt mechanisms, falls and direct blows (e.g., sports injuries or assaults) account for the majority of injuries.[4] Renal injuries from sports (e.g., skiing, snowboarding, and contact sports) tend to be isolated and can easily be overlooked.[5]

Pediatric renal injuries tend to be more common than in adults because children's kidneys are more mobile, are relatively larger, and have less perinephric adipose tissue. Blunt mechanisms are responsible for 90% of pediatric renal trauma.[6] Kidney injuries are more common than injuries to the spleen, liver, pancreas, and bowel in this population. However, due to more conservative approaches in management, even with high-grade injuries, pediatric renal trauma rarely leads to nephrectomy.[7]

Due to the long, tubular and mobile nature of the ureter and its location in the retroperitoneum (where it is well protected by the vertebrae and soft tissues), blunt traumatic injuries of the ureter are rare and virtually never occur in isolation. Most noniatrogenic ureteral injuries are due to penetrating mechanisms and are unilateral; the ureter is involved in up to 5% of penetrating injuries to the abdomen.[4]

After the kidney, the bladder is the most commonly injured genitourinary organ with blunt trauma. Bladder injuries occur in 1% to 2% of all blunt abdominal traumas and occur most frequently from motor vehicle collisions, which are responsible for approximately 50% of all bladder injuries.[1] Bladder injury most often occurs in the context of pelvic fractures or other intra-abdominal injuries. As a result, mortality rates in patients with blunt bladder trauma is as high as 22%, due mostly to the concomitant injuries.[8] The bladder also is subject to penetrating injury through the abdomen, rectum, or buttocks. Up to 80% of patients with penetrating bladder injuries also suffer bowel injuries.

Blunt trauma mechanisms, the majority of which are motor vehicle collisions, cause approximately 90% of urethral injuries. Males are five times more likely than women to suffer urethral injuries, due to the longer length and reduced mobility of the male urethra.[9] Similar to bladder injuries, significant blunt pelvic trauma is required to cause injuries to the urethra. As a result, concomitant injuries are often observed, particularly pelvic fractures or straddle-type injuries. Approximately 5% of pelvic fractures have an associated urethral injury.[10] Penetrating injuries to the urethra are rare (3% of all gunshot wounds) and are suspected on the basis of the nature and trajectory of the penetrating object.[11] Urethral trauma also can occur from misadventure during self-instrumentation, which is most often related to sexual activity. Urethral injury can cause significant morbidity, via stricture formation, incontinence, erectile dysfunction, and infertility. These injuries tend to occur in younger patients, and complications are common, even if urethral injuries are appropriately diagnosed and treated.[12]

The external genitalia, particularly the scrotal contents, are subjected to direct injury, which happens most frequently in sports-related trauma. Minor external trauma may occur with consumer products

(including zippers, sporting items, and moving furniture), and the large majority of these injuries are self-limited. Severe injuries, including penile fractures and testicular rupture, are rare but generally require emergent surgical management. These injuries also can lead to long-term reproductive, physiologic, and psychological consequences.[13]

The overall rates of external genital trauma are low in females, with the most common mechanism being childbirth-related injuries. However, blunt trauma, causing lacerations or hematomas, can occur. Unfortunately, in many parts of the world, female genital mutilation and sexual violence can lead to disfigurement, sexual dysfunction, and incontinence.[14]

Anatomy and Physiology

The genitourinary tract is divided into the upper tract (kidneys and ureters, including the renal pedicle), lower tract (bladder and urethra), and external genitalia (penis, scrotum, testicles, and vulva).

The kidneys are retroperitoneal organs that are encapsulated by fibrous tissue known as *Gerota fascia*. They lie against the psoas muscles, are surrounded by the ribs and spinal column, and are well-cushioned by perinephric fat, leaving them fairly well-protected (Fig. 39.1). This explains why isolated renal injury is rare in trauma, because it requires a significant mechanism to cause injury. However, the lower poles of the kidney do project inferior to the twelfth rib bilaterally, which makes them susceptible to trauma.[1] Due to their proportionately larger kidneys with less perirenal fat, weaker abdominal muscles, and a less rigid chest wall, children are at higher risk for renal injury.[6]

The renal pedicle—which includes the renal artery, renal vein, and the ureter—inserts into the kidney along the medial border, at the hilum. A longitudinal cross-section of the kidney reveals the outer renal cortex with inner medulla that compose the renal parenchyma (Fig. 39.2). These create and drain urine into the calyces, which flow into the renal pelvis, which then drains into the ureter.

The bladder is a muscular organ that lies in the abdomen at birth but descends into the pelvis at approximately 6 years old and is thus considered extraperitoneal. It is heavily protected by the bony pelvis, especially when it is not distended. However, when distended, the dome of the bladder rises into the abdomen (as high as the umbilicus), making it more prone to both blunt and penetrating trauma. Children are more prone to bladder injuries due to their underdeveloped pelvic structures.[15] Posteriorly, the bladder connects to the ureters on the superior aspect, and in males, it is adjacent to the seminal vesicle and vas deferens on the inferior side. Loose connective tissue surrounds the bladder laterally.

The male urethra is approximately 22 cm in length when measured from the bladder to the urethral meatus (Fig. 39.3). The urogenital diaphragm divides the posterior urethra (composed of the prostatic and membranous segments) from the anterior urethra (composed of the bulbous and penile segments). The fossa navicularis is the slightly dilated segment of the penile urethra contained within the glans. Although the anterior urethra is more mobile, the posterior urethra is anchored to the anterior pubic arch by the puboprostatic ligaments.[16] The female urethra is only approximately 5 cm long and is protected

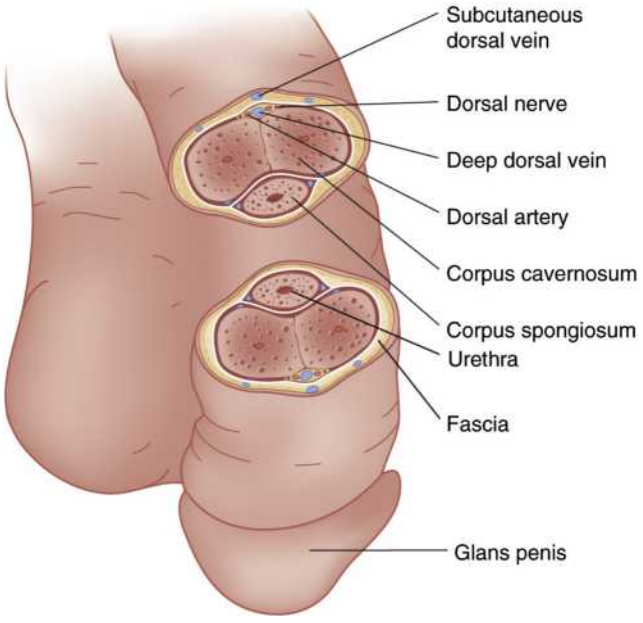

Fig. 39.5 Cross-sectional View of the Penis.

due to its close association with the vagina, which absorbs the majority of the force during trauma. In addition, the female urethra has no significant attachments, making it mobile, and reducing the likelihood of significant trauma.[17]

The testicles normally measure 5 × 3 × 2 cm each and are individually encapsulated by the fibrous tunica albuginea (Fig. 39.4). The encapsulated testicles are then surrounded by the tunica vaginalis, which has both a visceral and parietal surface. The potential space between these surfaces allows for hydroceles or hematoceles to form. Each half of the scrotum contains a separate testicle, spermatic cord, and epididymis.

The penis is composed of two paired corpora cavernosa along the dorsal aspect and a corpus spongiosum along the ventral surface (Fig. 39.5). Corpora cavernosa are filled with venous sinusoids that surround a central artery and engorge with blood during an erection, whereas the corpus spongiosum surrounds the urethra and forms the glans penis on its distal aspect. Each of the three is surrounded by a separate fascial sheath, which also is referred to as the *tunica albuginea.* Buck fascia, the deep fascia of the penis, immediately surrounds the three structures, and multiple other superficial fascial layers further surround Buck fascia. The superficial and deep dorsal veins provide most of the venous drainage

from the penis. The female external genitalia consist of the labia, vulva, and the vagina, as well as the clitoris. The thighs and groin provide relative protection, and isolated injuries to this area should raise suspicion for physical, sexual, or otherwise intentional abuse.[14]

Pathophysiology

Because it is fixed in space only by the renal pelvis and pedicle, the kidney is prone to acceleration and deceleration injuries from blunt trauma. The American Association for the Surgery of Trauma (AAST) guidelines for grading blunt renal trauma are essentially unchanged since their creation, with grades III, IV, and V defined as "high-grade" renal trauma (Table 39.1 and Fig. 39.6).[1] Higher-grade injuries not only require different treatments but are predictive of future morbidity, such as risk of chronic kidney disease and hypertension.[18] Lacerations and contusions typically occur from direct trauma, whereas renal artery avulsions can occur from deceleration mechanisms. Renal artery occlusion can occur when the renal artery is compressed between the anterior abdominal wall and vertebral bodies, or from arterial spasm due to surrounding contusions.[19] Penetrating injuries, typically due to gunshot and stab wounds, can cause similar patterns of injury as blunt injuries but tend to be more severe.

Blunt injuries can cause trauma to the ureter either directly from compression against fractured bony structures (e.g., transverse processes of lumbar vertebrae) or by deceleration mechanisms, which can cause a disruption at the ureteropelvic and the ureterovesical junctions.[4] Due to their hyperextensible vertebral columns, children are more prone to deceleration mechanisms. Penetrating injuries are almost exclusively unilateral, tend to occur in the distal third of the ureter, and carry a mortality rate of up to 6%. They are commonly associated with bowel and vascular injuries.[15]

Bladder injuries range from mural contusions (representing 20% of all injuries) to bladder ruptures, which are defined as lacerations through the entire wall of the bladder.[8] Ruptures are further classified into intraperitoneal bladder ruptures (IBRs) and extraperitoneal bladder ruptures (EBRs). Intraperitoneal injuries resulting from blunt trauma are typically caused by rupture of a distended bladder at its weakest point, which is the dome where it abuts the peritoneum. As a result, urine drains into the peritoneal cavity. Intraperitoneal ruptures tend to occur in high-impact injuries, such as motor vehicle collisions, but more recently up to 10% of bladder injuries have occurred from

TABLE 39.1 The American Association for the Surgery of Trauma Grading Scale for Classification of Renal Trauma

Grade	Type	Description
I	Contusion	Microscopic or gross hematuria
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confirmed to renal retroperitoneum
	Laceration	<1 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	>1 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through the renal cortex, medulla, collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum that devascularizes kidney

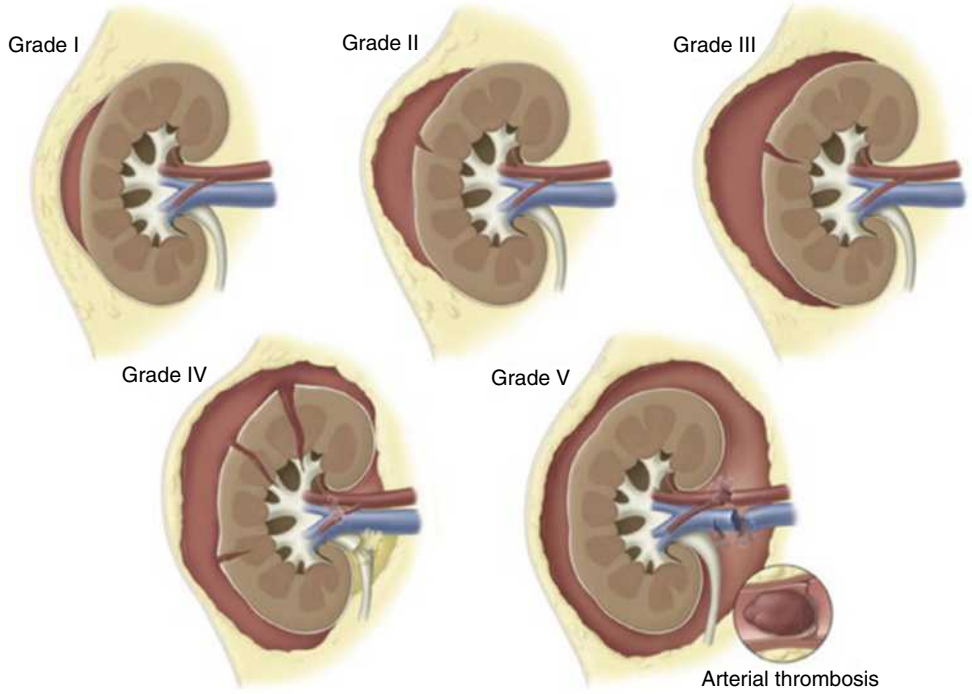

Fig. 39.6 Schematic of the American Association for the Surgery of Trauma (AAST) grading scale for renal trauma. (From Myers JB, Brant WO, Broghammer JA. High-grade renal injuries: radiographic findings correlated with intervention for renal hemorrhage. *Urol Clin North Am* 2013;40:335–341.)

sports-related abdominal trauma.[15] Case reports of nontraumatic IBRs have also been reported in patients with forceful vomiting.[20,21] EBRs, which account for the majority of bladder ruptures, occur as the result of direct compression, shear forces at the bladder base, or lacerations from bony spicules from pelvic fractures.[10] These ruptures result in urine draining into the pelvic cavity. Approximately 10% of bladder injuries are both intraperitoneal and extraperitoneal.[1,22]

With blunt trauma to the pelvis, shearing forces transmitted through the urogenital diaphragm create tension along the male urethra, most often between the anterior and posterior segments at the bulbomembranous junction. These forces occur commonly in unstable pelvic fractures, bilateral ischiopubic rami fractures, and symphysis pubis diastasis injuries. Injuries can range from stretching, to partial lacerations, to complete disruptions of the urethra; the latter of which accounts for 50% to 65% of urethral injuries. The majority of these injuries involve the posterior urethra, and the most severe injuries are complex posterior injuries involving the bladder neck or rectum.[1]

Blunt anterior urethral injuries, which are four times less common than posterior injuries, are often caused by straddle-type mechanisms, which result in crushing of the bulbar urethra against the inferior aspect of the pubic bone (Fig. 39.7).[23] These injuries occur more commonly in children and can be easily missed, potentially resulting in future strictures.[24] Gunshot wounds and other penetrating injuries more commonly involve the anterior urethra than the posterior urethra.[11] Urethral injuries in adult females are rare due to the urethra short course and relative mobility. However, female children are at higher risk, and urethral injuries in this population are associated with pelvic circle disruptions, multiple pelvic fractures, vaginal lacerations, hematomas, or sacral spine injuries.[25]

In addition to testicular rupture, which is caused by disruption of the testicular tunica albuginea, blunt trauma can also lead to scrotal hematomas, hematocele, spermatic cord injuries, testicular contusions, testicular fractures, testicular dislocation, and, rarely, traumatic testicular torsion or epididymitis.[26] Testicular hematomas form within the testicle and may be associated with testicular rupture, whereas testicular fractures are defined as linear avascular areas within the testicular parenchyma without rupture of the tunica albuginea. More than half of patients presenting to the emergency department (ED) with scrotal trauma may have a ruptured tunica albuginea (i.e., testicular rupture), although it is a rare injury.[1] Testicular dislocation occurs when blunt trauma forces the extrascrotal migration of one or both testicles, although bilateral dislocations are rare. They migrate along the course of the spermatic cord and typically are found in the superficial inguinal area, but they can even be found in the suprapubic region. Penetrating injuries violate the tunica albuginea in more than half of cases.[1]

Penile fractures, due to tears of the tunica albuginea, account for the majority of blunt penile injuries that present to the ED. Blunt trauma can also lead to rupture of the dorsal veins or artery, resulting in local ecchymosis that can be easily mistaken for a penile fracture, and is therefore termed a *false penile fracture*.[27] In these cases, the tunica albuginea is typically intact, and patients do not require immediate operative exploration.[28] Penetrating injuries to the penis involves the urethra in up to 29% of cases and can also result in penile amputation, which is more common in patients with a psychiatric history.[13]

Nonsexual genital injuries in females are most often due to straddle injuries in young girls, but other blunt and penetrating injuries do occur and are usually more severe. The labia are most frequently involved, as well as the perineum. Penetrating injuries can involve the rectum as well as urethra, and these deeper injuries can easily be missed in young girls if a thorough examination is not performed.[14]

The diagnostic and management approach to each organ varies, necessitating a basic understanding of the anatomy and traumatic pathophysiology of each individual organ. The majority of cases require early urologic consultation. The clinical features, diagnostic approach, and management guidelines for the specific organs are discussed in the following sections.

Renal Trauma

Clinical Features

The history for patients with renal trauma includes the mechanism of injury for blunt trauma and the type of projectile or weapon for penetrating injury. Any high-energy impact or direct blow to the flank or abdomen can lead to renal injuries. Various other traumatic injuries tend to accompany renal injuries due to the significant anatomic protections of the kidneys. Gross or microscopic hematuria warrants careful consideration for genitourinary injury, although the degree of hematuria does not necessarily correlate with the degree or grade of injury, and significant genitourinary trauma can occur without hematuria.[2] Importantly, hematuria can represent injury at any level of the genitourinary system and does not localize to the kidneys. Renal injury

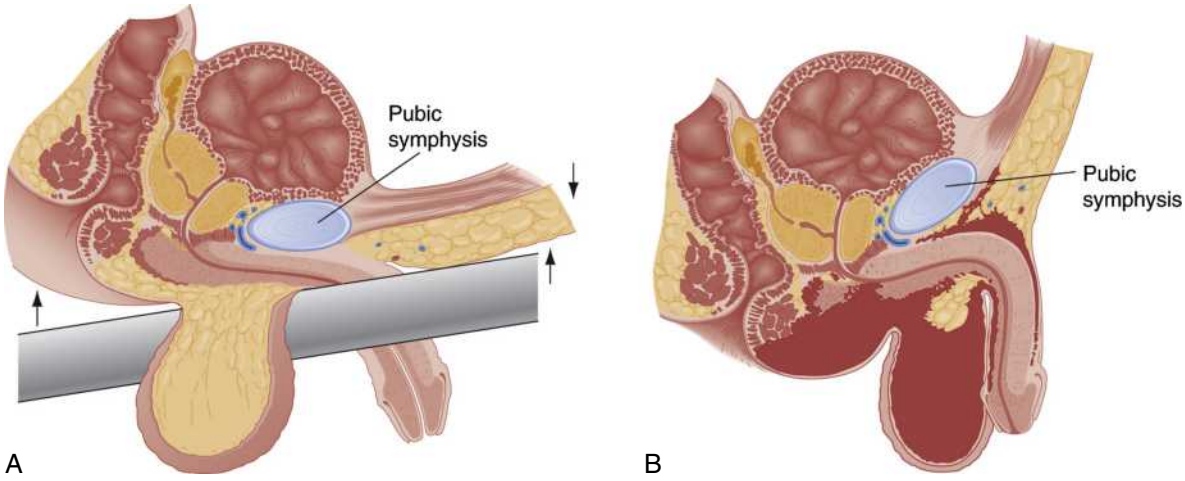

Fig. 39.7 Injury to the bulbous urethra due to straddle mechanism. (A) Mechanism: Usually a perineal blow or fall astride an object, crushing the urethra against inferior edge of pubic symphysis. (B) Extravasation of blood and urine enclosed within Colles fascia. (From McAninch JW. Injuries to the genitourinary tract. In: Tanagho EA, McAninch JW, eds. *Smith's general urology*. 14th ed. Norwalk, CT: Appleton & Lange; 1995.)

requiring intervention is rare in the absence of gross hematuria or shock. Examination of the patient with multisystem trauma may reveal shock; flank tenderness, fullness, or ecchymosis; loss of flank contour; obviously fractured ribs; abdominal tenderness or distention; or a palpable abdominal mass.[4]

Differential Diagnoses

Blunt or penetrating trauma can result in a range of injuries to the kidney and the vascular supply to the kidney, as shown in Table 39.1. Injuries to the renal parenchyma can cause contusions or lacerations within the kidney or hematomas surrounding the kidney. Vascular injuries can involve the renal artery or vein and vary in significance. Minor injuries to the vascular supply can lead to a contained hematoma, but hilar avulsion can result in complete devascularization of the kidney.[1]

Diagnostic Testing

Although significant renal injury can occur without causing hematuria, 95% of all patients with renal trauma have some hematuria on urinalysis, which is defined as more than five red blood cells per high-power field, or a positive urine dipstick. Patients with multisystem trauma, especially with evidence of blood loss, require a complete blood count and type and screen. Creatinine drawn within an hour of injury reflects renal function prior to the injury and thus serves as a baseline for future testing.[4]

Gross hematuria in a patient with a mechanism consistent with possible renal injury requires further investigation. Conversely, microscopic hematuria in a blunt trauma patient without shock is not a definite indication for renal imaging, even if there is evidence of mild local trauma, in the absence of other clinical signs. Although renal injuries may uncommonly be identified on imaging, the injuries are mild and patients typically do not require intervention. Imaging should be performed, with either gross or microscopic hematuria, in trauma patients with evidence of hemodynamic instability (systolic blood pressure less than 90 mm Hg), presence of lower rib fractures, significant flank ecchymosis, evidence of intraperitoneal injury, or specific mechanisms (e.g., rapid decelerations, significant blow to flank, or penetrating injuries). In addition, with gross hematuria, imaging should include the entire urinary tract or localized to the lower tract (bladder and urethra), depending on the mechanism and location of the injury.[1]

Multidetector computed tomography (CT) with intravenous (IV) contrast is the gold standard to evaluate for renal injury, with nearly 100% sensitivity and specificity.[22] CT can evaluate for renal lacerations, hematomas, extravasation of contrast, devascularized renal segments, and urinary extravasation and is used to provide a grade for the severity of renal trauma (Fig. 39.8). When renal injuries are highly suspected or visualized in real time, delayed images should be performed 10 minutes after administration of IV contrast to better evaluate the extent of injury,

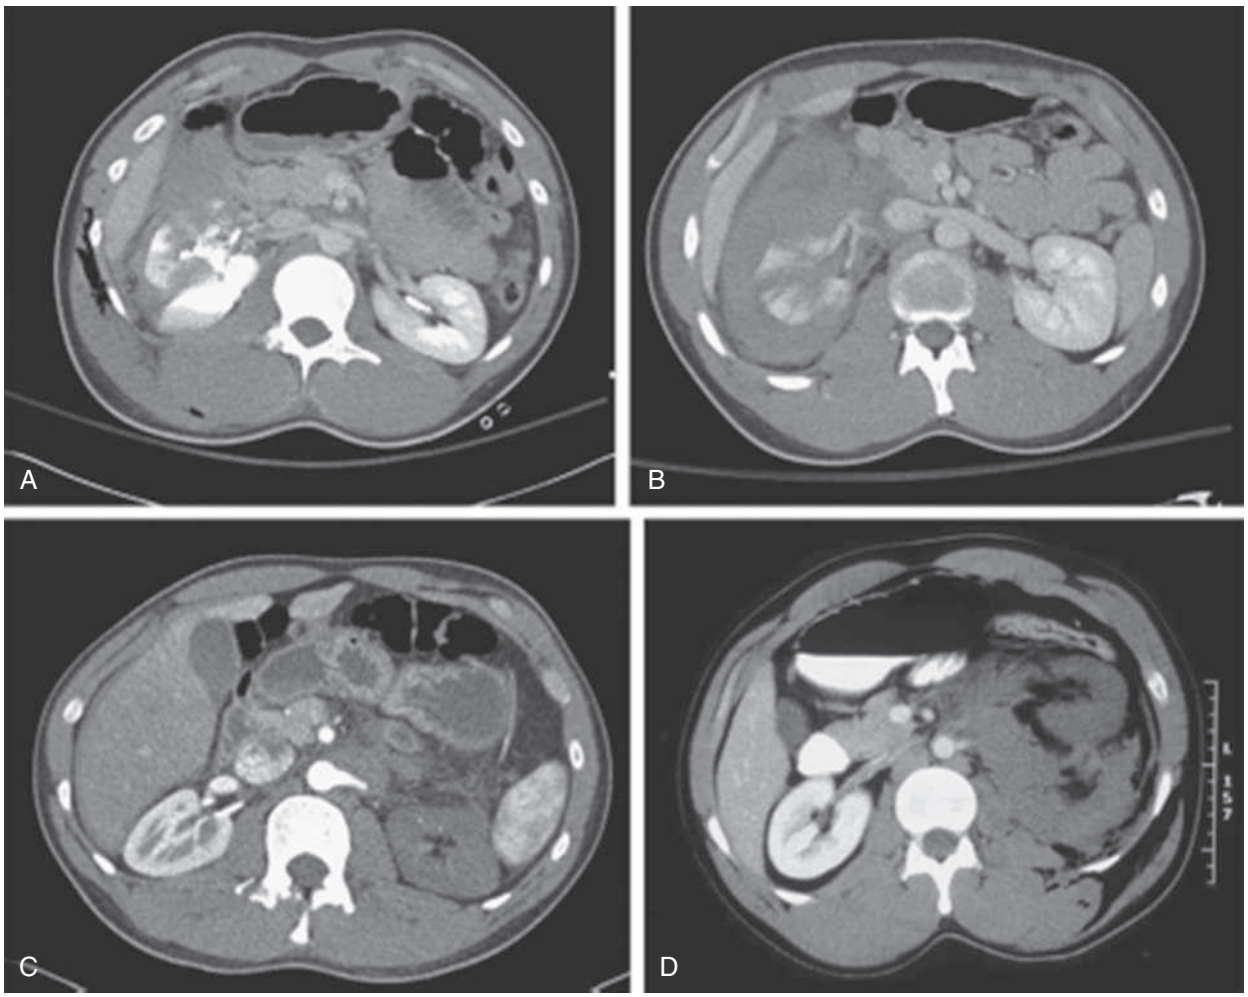

Fig. 39.8 High-grade Renal Injuries. (A) Grade IV injury with urinary extravasation. (B) Severe grade IV laceration, also referred to as *shattered kidney*. (C and D) Grade V injuries with devascularization of the affected kidney. (From Myers JB, Brant WO, Broghammer JA: High-grade renal injuries: radiographic findings correlated with intervention for renal hemorrhage. *Urol Clin North Am* 2013;40:335–341.)

as well as to assess for collecting system disruption, possible urinary extravasation, or accompanying ureteral damage. (Fig. 39.9).[1] In pediatrics, CT with IV contrast remains the gold standard, and obtaining initial delayed imaging can result in avoidance of repeated imaging later during the hospitalization, lowering the overall radiation to the child.[29]

Ultrasound can demonstrate renal injuries but has historically had lower sensitivity and specificity than CT, but the quality and predictability is operator dependent. It is also difficult to determine the depth and extent of renal lacerations, and it is often unclear if fluid seen surrounding the kidney on ultrasound represents urine or blood. However, unlike CT, ultrasound can be performed at the bedside if the patient is unstable and is often used in various other ways during an initial evaluation of a multisystem trauma patient because views of both kidneys are obtained during a focused assessment with sonography in trauma (FAST) examination. Recent studies have demonstrated comparable diagnostic accuracy with renal ultrasound in pediatric patients in both isolated renal injuries and multisystem trauma patients. Importantly, either radiologists or ultrasound technicians were performing the studies, and these data might not be applicable without those specialists present.[30]

Management

Multisystem trauma is managed in collaboration with a general or trauma surgeon, and prompt consultation with a urologic surgeon is indicated when there is injury to the urinary tract. Fig. 39.10 represents an algorithm for the management of blunt trauma to the kidneys. After renal trauma is identified on imaging, hemodynamic instability determines the next intervention. If the patient is unstable despite fluid resuscitation, they should undergo surgical exploration, with the extent of renal trauma determined intraoperatively. Hemodynamically stable patients found to have minor renal injuries (grade I to III) typically require only conservative management (including fluid resuscitation and observation). High-grade injuries (grade IV and V) are more likely to require operative intervention; however, over the past decade, even high-grade injuries (grade IV and V) are increasingly treated nonoperatively initially, with comparable outcomes.[31]

Therapeutic options for blunt renal trauma include nephrectomy, ureteric stenting, percutaneous drainage, and arterial embolization. Recent changes in management have increasingly focused on nonoperative therapy, leading to increased renal salvage in even high-grade injuries. Surgical practice has shifted away from early exploration due to the high number of nephrectomies performed with early exploration.[32] Both European and American urotrauma guidelines advocate for nonoperative initial management for all hemodynamically stable patients. The rates of renal salvage and decreased morbidity has improved alongside more advance endoscopic and transarterial embolization techniques.[33] This shift has been even more pronounced in the pediatric population, where the renal salvage rate now approaches 99%. In the past, penetrating renal injuries mandated urgent surgical exploration. More recently, urologists treat penetrating injuries with observation or embolization. Importantly, some injuries might require operative intervention, but morbidity and nephrectomies are decreased if operative management is performed in a delayed fashion.[1,34,35]

Although initial nonoperative management is preferred, certain factors do predict future need for operative management. Ten percent of grade IV injuries will require an open surgical procedure, and this number increases to approximately 50% for grade V injuries.[33] In addition, deceleration mechanisms, persistent hemorrhage, fevers, multiple comorbid injuries, and initial angioembolization all predict the need for surgical intervention.[7] The decision to obtain repeat CT imaging should be guided by individual patient characteristics and is not necessary for every patient with a renal injury.[36] Hemodynamic instability, decreased hemoglobin, and fevers are the most common reasons for obtaining repeat CT.

Early complications of renal trauma include persistent bleeding, infection (urinary tract infections, perinephric abscesses, and sepsis), persistent urinary extravasation and urinoma, and transient hypertension. In general, early antibiotics should be considered for all patients with renal trauma to potentially avoid future urinary tract infections and perinephric abscess formation. Long term, patients most commonly suffer from chronic kidney disease and hypertension and can develop urinary fistulae and arteriovenous malformations. The risk of chronic complications increases with the grade of the injury.[4] Grade III, IV, and V injuries are associated with a decrease in renal function of 15%, 30%, and 65%, respectively, after trauma. High-grade injuries are associated with increased rates of hypertension as well, because grades IV and V are associated with a 3.5-fold higher risk of being diagnosed with hypertension in the future.[18]

Disposition

Patients with traumatic renal injury generally require urgent evaluation by a urologist. Despite low rates of early complications, it recommended that patients with renal injuries be at least observed for repeat examinations and serial diagnostic studies. Hospital length of stays tends to be of similar with conservative or operative management.[37] As with many traumatically injured patients, those with renal injuries tend to have better outcomes in high-volume tertiary care centers, where patients require fewer operations and have improved renal salvage rates.[38] Because the majority of patients with renal injuries have concomitant traumatic injuries, consultation with both trauma and urologic surgery services is important in determining the appropriate disposition for these patients.

Ureteral Trauma

Clinical Features

There are no pathognomonic clinical signs of ureteral injury, and suspicion must be based on mechanism and signs of other traumatic injuries on physical exam. These include signs of intra-abdominal or retroperitoneal injury, including flank ecchymosis, gross or microscopic hematuria, and abdominal distention or tenderness. However, hematuria is seen in less than half of patients and is usually microscopic. Associated injuries include fractures of the transverse process of lumbar vertebrae, pelvic fractures, bowel injuries, and vascular damage, particularly of the iliac vessels given their proximity to the ureters. Importantly, because the majority of these patients have multisystem traumatic injuries, they typically do not have complaints attributable to the ureter, despite having a significant injury. Given their subtle presentation, if not rapidly diagnosed by imaging or intraoperatively, ureteral injuries often do not declare themselves until days later when patients present with sepsis (from urinary extravasation), hydronephrosis from obstruction, or a urinary fistula.[15]

Differential Diagnoses

Blunt trauma affecting the ureter can lead to stretching and resultant hematomas or, if more severe, partial or complete disruption of the ureteral wall.[15] Penetrating injuries involving the ureter generally result in complete or partial transection.[11]

Diagnostic Testing

Hematuria is not a reliable indicator of ureteral trauma because it is present in less than 50% of patients. However, blunt ureteral injury is rare, and further diagnostic evaluation for ureteral injury is reserved for patients with unexplained persistent hematuria or evidence of injury adjacent to the ureter, such as retroperitoneal vascular injury,

Fig. 39.11 Intravenous (IV) urography revealing an injury to the left distal ureter, resulting in contrast extravasation. (From Cutinha P, Venugopal S, Salim F. Genitourinary trauma. *Surgery [Oxford].* 2013;31:362–370.)

vertebral fractures, or pelvic fractures. Penetrating injuries in the location of the ureters should prompt imaging or operative exploration. The best modality for diagnosing ureteral injury is CT scan with IV contrast (CT urogram).[1]

IV pyelography/urography and retrograde pyelography (Fig. 39.11) were once used to diagnose ureteral injury, but they have been supplanted by CT scanning. A CT scan performed immediately after the administration of IV contrast can potentially miss ureteral injuries, and 10-minute delayed CT urogram imaging (allowing for contrast to opacify the collecting system and ureters) is recommended.[39] CT findings of ureteral injury include contrast extravasation, a delayed pyelogram, hydronephrosis, low-density retroperitoneal fluid (representing urinary extravasation), or lack of contrast distal to the ureteral injury.[15] Retrograde or anterograde urography is the gold standard for confirmation in stable patients with unclear or potentially delayed ureteral injury,[4] In unstable patients requiring surgical intervention, a single image intraoperative IV pyelogram can be performed to directly assess the ureters.[15]

Management

With minor injuries, including contusions and partial lacerations, ureteral stenting is typically sufficient. However, if enough tissue is devitalized, short-segment removal and primary anastomosis may be necessary. Additional options include percutaneous nephrostomy for unstable patients and ureteral reimplantation into the bladder. Rarely, severe injuries require nephrectomies, typically when renal function is less than 20% of baseline.[15]

Almost one-quarter of all patients develop a complication after ureteral injury, which are rarely life threatening but can occasionally lead to the loss of the affected kidney. Urinary leaks leading to sepsis or fistulas, as well as strictures, are among the most common complications. These complications are frequently seen when diagnosis of the initial injury is delayed. If suspicion is high, a repeat CT urogram or retrograde pyelogram should be performed.[15]

Disposition

As with most urogenital trauma, prompt consultation with a urologic surgeon is necessary for patients with ureteral injuries, because nearly all will require admission and some type of procedural or operative intervention.

Bladder Trauma

Clinical Features

In contrast to ureteral injuries, hematuria is the hallmark of a bladder injury, with gross hematuria noted in 72% of patients with blunt trauma to the bladder and up to 95% of patients with penetrating bladder trauma.[1] Other signs and symptoms include abdominal tenderness or distention, blood at the urethral meatus, the inability to void, ecchymosis, or entrance and exit wounds in the perineum, thigh, or abdomen.[23]

Differential Diagnoses

Differentiating IBR from EBR is of the utmost importance due to significant differences in management. Intraperitoneal injuries are most often caused by blunt force abdominal trauma in a patient with a distended bladder. Extraperitoneal injuries are usually associated with some form of pelvic trauma. Gross hematuria should also raise suspicion for other injuries in the genitourinary tract aside from bladder injuries.

Diagnostic Testing

Other than urinalysis, laboratory evaluation is not useful in diagnosis of acute bladder injury. Gross hematuria is present in the majority of cases; those without gross hematuria will have microscopic hematuria. Approximately 5% of bladder ruptures will not have gross hematuria; however, if there are less than 25 red blood cells per high-powered field on microscopic urine analysis, a rupture is extremely unlikely.[11] High-energy pelvic fractures, such as symphysis diastasis and displaced obturator ring fractures, should also raise the suspicion of bladder injury.[10]

All stable trauma patients with gross hematuria and pelvic fracture should undergo cystographic imaging, due to the high likelihood of bladder injury. Not all patients with microscopic hematuria and pelvic fracture require imaging for bladder injury; however, certain fracture patterns should raise suspicion and prompt investigation, as well as clinical signs of bladder rupture. These fractures include pubic symphysis diastasis as well as significantly displaced obturator ring or pubic rami fractures.[1] Gross or microscopic hematuria in patients with a penetrating injury suggesting a pelvic trajectory require further imaging.[11] CT scan performed with IV contrast alone does not sufficiently distend the bladder to evaluate for mural defects, leading to false-negatives, and thus retrograde "stress" cystography should be performed. This involves diluting 30 mL of water-soluble ionic contrast in a 500-mL bag of warmed saline. Approximately 300 to 400 mL of this solution is then introduced into the bladder via a Foley catheter using gravity.[22] Foley catheterization should not be performed unless the clinician is confident that a urethral injury is not present (see discussion following). By distending the bladder, thrombi that may have formed along the bladder wall are dislodged, allowing for urinary extravasation. Images are then acquired to assess for rupture, either by fluoroscopy or CT scan. Conventional fluoroscopic cystography can assess for urinary extravasation (Figs. 39.12 and 39.13). However, CT imaging is more sensitive (95%) and can evaluate for foreign body involvement from fractures or bladder neck injuries. An EBR may demonstrate a "molar tooth" appearance on cystography, which represents contrast tracking along the pelvic fascial planes (Fig. 39.14), whereas an IBR reveals contrast material outlining the intraperitoneal structures (Fig. 39.15).[39]

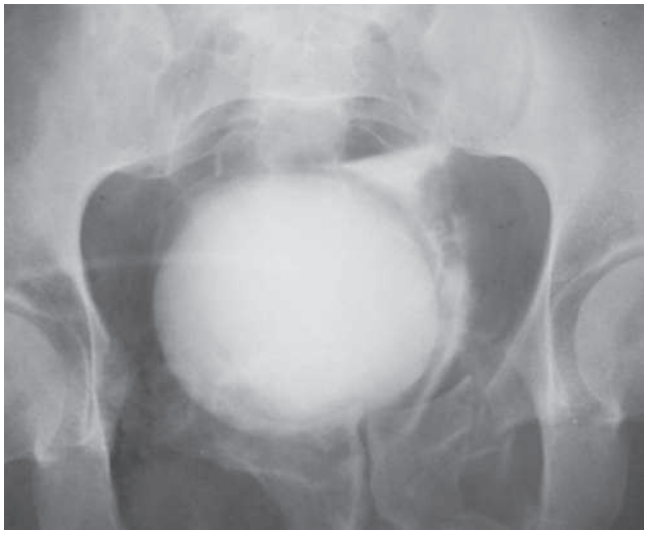

Fig. 39.12 Extraperitoneal Bladder Rupture on Retrograde Cystography. Contrast extravasation is limited to the pelvis. (From Cutinha P, Venugopal S, Salim F. Genitourinary trauma. *Surgery [Oxford].* 2013;31:362–370.)

Fig. 39.13 Intraperitoneal Bladder Rupture on Retrograde Cystography. Extravasating contrast can be seen outlining bowel. (From Cutinha P, Venugopal S, Salim F. Genitourinary trauma. *Surgery [Oxford].* 2013;31:362–370.)

(A) The *arrowhead* overlying the bladder points to the location of extravasation into the perivesicular spaces. (B and C) Contrast extravasation continues along the left retroperitoneum, extending into the perirenal space. (D) The rupture was likely caused by the displaced ramus fracture fragment which is seen violating the bladder wall. There is an associated lumbar spine fracture noted in (C). (From Avery LL, Scheinfeld MH. Imaging of male pelvic trauma. *Radiol Clin North Am.* 2012;50:1201–1217.)

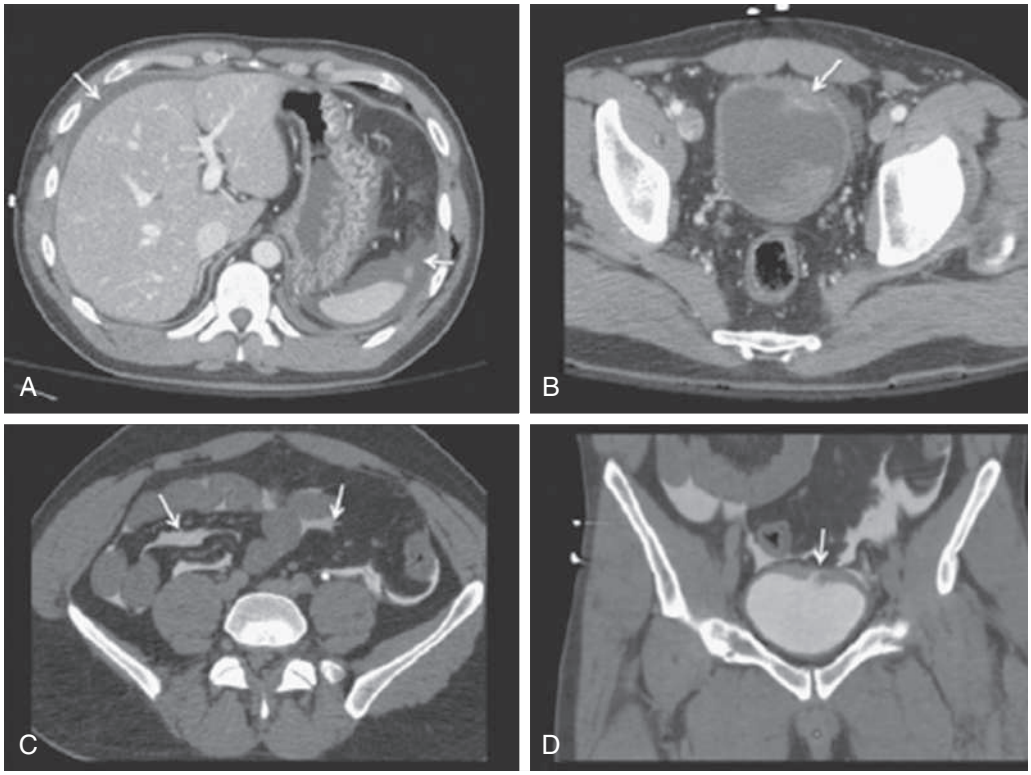

Fig. 39.15 Computed tomography (CT) images from a patient with intraperitoneal bladder rupture (IBR). (A and B) Images acquired immediately after intravenous (IV) contrast administration reveal fluid around the liver and spleen, as well as clot within the bladder and left anterior bladder wall. CT cystography reveals intraperitoneal extravasation of contrast (C) with a disruption of the dome of the bladder (D). (From Avery LL, Scheinfeld MH. Imaging of male pelvic trauma. *Radiol Clin North Am.* 2012;50:1201–1217.)

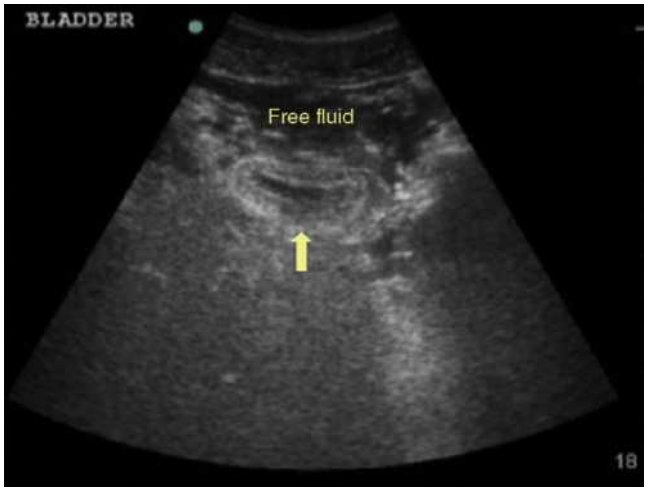

Fig. 39.16 Ultrasound Image of Bladder Rupture. The bladder is contracted, with an irregular bladder wall posteriorly *(arrow),* and free fluid anteriorly. (From Wu TS, Pearson TC, Meiners S, et al. Bedside ultrasound diagnosis of a traumatic bladder rupture. *J Emerg Med.* 2011;41:520–523.)

Bedside diagnostic ultrasonography can identify bladder rupture but has poor sensitivity (Fig. 39.16).[40] As with any evaluation using ultrasound, this technique is highly operator dependent.

Management

The distinction between EBR and IBR is important because the management differs. Contusions and extraperitoneal injuries due to blunt trauma are typically managed conservatively with Foley catheterization. Operative repair is indicated in a few situations, such as concomitant operative intra-abdominal injuries, bladder neck injuries, or bone fragments imbedded in the bladder wall, or if open reduction is performed on pelvic fractures.[1] Open repair of EBR results in improved outcomes and decreased hardware site infections in these cases.[41,42] In contrast, given the extremely low likelihood of IBR and penetrating injuries healing with conservative therapy, almost all patients with these types of injuries are taken to the operating room for exploration and direct repair.[1] Without surgery, there is an extremely high likelihood of complications, which include infections and fistula formation.

Compared with patients with pelvic fracture alone, a concomitant bladder injury is associated with a 75% increase in mortality. Due to the significant mechanism needed to cause an IBR, these injuries are associated with an approximate 20% mortality, which is 12 times more than is seen with isolated EBR. Operative repair decreases the mortality risk by nearly 60%.[37] Extraperitoneal injuries treated nonoperatively rarely lead to complications such as fistula formation or infections.[43] Penetrating rectal injuries leading to bladder involvement can result in abscess, bladder stones, urethral strictures, and fistulae. The high likelihood of potentially serious complications underscores the importance of performing retrograde cystography, when indicated, to diagnose all cases of bladder injury.

Disposition

As with other genitourinary injuries, bladder injuries should ultimately be managed by an experienced trauma surgeon or urologist. The vast majority of patients will be admitted, due to the need for either operative repair or transurethral bladder drainage and monitoring for complications.

Urethral Trauma

Clinical Features

The "classic" presentation of posterior urethral injury includes blood at the urethral meatus, urinary retention, and a "high-riding" prostate on digital rectal examination (DRE).[1] However, DRE lacks sensitivity because the prostate can be obscured by a pelvic hematoma, which is common after pelvic fractures. Therefore DRE should be focused on detecting rectal injuries, and it should not be used to diagnose urethral injury.[11] Similarly, a vaginal exam should be performed in females to evaluate for associated vaginal lacerations or hematomas, which are common with urethral injuries. Other findings include swelling or ecchymosis of the perineum or penis (including "butterfly bruising" seen with anterior injuries that violate Buck fascia; Fig. 39.17) and a distended bladder due to the inability to void.

Blood at the urethral meatus, although not entirely reliable, is the most common clinical sign and present in up to 90% of all urethral injuries. As a result, absence of blood at the meatus plus the lack of a genital hematoma, bruising, or swelling decrease the likelihood of urethral injury. Even without these signs, if patients with significant pelvic injury develop difficulty voiding, investigation for urethral injury is warranted. The degree of hematuria is not correlated with the degree of injury; in fact, a transection can cause a minimal amount of microscopic hematuria, whereas a contusion can induce copious bleeding.[1]

Fig. 39.17 "Butterfly Pattern" of Ecchymosis of the Scrotum and Perineum. (From Mundy AR, Andrich DE. Urethral trauma. Part I: introduction, history, anatomy, pathology, assessment and emergency management. *BJU Int.* 2011;108:310–327.)

Differential Diagnoses

Mild blunt-force injuries to the urethra can result in stretching of the urethra or a contusion of the wall. More severe injuries include partial or complete disruption of the wall. Penetrating injuries usually result in some sort of disruption of the lumen of the urethra. If complete disruption occurs, the amount of urethral separation is important because more than 2 cm of disruption carries a worse prognosis and may change the timing and approach of management.[23]

Diagnostic Testing

Retrograde urethrography (RUG) is the gold standard for diagnosing urethral injuries. RUG should be performed if there is blood at the urethral meatus, or other findings consistent with urethral injury (e.g., perineal or pelvic ecchymosis or swelling), prior to bladder catheterization (Fig. 39.18).[22] The technique for performing RUG is detailed in Box 39.1 and depicted in Fig. 39.19. A scout film that can demonstrate preexisting calcifications is important to avoid false-positive diagnoses, and then it can be compared with postcontrast images. Both anterior-posterior (AP) and lateral films should be obtained to avoid false-negatives in which the contrast extravasates directly posterior to the urethra. Urethrography can determine the location (anterior and posterior) and extent (partial versus complete) of the injury, and it has excellent sensitivity and specificity. Fig. 39.20 depicts a potential schematic of a urethral injury with the resultant RUG image. If a urinary catheter has already been placed prior to suspicion of a urethral injury, a pericatheter RUG can be performed by introducing a 3-Fr catheter into the fossa navicularis and then introducing a small amount of contrast.[1]

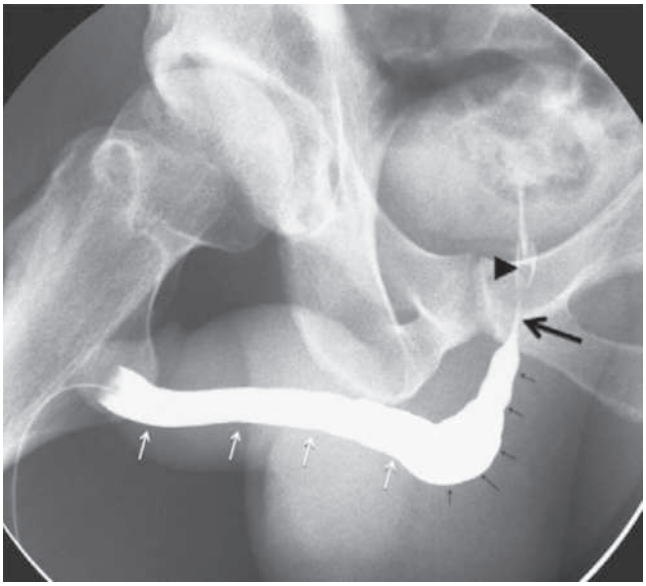

Fig. 39.18 Normal Retro Urethrogram. *White arrows* point to the penile urethra, and *black arrows* point to the bulbous urethra, which together form the anterior urethra. The posterior urethra is composed of the membranous urethra *(black arrow)* and the prostatic urethra *(black arrowhead)*. (From Avery LL, Scheinfeld MH. Imaging of male pelvic trauma. *Radiol Clin North Am.* 2012;50:1201–1217.)

Management

The immediate goal with urethral injury is to secure catheter drainage of the bladder. In addition, continued extravasation of urine through a urethral laceration can lead to infection. Therefore, if a urethral injury is diagnosed, a suprapubic catheter should be placed as soon as possible. Fig. 39.21 details this procedure, which should be performed under ultrasound guidance to avoid injury to the bowels. Alternatively, urethral catheterization can be attempted by experienced providers (typically urologic surgeons) in selected patients; however, repeated attempts, even by urologists, should still be avoided.[1]

After suprapubic drainage is established, the surgical management of urethral injuries can be delayed in favor of treating other life-threatening injuries, except in the case of penetrating injuries or concomitant bladder neck injuries, which should be explored and débrided immediately in the absence of other life-threats. There are multiple options regarding the timing of treatment depending on the location and extent of the urethral disruption, with some controversy

BOX 39.1 Technique for Performing Retrograde Urethrography

1. A 16- or 18-Fr Foley catheter or a hysterosalpingogram catheter is flushed with radiopaque contrast to avoid air bubbles.
2. The glans penis and urethral meatus are cleaned with antiseptic.
3. The catheter is inserted into the penis, and the balloon is partially inflated (1–2 mL) in the fossa navicularis.
4. The penis is then pulled laterally to straighten the urethra under moderate traction.
5. A precontrast "scout" image is obtained because prostatic calcifications may be confused for extravasated contrast.
6. Under fluoroscopic visualization, 20–30 mL of contrast is injected with the goal of filling the entire urethra.
7. If spasm of the external sphincter prevents posterior urethral filling, slow, gentle pressure may allow opacification.
8. Static images are obtained to demonstrate the identified pathologic condition.

From Avery LL, Scheinfeld MH. Imaging of male pelvic trauma. *Radiol Clin North Am.* 2012;50:1201–1217.

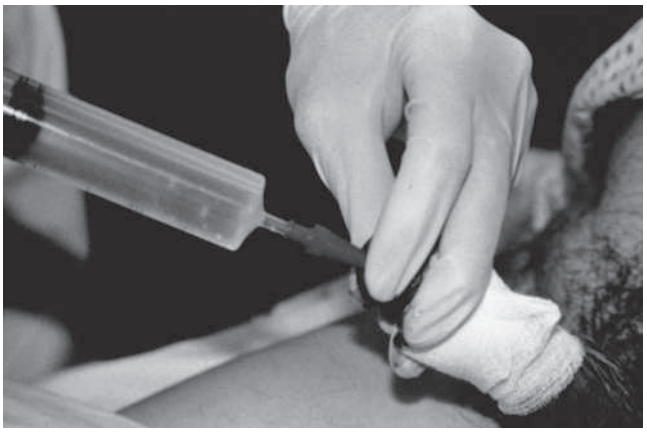

Fig. 39.19 Christmas tree adapter on the end of a 60-mL syringe has been gently placed inside the fossa navicularis in preparation for retrograde urethrography (RUG).

regarding primary repair versus delayed. However, delayed repair allows time for inflammation to decrease and is associated with lower rates of erectile dysfunction, urinary incontinence, and stricture formation.[23]

The complications from urethral disruptions are significant and can negatively impact future quality of life. Complications of urethral injury include urethral stricture, urinary incontinence, and erectile dysfunction, which effects up to 90% of men suffering urethral injuries.[12] Almost half of all children with pelvic fractures and associated urethral injury will exhibit erectile dysfunction at puberty. In children, a higher risk is seen with urethral gap lengths more than 2.5 cm and lateral prostatic displacement. Of note, this is thought to be due more to the accompanying pelvic fractures than the urethral injury or reconstruction. The cause of erectile dysfunction is thought to be neurogenic in most cases, but it can be vasogenic or mixed in some cases.[24] A higher rate of future stress incontinence is seen in women with urethral trauma.

Disposition

Patients with confirmed urethral injuries should be rapidly evaluated and treated by a urologic surgeon and thus either be admitted or transferred to an appropriate tertiary-care institution.

Genital Trauma

Clinical Features

Patients with scrotal injuries may present immediately with swelling and pain but often do not present acutely; in one study, patients had median presentation durations of 3 days.[44] On examination, there can be marked unilateral swelling, ecchymosis, and tenderness. Due to swelling, it is often difficult to distinguish between the different types of testicular injury on examination, and imaging is necessary. Blunt force of at least 50 kg is needed to cause a rupture of the tunica albuginea with extrusion of the seminiferous tubules, resulting in testicular fracture. Typically, the right testicle is more likely to be ruptured than the left, due to its larger relative size and more cranial position.[26]

Penile injuries result in pain, swelling, and ecchymosis. In the setting of blunt or penetrating injuries, blood at the urethral meatus, gross hematuria, or the inability to void suggests a concomitant urethral injury.[1] False penile fractures present with the swelling and ecchymosis

(From Nicola R, Menias CO, Mellnick V, et al. Sports-related genitourinary trauma in the male athlete. *Emerg Radiol.* 2015;22[2]:157–168.)

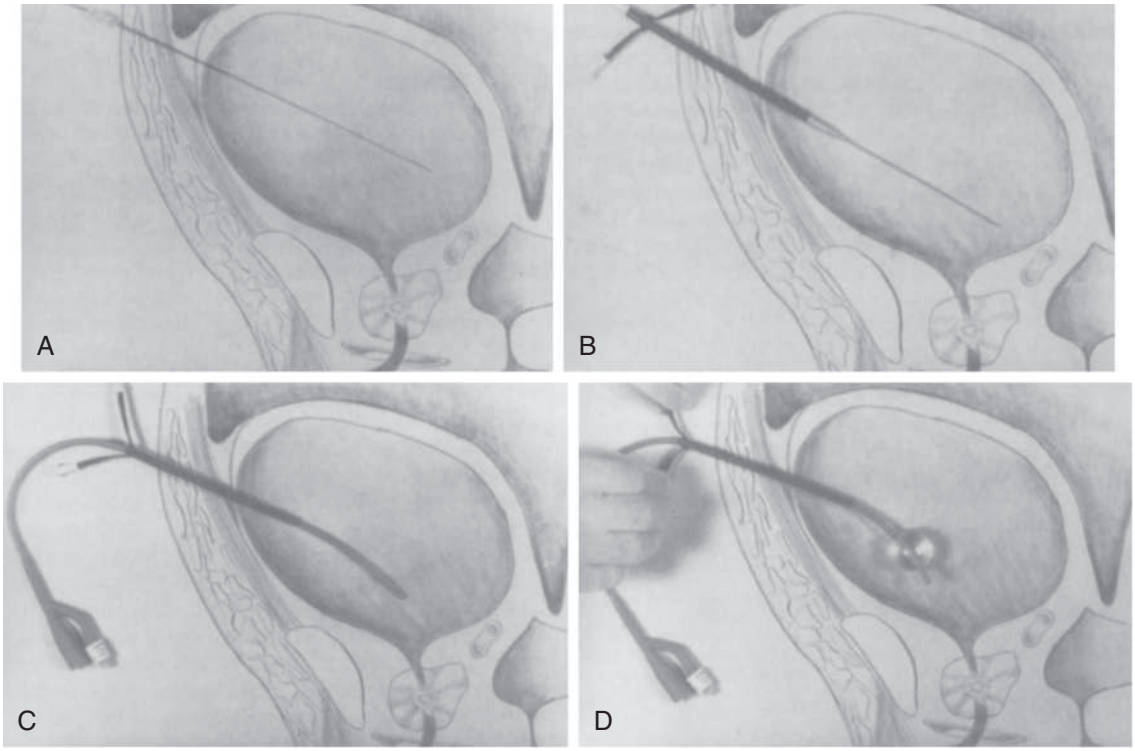

Fig. 39.21 Percutaneous Placement of a Suprapubic Tube with Peel-Away Sheath Introducer. (A) An 18-gauge needle is in the bladder. A guidewire is advanced through the needle. (B) A dilator and peel-away sheath are advanced over the guidewire. (C) The dilator and guidewire are removed. Through the peel-away sheath, an appropriately sized catheter can be introduced into the bladder. (D) The balloon is inflated, and the sheath is pulled back and peeled away. (From O'Brien WM. Percutaneous placement of suprapubic with peel away sheath introducer. *J Urol.* 1991;145:1015.)

that is seen with penile fractures, but patients more often experience a more gradual detumescence and do not typically notice the audible "popping" sound that accompanies most cases of penile fracture (Fig. 39.22). However, it is very difficult to make a clinical distinction between true and false penile fractures, and many of these cases still require imaging and possibly surgical exploration.[45]

True penile fractures are relatively uncommon but are also likely underreported. It is defined as a rupture of the tunica albuginea surrounding any of the three corpora of the penis. The tunica albuginea stretches when the penis is erect, making it thin and inflexible and thus more prone to rupture with lateral bending.[45] In the Western hemisphere, penile fracture most often occurs when the penis slips out of the vagina during intercourse and is accidentally thrust against the perineum or pubic symphysis. However, in the Mediterranean and Middle East, the most common cause is *taghaandan*—where the erect penis is forcibly pushed down to achieve detumescence.[45] Penile fractures are associated with urethral injuries in 20% to 50% of cases, and urethral injuries are more likely in cases of bilateral corporal fractures or when blood is noted at the urethral meatus (Fig. 39.23). Given the high rate of urethral coinjuries, RUG or cystoscopy should be considered for all patients with penile fracture.[13] Patients with penile fracture experience immediate pain, hear an audible "pop," and experience rapid detumescence with a resultant penile hematoma and swelling. Ecchymosis typically is present along the entire shaft of the penis; however, if Buck fascia is also torn, a "butterfly pattern" (see Fig. 39.17) of ecchymosis can be seen in the perineal region. The swelling and color caused by penile fractures can result in an "eggplant deformity," and

Fig. 39.23 Penile fracture causing penile and scrotal ecchymosis and blood that has emanated from the urethral meatus, suggesting urethral injury. (From Hoag NA, Hennessey K, So A. Penile fracture with bilateral corporeal rupture and complete urethral disruption: case report and literature review. *Can Urol Assoc J.* 2011;5:E23–E26.)

Fig. 39.24 Penile Fracture and Hematoma Causing an "Eggplant Deformity." (From Mundy AR, Andrich DE: Urethral trauma. Part II: types of injury and their management. *BJU Int.* 2011;108:630–650.)

the penis tends to deviate away from the damaged side (Fig. 39.24).[45] A defect in the tunica albuginea may be palpated along the shaft of the penis, which is known as the *Rolling sign*.

Injuries to the female genitalia can result in labial swelling or ecchymosis, but consideration should be given to performing procedural sedation or even general anesthesia to allow for adequate examination to assess the entire extent of their injuries, especially in young girls. An examination under anesthesia is suggested for female patients who are younger than 10 years old who present with perineal bleeding, hematoma, or swelling resulting from falls, assaults, or playground activities. Studies have shown that thorough examinations are underperformed in this population, resulting in missed diagnoses, which can lead to significant long-term morbidity.[14]

Differential Diagnoses

Blunt trauma to the scrotum can lead to testicular rupture, testicular dislocation, testicular fracture (parenchymal injury contained within the tunica albuginea), intraparenchymal contusions, hematoceles, or scrotal hematomas. Blunt trauma to the penis can cause penile fractures or false penile fractures, which can be difficult to distinguish based on examination alone. Urethral injury can sometimes occur as a result of blunt penile trauma and often accompanies penile fractures. Penetrating injuries to the male genitalia often cause a disruption to the tunica albuginea of the penis or scrotum, but they can lead to amputation as well.

Blunt trauma in females can cause labial and vaginal contusions, hematomas, and lacerations. Severe vulvar trauma, either from blunt or penetrating mechanisms, can lead to rectal injuries as well.[1] In children with genital burn injuries, consideration must be made for intentional abuse and other accompanying injuries.[46]

Diagnostic Testing

Due to the external nature of the genitalia, diagnoses of genital trauma can be made clinically, as opposed to other genitourinary trauma, which often require imaging studies. Scrotal injuries typically present with swelling, pain, bruising, lacerations, or skin loss. However, due to swelling, the examination can be limited, and imaging may be necessary to distinguish serious pathology in both penile and testicular injuries.

Imaging

Scrotal ultrasound is the imaging modality of choice when evaluating for testicular injury because of its accuracy, as well as its availability. The ability to evaluate flow using Doppler is extremely useful when determining viability and vulnerability of tissue. Along with testicular rupture, ultrasound can diagnose fractures, hematomas, hematoceles, and contusions. MRI can be used with accurate results but is less practical given its long acquisition time and the limited availability. For testicular rupture, the sensitivity of ultrasonography approaches 100% and should focus on testicular echotexture, as well as the contour of the testicle.[47] Irregularities of the contour or a discontinuity of the tunica albuginea suggest testicular rupture (Fig. 39.25). If there is concern for alternate pelvic injury or fracture, CT imaging can be considered.[48]

Ultrasound is also the preferred modality for penile imaging. It can diagnose penile fracture but can also be used to evaluate the blood flow in penile arteries and veins. However, unlike scrotal ultrasound, penile ultrasound is less often obtained because the diagnosis of penile fracture is usually made clinically. However, due to the extensive exploration required to evaluate for penile fracture, ultrasound is gaining more popularity because it can reveal a defect in the tunica albuginea with extruding hematoma, as well as assess blood flow in the arteries and veins (Fig. 39.26). Ultrasound is also useful to distinguish false from true penile fractures. Magnetic resonance imaging (MRI) provides similar diagnostic information but in a less timely and less cost-effective manner.[27]

RUG should be considered if there are concerns about concomitant urethral injury (Fig. 39.27).[27]

Management

Testicular and penile fractures require prompt urologic consultation and surgery. With any type of penetrating injury to the scrotum or

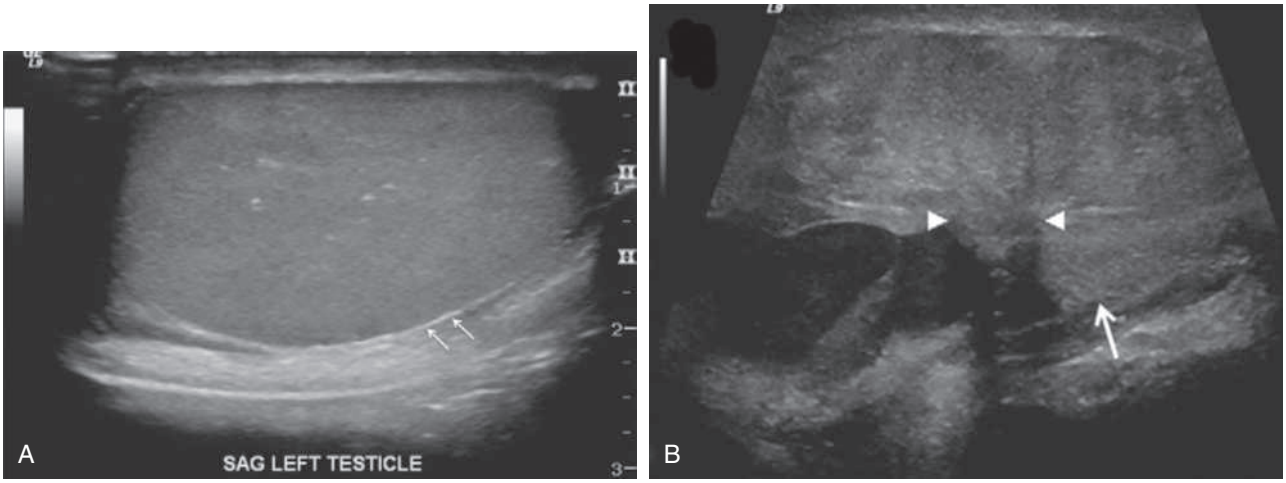

Fig. 39.25 (A) Normal testicular ultrasound. *Arrows* define the thin tunica albuginea. penis, surgical exploration is typically indicated to evaluate for injuries to the urethra, corpus cavernosum, and tunica albuginea that could result in significant long-term morbidity[28] Prognosis after penile fractures is generally good, but cosmetic abnormalities can occur, even with prompt surgical repair.[45]

For testicular rupture, operative intervention focuses on débriding nonviable tissue and closing the tunica albuginea, although orchiectomy is performed if the testicle is deemed nonviable.[1] Operative management is best done immediately because testicular salvage rates drop from 90% to 45% after 72 hours.[26] Even with immediate surgery, penetrating testicular rupture results in a 35% rate of orchiectomy due to testicular necrosis or unhealthy parenchyma. If the testes or spermatic cord suffered complete amputation, microsurgery might be required at a specialized center.[13]

Typically, small scrotal hematomas respond well to rest and nonsteroidal antiinflammatory drug (NSAID) therapy. However, scrotal hematoceles and expanding or large scrotal hematomas may lead to testicular ischemia due to local pressure effects on blood vessels and thus may require surgical exploration. Reduction of testicular dislocations should be attempted by applying gentle caudad pressure following the course of the spermatic cord. After reduction of the testes, a repeat ultrasound should evaluate vascular supply. If vascular flow

Fig. 39.27 Retrograde urethrogram revealing anterior urethral injury and contrast extravasation in the setting of a penile fracture. (From Cutinha P, Venugopal S, Salim F. Genitourinary trauma. *Surgery [Oxford].* 2013;31:362–370.)

is adequate, delayed operative fixation is usually recommended. If the reduction is unsuccessful, immediate orchiopexy is may be required.[44]

Amputations of either the testicles or penis require immediate surgical evaluation. In the interim, the amputated part should be wrapped in saline soaked gauze and then placed in a sealed bag, which can then be placed in another bag that is filled with ice.[13] The amputated part should never be placed directly on ice. Direct pressure is usually adequate to achieve hemostasis. Reimplantation is more successful within the first 24 hours and, counterintuitively, when the amputation is complete rather than partial.[49]

Injuries to the female genitalia may need the operative examination (and repair) under anesthesia for extensive lacerations involving the labia, perineum, and posterior fourchette. Again, the threshold for an examination under anesthesia should be extremely low, especially in the pediatric population.[14]

Zipper injuries should be evaluated thoroughly for underlying trauma to the penis (or scrotum when involved). If the zipper is stuck, the cloth between the interlocked dentition of the zipper can be cut. However, if the penis is caught in the buckle of the fastener, unzipping can be attempted, and mineral oil may help with removal. If this proves unsuccessful, the medial bar of the zipper can be cut with bone or wire cutters to separate the face plates. Occasionally, circumcision or an elliptical incision of the penile skin will need to be performed to achieve release.

Burns to the external genitalia are usually not seen in isolation, and the thin skin of the penis makes it quite vulnerable to full-thickness burns. Patients with significant partial- or full-thickness burns should be evaluated at a burn center as soon as possible. More than 10% of these patients will need surgical débridement, and most patients will require at least 24 hours of pain control. More commonly, burn centers are using enzymatic débridement successfully.[46]

Occasionally, patients will present with constricting rings that have created local ischemia and swelling, and attempts at removal should be made as quickly as possible to prevent tissue necrosis from ischemia. In this case, bolt cutters may be necessary, with proper analgesia and sedation if needed.

External genitalia injuries lead to complications both in cosmetics and function. Scrotal injuries leading to orchiectomy can be a source of infertility but can also alter hormonal function. Other complications include voiding dysfunction and erectile dysfunction. Many of the complications of penile injury are cosmetic in nature, including penile curvature and plaque or nodule formation superficially after penile fracture, but the likelihood is significantly decreased with surgery. Still, urethral injury can lead to stricture formation, penile abscess, permanent curvature, and painful erections, even if repair is successful.[45]

A delay in diagnosing female genital injury can lead to urinary or fecal incontinence, chronic fissures, rectovaginal fistula, or even vaginal stenosis, highlighting the importance of a thorough physical examination.[14]

Disposition

Most external genital traumatic injuries require prompt urologic consultation and management, and will require admission or transfer to a center with appropriate capabilities. Any full-thickness burns to the genitals should prompt transfer to a burn center.

CHAPTER 39: QUESTIONS AND ANSWERS

1. Which of the following scenarios associated with clinically significant blunt renal injuries in adult patients would the *least likely* to warrant further evaluation?
   - **a.** A sudden decelerating mechanism of injury in a patient without microhematuria
   - **b.** A sudden decelerating mechanism of injury in a patient without shock
   - **c.** Gross hematuria
   - **d.** Microscopic hematuria
   - **e.** Microscopic hematuria in a patient with shock

Answer: d. Renal injury requiring intervention is rare in the absence of gross hematuria or shock. Gross hematuria warrants careful evaluation for significant genitourinary injury, although the degree of hematuria does not necessarily correlate with the degree or grade of injury and significant genitourinary trauma can occur without hematuria. Microscopic hematuria in a blunt trauma patient without shock is not an indication for renal imaging, even if there is evidence of local trauma (e.g., costovertebral angle tenderness or localized ecchymosis). Although renal injury may uncommonly be identified on imaging for these patients, the injuries are mild and do not require intervention. Hemodynamic instability with evidence of intraperitoneal injury on abdominal examination, presence of pelvic fracture, a penetrating trauma mechanism, or presence of lower rib fractures, with or without hematuria, are indications for further investigation. In addition, imaging is advisable for patients with gross hematuria, targeted to the entire urinary tract or localized to the lower tract (bladder and urethra), depending on the mechanism and location of the trauma.

2. A 27-year-old male presents after a motor vehicle collision complaining of abdominal pain. He was the restrained driver of a car struck on the driver's side by a delivery truck. His vital signs are blood pressure 118/72, heart rate 70 beats/min, and respiratory rate 16 breaths/min. Physical examination reveals left upper quadrant abdominal tenderness without guarding or rebound tenderness. There is no blood at the urethral meatus or scrotal hematoma. A Foley catheter is placed without difficulty and drains gross blood. A radiograph of the pelvis reveals fractures of the left superior and inferior pubic rami, and a focused assessment with sonography in trauma (FAST) examination reveals free fluid in the splenorenal pouch. Which of the following diagnostic strategies is most appropriate?
   - **a.** Intravenous (IV) contrast-enhanced computed tomography (CT) of the abdomen and pelvis with delayed images of the bladder after clamping the Foley catheter to allow the IV contrast to collect in the bladder
   - **b.** IV contrast-enhanced CT of the abdomen and pelvis with delayed images of the renal collecting system
   - **c.** IV contrast-enhanced CT scan of the abdomen and pelvis and retrograde CT cystogram
   - **d.** IV contrast-enhanced CT of the abdomen and pelvis and retrograde urethrogram
   - **e.** Retrograde cystogram followed by IV pyelogram

Answer: c. This patient has clinical features concerning for several possible injuries, including a splenic laceration, renal injury, and bladder rupture. Significant urethral injury is less likely, given the examination findings and ease of Foley catheter placement. Because the patient is stable without apparent indication for laparotomy, the most appropriate diagnostic evaluation would be IV contrast-enhanced CT of the abdomen and pelvis and retrograde CT cystogram. The former will evaluate for solid organ injury and the latter for bladder rupture. It is essential that cystography not be obtained in an antegrade fashion, because such studies (e.g., injecting IV contrast material, clamping the Foley catheter, and allowing the examination to depend on antegrade filling of the bladder from renal excretion of progressively dilute contrast material) may produce incomplete and spurious findings because of inadequate distention of the bladder.

3. A 72-year-old male presents with flank and pelvis pain after he slipped and fell on an icy sidewalk. His examination reveals normal vital signs and abrasions over the left flank and left iliac crest and is otherwise unremarkable. He has grossly clear urine, but a urinalysis reveals 25 red blood cells per high-power field. Radiographs of the pelvis and hips reveal no fracture, and the patient is able to ambulate without difficulty. What is the most appropriate next step?
   - **a.** Obtain a renal ultrasound scan.
   - **b.** Obtain an IV contrast-enhanced CT of the abdomen and pelvis.
   - **c.** Perform a retrograde cystogram.
   - **d.** Perform a retrograde urethrogram.
   - **e.** Treat the patient's pain and discharge him home with outpatient urology follow-up in 1 week.

Answer: e. A significant genitourinary injury is unlikely, given the patient's history, physical examination, and urine findings. However, outpatient urology follow-up until microhematuria has cleared is advisable to be certain that it does not represent another more serious underlying (nontraumatic) condition.

4. A 35-year-old female presents after being stabbed with an ice pick during a robbery. Her examination is normal except for a 0.5-cm, hemostatic wound to the right flank at the level of the second lumbar vertebrae. Bedside ultrasonography reveals no free intra-abdominal fluid. Her urinalysis does not contain blood. What is the most appropriate next step?
   - **a.** Obtain a renal ultrasound scan.
   - **b.** Obtain an IV contrast-enhanced CT scan of the abdomen and pelvis, with additional images of the renal collecting system 10 minutes after contrast injection.
   - **c.** Perform a retrograde cystogram.
   - **d.** Perform a retrograde urethrogram.
   - **e.** Treat the patient's pain, counsel her on appropriate wound care, and discharge her home with outpatient urology follow-up in 1 week.

Answer: b. In cases of penetrating renal trauma, the presence or absence of hematuria is not a reliable predictor of upper urinary tract injury. The location of the penetrating injury in relation to the urinary tract is the most important determining factor in deciding the need for radiographic investigation. Therefore the absence of hematuria in a patient with a gunshot or stab wound in proximity to the urinary tract does not eliminate the need for IV contrast-enhanced CT as the initial diagnostic examination. Significant injuries to the kidney and ureter may occur in penetrating trauma without hematuria. Additional images obtained at 10 minutes after contrast injection are indicated to evaluate for delayed contrast extravasation and to maximize the sensitivity of the study.

5. A 25-year-old male presents after an unfortunate incident resulting in a scrotal injury and a left testicle that was traumatically amputated (the patient brings the amputated testicle with him in a towel). Which of the following would be *least* indicated?
   - **a.** Analgesics for the patient
   - **b.** Emergent urologic consultation

c. Place the amputated testicle directly on ice
d. Prepare the patient for possible operative exploration by the surgeon
e. Wrap the amputated testicle in saline soaked gauze

Answer: c. Amputations of either the testicles or penis require immediate surgical evaluation. In the interim, the amputated part should be wrapped in saline-soaked gauze, and then placed in a sealed bag, which can then be placed in another bag that is filled with ice. The amputated part should never be placed directly on ice. Direct pressure is usually adequate to achieve hemostasis.

6. A 30-year-old female presents after blunt abdominal trauma after a motor vehicle collision, and an ultrasound demonstrates free fluid. You suspect a bladder rupture. A true statement about this entity includes which of the following:
a. A bladder contusion may be successfully managed with Foley catheterization drainage.
b. Extraperitoneal bladder injuries are typically managed with surgical intervention.
c. It is less important to distinguish an intraperitoneal from an extraperitoneal bladder rupture (EBR) because the management options are essentially the same.
d. Most patients with an intraperitoneal bladder rupture (IBR) will resolve with Foley catheter drainage.
e. Most penetrating bladder injuries will resolve with Foley catheter drainage.

Answer: a. The distinction between EBR and IBR is important because the management differs. Contusions and extraperitoneal injuries due to blunt trauma are typically managed conservatively with Foley catheterization, unless they are complicated by other intra-abdominal injuries, bladder neck injuries, or bone fragments in the bladder wall or if open reduction is performed on an associated pelvic fracture. In contrast, given the extremely low likelihood of IBR and penetrating injuries healing with conservative therapy, almost all patients with these types of injuries are taken to the operating room for exploration and repair. Without surgery, there is an extremely high likelihood of complications, which include infections and fistula formation.

40

Peripheral Vascular Trauma

Ali S. Raja

KEY CONCEPTS

- The overall condition of the patient with an acute peripheral vascular injury determines the extent of emergency department (ED) evaluation and stabilization. Critically injured patients may require immediate surgery, which should not be delayed for confirmatory studies of obvious vascular injury.
- Arterial injury may be readily apparent or clinically occult. In patients with high-energy blunt mechanisms, computed tomography angiography (CTA) should be the initial diagnostic modality of choice. In patients with lower-energy mechanisms, serial physical examinations may be performed instead.
- Symptoms of arterial injury may be delayed by hours to months after the initial injury. Late onset of symptoms suggests delayed thrombosis, pseudoaneurysm or arteriovenous fistula (AVF) formation, compartment syndrome, or intermittent claudication, resulting from stenosis or reliance on small-caliber collateral vessels for arterial perfusion.
- Compartment syndrome frequently develops in extremities with arterial injury, particularly injuries of the lower leg, and fasciotomy is often required.
- Many vascular injuries are amenable to endovascular treatment with self-expanding stents. This results in fewer complications, lower cost, and earlier discharge from the hospital.

FOUNDATIONS

Background and Importance

Injury to the major peripheral arteries or veins may not always be life threatening, but it invariably poses a threat to the viability of the affected extremity. Historically, due to the rapidity of exsanguination, injury to major vessels was often fatal in the field, and most patients who survived to hospital arrival had relatively minor vascular injuries. However, with the advent of modern emergency medical service (EMS) systems with advanced extrication methods and rapid transport, more patients with major vascular injuries are reaching the emergency department (ED) alive. In addition, the incidence of both penetrating injuries from interpersonal violence and blunt injuries from motor vehicle–related trauma has increased dramatically over the past 50 years. Consequently, emergency clinicians are frequently confronted with critically ill patients harboring overt (or occult) peripheral vascular injuries.

Management of these vascular injuries has also evolved, with advances in diagnostic methods and surgical techniques. Treatment of vascular injuries before and during World War II resulted in limb amputation rates of 50% to 75%. Advances during the Korean and Vietnam wars reduced amputation rates to 5% to 15%, which approach the current rates of amputation for civilian injuries.

Tremendous progress has also been achieved in diagnostic and therapeutic techniques for dealing with peripheral vascular injuries, and several noninvasive diagnostic modalities have emerged as accurate alternatives to surgical exploration and angiography. These techniques are readily used in the ED setting, and the goal of timely detection and repair of serious vascular injuries is achievable in the majority of cases.

Peripheral vascular injuries are divided almost equally between blunt and penetrating mechanisms.[1] Major venous injuries are present in up to 50% of gunshot wound cases, and more than 80% of these have associated arterial injuries. In addition, due to the increased use of percutaneous endovascular diagnostic and therapeutic procedures, the incidence of iatrogenic vascular injuries has increased and accounts for up to one-third of all cases in some series.[2]

Anatomy and Physiology

The major vessels and their relevant anatomy are described in the following sections (Figs. 40.1 and 40.2).

Upper Extremity

The right subclavian artery arises from the brachiocephalic artery, and the left arises from the arch of the aorta. From their origin, they course posterior and inferior to the clavicles to the outer margins of the first ribs, where they become the axillary artery and vein. The left subclavian artery rises higher than the right and extends into the root of the neck.

The axillary artery courses from the lateral border of the first rib to the inferior border of the teres major muscle, where it becomes the brachial artery. The axillary vein runs medial to the artery. Due to the extensive anastomotic arterial connections around the shoulder joint, up to half of patients with axillary artery injuries will have palpable pulses as a result of collateral circulation. Because of the close proximity of the brachial plexus and the axillary vessels, significant denervation of the upper extremity can occur.

The brachial artery begins at the lower border of the teres major muscle and divides into the radial and ulnar arteries at the level of the proximal aspect of the radial head. The median and ulnar nerves and the basilic vein are in close proximity to the brachial artery. The profunda brachii artery is a major branch that arises slightly after the origin of the brachial artery and often contributes adequate collateral flow if the brachial artery is injured distal to this branch point.

The radial artery originates in the cubital fossa and runs superficially to the distal end of the radius, where it ultimately joins the deep branch of the ulnar artery to form the deep palmar arch of the hand. The ulnar artery begins in the cubital fossa and runs with the ulnar nerve anterior to the flexor retinaculum, at which point it joins the radial artery to form the superficial palmar arch of the hand.

Lower Extremity

The external iliac vessels become the common femoral vessels at the inguinal ligament. After bifurcation of the profunda femoris artery in the femoral triangle, the femoral artery continues as the superficial

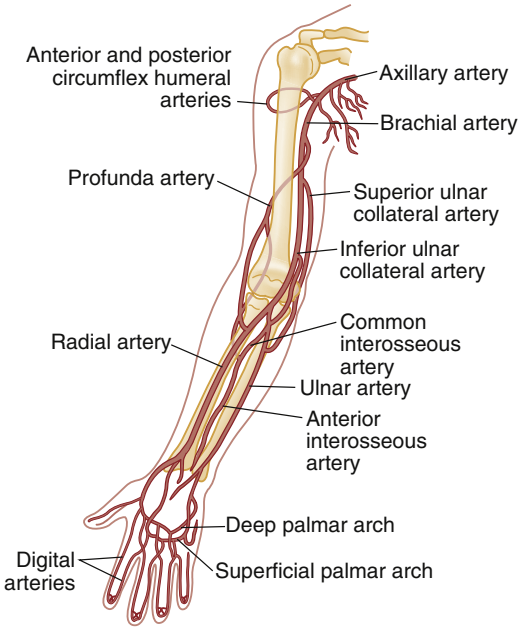

Fig. 40.1 Major Arteries of the Upper Limb. (From Snell R, Smith M, eds. *Clinical anatomy for emergency medicine*. St Louis: Mosby; 1993.)

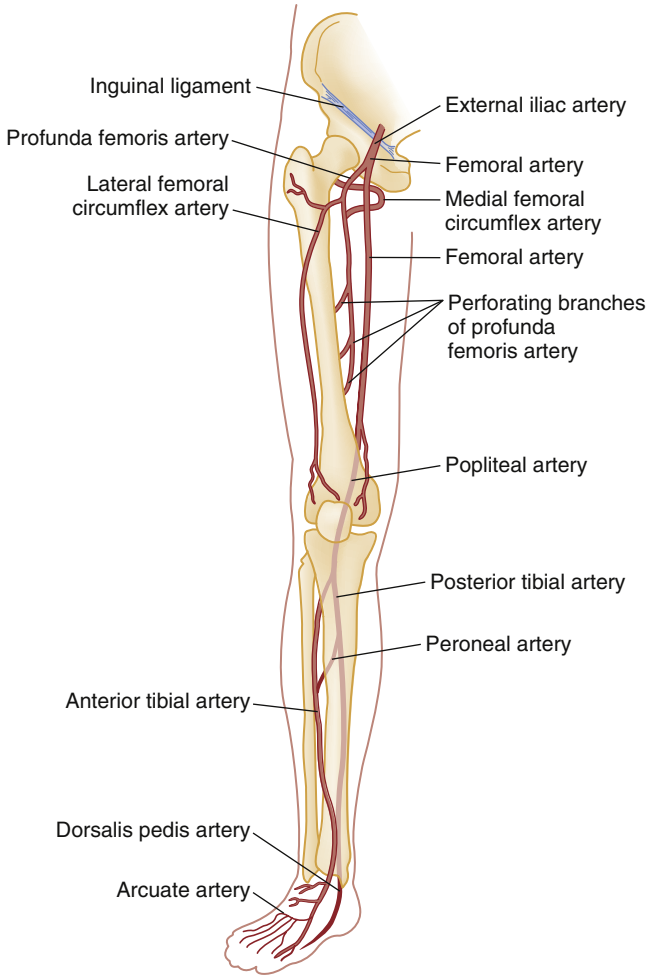

Fig. 40.2 Major Arteries of the Lower Limb. (From Snell R, Smith M, eds. *Clinical anatomy for emergency medicine*. St Louis: Mosby; 1993.)

femoral artery almost vertically to the adductor tubercle of the femur and enters the popliteal fossa as the popliteal artery. Extensive proximal collaterals are present around the hip joint, including the gluteal, obturator, and pudendal branches of the iliac artery.

The popliteal artery gives off the genicular branches in the popliteal fossa and then divides into the anterior and posterior tibial arteries at the lower border of the popliteus muscle. The peroneal artery arises from the posterior tibial artery slightly after its origin. The anterior and posterior tibial arteries and the peroneal artery form the trifurcation of the popliteal artery, and each run with a corresponding vein and nerve in different compartments of the leg.

The popliteal artery divides into three branches—the anterior and posterior tibial and the peroneal arteries—at the inferior margin of the popliteal fossa. Injuries below the trifurcation at the knee may require repair if classic "hard" findings of arterial injury are apparent in the foot or if two of the three arteries are occluded. The most common blunt trauma cause of popliteal artery injury is a posterior knee dislocation in which bony elements directly lacerate or cause thrombosis of the artery. Anterior knee dislocations may cause excessive stretch on the popliteal vessels resulting in arterial thrombosis, but this injury is relatively rare. Up to one-third of knee dislocations result in popliteal artery injury. Twenty-five percent of cases have an associated injury to the peroneal and posterior tibial nerves.

Pathophysiology

Blunt and penetrating types of trauma result in similar spectra of vascular injuries, although their mechanisms of injury differ. Although blunt vascular injuries are less common than penetrating injuries, they are often more severe and more commonly result in amputation because of associated injuries to nerves, bone, tendons, and soft tissue. Certain mechanisms of injury, such as animal bites that crush and lacerate vessels, can involve both penetrating and blunt mechanisms (See Chapter 52).

Penetrating Trauma

Gunshot wounds can cause direct arterial lacerations or transections, in addition to concussive injuries distal to the track of the bullet. These latter injuries tend to tear into the intima of an artery, with subsequent thromboses that may not become apparent for hours to months after the injury. Bullets may ricochet off bone, making predicting trajectories less accurate than with stab wounds.

Stab wounds cause vascular injuries by completely or partially transecting vessels. Partial laceration of an artery may produce few symptoms of arterial insufficiency on initial evaluation but result in delayed complications. The vascular structures at risk can be predicted more reliably with stab wounds than with gunshot wounds by taking into consideration the anatomic location, causative implement, depth, and direction of the wound.

Shotgun wounds are less common than gunshot or stab wounds, but they can cause injuries varying from minor soft tissue wounds to massive destruction of soft tissue and bone, depending primarily on the range from which the shotgun was fired. The presence of multiple missiles ranging from 9 or 10 (buckshot) to dozens (birdshot) also complicates the evaluation of these injuries because of the many potential sites of potential vascular injury. In addition, close-range shotgun wounds (<3 meters) can cause significant blunt trauma to blood vessels, as well as a higher rate of bone and nerve injury than might occur with gunshot wounds. Migration of pellets or bullets proximally through the venous system to the heart, or migration through an artery with subsequent distal occlusion, has been reported frequently as a delayed complication.[3]

Blunt Trauma

Blunt injury involves either avulsion forces that can stretch vessels beyond their capacities or direct crushing injuries that disrupt vessel walls. In addition, fracture fragments resulting from blunt extremity trauma can lacerate or entrap vessels. These vascular injuries can range from small intimal tears to complete avulsions of arteries and nerves. Open avulsion injury of an extremity is particularly severe because the skin, which is very pliable, is the final structure to tear. Once torn, it is inevitable that vessels and nerves will tear as well. Vascular injuries should also be suspected in patients with massive soft tissue avulsions or crush injuries, displaced long bone fractures, electrical or lightning injuries, and severe burns. In addition, compartment syndrome from trauma or prolonged immobilization as a result of stroke, coma, or drug overdose is another cause. Bites inflicted by large animals, such as dogs, are particularly prone to arterial injury and wound complications.[4] Collateral circulation may continue to perfuse the limb, but injuries that occur proximal to the collateral branch point—or that involve both the main trunk and collateral branches—will preclude adequate flow.

Distal ischemia results from the inability of tissues to continue aerobic metabolism. Eventually, anaerobic metabolism consumes all substrate, thereby resulting in the accumulation of lactic acid. As ischemia progresses, cellular integrity is compromised, and irreversible cell death occurs. A vicious cycle of tissue edema and further impairment of the blood supply occurs. When no specific measures are taken to cool the involved extremity, the limb essentially undergoes "warm ischemia" at ambient temperature. After 6 hours of complete warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificially cooling the limb to near-freezing temperature ("cold ischemia") will reduce the metabolic demands and greatly prolong the tissue's tolerance of ischemia to 24 hours or more.

Vascular Injuries

Two main types of vascular injury can result from trauma: *occlusive injuries* (transections, thromboses, and reversible spasm), in which all perfusion distal to the occlusion is lost, and *nonocclusive injuries* (intimal flaps, dissections, arteriovenous fistulas [AVFs], and pseudoaneurysms), which include mechanical defects to vessel walls that may or may not lead to decreased distal blood flow.

Complete occlusive injury

Transection. The most common vascular injury is complete transection, in which distal flow is effectively eliminated. Cleanly transected arteries will often retract and undergo spasm to minimize blood loss. With longitudinal arterial lacerations and venous injuries, blood loss cannot be minimized by this physiologic response and therefore tends to result in greater blood loss. Pulsatile bleeding may quickly lead to exsanguinating hemorrhage and shock.

Thrombosis. Intraluminal thrombosis (Fig. 40.3) may occur in an injured artery acutely (within 24 hours) or may be delayed for many months. Acute thrombosis is initiated by stasis resulting from compression of the artery or from a disruption in the intima of an artery that becomes a nidus for thrombus formation. As the thrombus propagates, complete occlusion of the vessel can occur. Delayed thrombosis can occur months to years after injury if the injured vessel heals with stricture formation, resulting in decreased distal flow, followed by stasis and clot formation.

Reversible arterial spasm. The precise cause and incidence of significant reversible arterial spasm after trauma are unknown. In the case of arterial transection, arterial spasm is beneficial and limits hemorrhage. However, in other cases, the segmental arterial spasm occurs at some distance from the site of traumatic injury and can produce severe distal ischemia. Arterial spasm is particularly common in children. In many series, segmental arterial spasm is the most common arteriographic finding (Fig. 40.4). However, symptoms of ischemia should not be assumed to be a result of arterial spasm; that diagnosis is based on arteriographic results only.

Fig. 40.3 Complete thrombosis *(arrow)* of the distal brachial artery after reduction of a posterior elbow dislocation. (Courtesy D. Demetreades, MD.)

Nonocclusive injuries

Intimal flap. An intimal flap occurs when there is a break in the vessel intima, generally from excessive stretch or concussive forces. Although flow is not altered by small flaps and the associated soft tissue wounds often appear benign initially, these intimal flaps may become a nidus for thrombosis that can occur hours to months after the initial injury.

Pseudoaneurysm. A true aneurysm contains all three layers of the vessel wall (intima, media, and adventitia) and is rarely caused by trauma. A pseudoaneurysm is formed following a tear in a vessel wherein the hemorrhage is contained by surrounding fascia and the resulting hematoma is gradually encased by a capsule of fibrous tissue, analogous in consistency to the adventitia of a normal vessel (Fig. 40.5). Because it is relatively thin walled, rupture of a pseudoaneurysm is a distinct possibility. In addition, because its diameter inevitably expands under arterial pressure over days to months, compression of adjacent tissue may result in neuropathy, venous obstruction with resultant peripheral edema and venous thrombosis, and even erosion into adjacent bone. The cavity of a pseudoaneurysm is in direct communication with the lumen of the vessel, so embolization of mural clots may produce distal arterial occlusion. Pseudoaneurysms may be diagnosed months to years after an injury when a patient manifests symptoms of compression neuropathy or peripheral arterial embolism or for investigation of a soft tissue "tumor" that represents the growing aneurysm.

Arteriovenous fistula. An AVF is formed when both an artery and an adjacent vein are injured. Higher-pressure arterial flow is directed into the lower-pressure vein, thereby diverting the blood supply to distal tissues and engorging the distal veins. Because the aperture of the fistula is often relatively narrow and thus results in turbulent flow, a bruit and palpable thrill are common bedside diagnostic findings. Symptoms are primarily those of distal ischemia, but rarely,

Fig. 40.4 Acute Arterial Spam of the Brachial Artery. (From Arquilla B, Gupta R, Gernshiemer J, et al: Acute arterial spasm in an extremity caused by inadvertent intra-arterial injection successfully treated in the emergency department. *J Emerg Med* 2000;19[2]:139–143.)

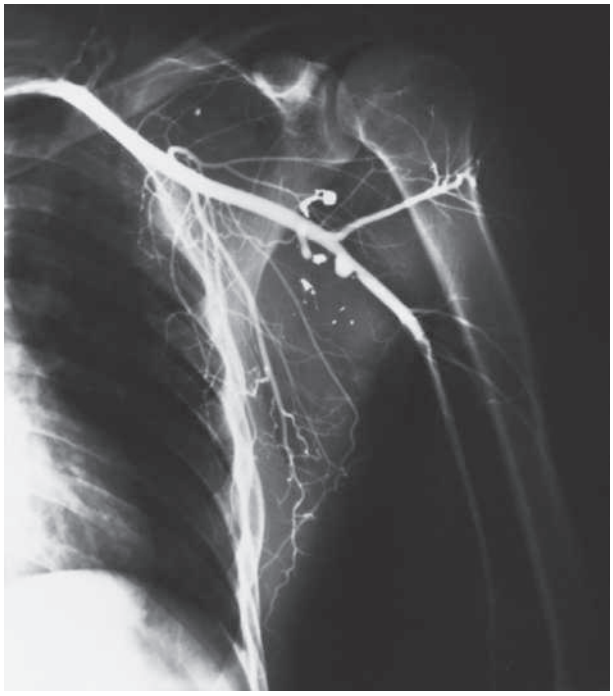

Fig. 40.5 Multiple small pseudoaneurysms of the axillary artery after penetrating injury. (Courtesy D. Demetreades, MD.)

high-output congestive heart failure may occur when large central vessels are involved. Symptoms are often delayed for months because it takes time for the fistula to mature.

Compartment Syndrome

Compartment syndrome is most common after crush injury or a long bone fracture but may also be seen after reperfusion of an ischemic limb. Initially, blood flow is diminished, and the injury is considered nonocclusive. Progressive edema elevates tissue pressure above capillary pressure, thus ending arterial perfusion and initiating a cascade of events that results in compartment syndrome. The risk for this complication is increased when ischemia time is prolonged; in the presence of combined arterial and venous injury; after ligation or repair of a major artery or vein; or in the presence of significant soft tissue injury, frequently concomitant with a long bone fracture. After restoration of arterial flow to a previously ischemic limb, a cascade of reperfusion injury results from release of oxygen free radicals, lipid peroxidation, and influx of intracellular calcium. These mediators give rise to progressive cellular damage, edema, and necrosis, thereby propagating the vicious cycle that increases compartment pressure. Consequently, frequent reexamination of the limb is indicated to assess compartment pressure after arterial repair or in the high-risk circumstances listed earlier. Compartment syndrome is discussed in more detail in Chapter 41.

CLINICAL FEATURES

Detection and treatment of vascular injuries take place within the context of the overall resuscitation of the patient according to established principles of trauma care.[5] If the source of bleeding is readily identifiable, it is compressed with digital pressure. Although control of active bleeding is being achieved in this manner, detection and treatment of other life-threatening injuries proceed concurrently. Peripheral vascular injury can occur coincident with other life-threatening trauma, which may take higher priority in resuscitation. In other cases, peripheral vascular injury may be the most serious or only injury, and evaluation and management of this type of injury can proceed directly. Many patients have no evidence of injury but are considered at risk for vascular injury because of penetrating wounds that traverse the course of major neurovascular bundles or because they have sustained high-risk injuries, such as posterior knee dislocation. In addition, patients without acute trauma but with symptoms of intermittent claudication or with unexplained peripheral embolization and a history of previous trauma to the extremity should be suspected of having occult arterial injury.

Peripheral vascular injury can be divided into three categories by physical examination: hard findings, soft findings, and asymptomatic high-risk wounds based on the mechanism of injury.

Hard Findings of Vascular Injury

Many patients have classic "hard" findings of arterial injury, listed in Table 40.1. The incidence of arterial injury in patients with any hard finding is consistently greater than 90%, and the presence of these findings requires further investigation by emergency angiography/computed tomography angiography (CTA) or, more commonly, immediate surgical intervention, depending on the duration of warm ischemia and the overall status of the patient.[6]

Soft Findings of Vascular Injury

An additional group of patients have "soft findings" of vascular injury (see Table 40.1). Up to 35% of patients with "soft" findings of vascular injury have positive angiographic studies, although only a small proportion of these injuries require emergency repair.

The significance of prolonged capillary refill (>2 seconds) is controversial; some experts find it to be a reliable sign of vascular injury (when combined with a pulse deficit) and consider delayed capillary refill to be a valid "soft sign" of vascular injury. However, capillary refill is age, gender, and temperature dependent. Of note, an arbitrary 2 second cutoff may result in a significant false-positive rate, especially in older patients.[7] Delayed capillary refill by itself is an unreliable predictor of arterial injury, but the presence of delayed capillary refill in

TABLE 40.1 Clinical Features of Vascular Injury

Hard Findings	Soft Findings
Pulsatile hemorrhage	History of significant hemorrhage at scene
Expanding hematoma	Nonexpanding hematoma
Absent distal pulses	Diminished pulse or ABI of injured extremity
Palpable thrill	Extremity peripheral nerve deficit
Audible bruit	Bony injury or proximate penetrating wound

ABI, Ankle-brachial index.

conjunction with a proximate penetrating injury or the presence of one or more soft signs warrants repeated hourly examinations.

Isolated penetrating injury to a peripheral nerve is commonly associated with vascular injury because of the close proximity of these structures within the neurovascular bundles. Vascular injury occurs in up to half of cases of penetrating peripheral nerve injury and vice versa.[8] It can be difficult to determine whether pain, paresthesias, or paralysis are caused by a primary nerve injury, an associated vascular injury causing compression of the nerve, or compartment syndrome. In general, primary nerve injury occurs immediately at the time of injury, whereas vascular neuropathy occurs over minutes to hours after the injury.

Asymptomatic High-Risk Wounds

Major neurovascular bundles include large limb arteries proximal to critical branch points (Table 40.2). Proximity of a penetrating wound to a neurovascular bundle is defined variably as within 1 cm, 1 inch, or 5 cm. This concept is useful in evaluating patients with penetrating injury but without evidence of vascular injury. We consider penetrating wounds that occur within 1 cm of a major neurovascular bundle or whose presumed trajectory has crossed such a bundle to be sufficiently likely to produce an occult vascular injury that they warrant frequent (every 30 to 60 minutes) evaluation for the first 4 to 6 hours to ensure that a developing vascular injury is not missed within the warm ischemia window. However, routine imaging is not indicated based on proximity alone.

In addition, a small minority of patients with high-risk injuries, such as bites from large dogs or other animals, displaced fractures, crush injuries, or major joint dislocations (especially knee dislocation), may have occult vascular injuries that are not initially detected on physical examination. The risk of missing such injuries is that the traditional 6-hour window of warm ischemia time will be exceeded, or the patient will experience delayed complications resulting in limb loss. Patients with intimal flaps may be completely asymptomatic initially but can subsequently develop arterial thrombosis. Similarly, pseudoaneurysms progressively enlarge to produce compression of adjacent structures but may be very small and undetectable on initial physical examination. Consequently, these patients also should undergo serial physical examinations.

Due to their noncompressible location, blunt subclavian injuries can be particularly challenging. These are often associated with clavicular fracture or dislocation. Isolated first rib fractures are rarely combined with vascular injury unless posterior displacement occurs. Shear injury of the subclavian artery can occur as a result of a loose shoulder restraint during a motor vehicle collision (MVC). Counterintuitively, penetrating subclavian vein injuries are even more lethal than those to the artery because, in addition to massive blood loss, there is a relatively high risk of massive air embolism, which is frequently fatal.

TABLE 40.2 Major Neurovascular Bundles

Major Artery	Proximate Plexus/Nerve
Axillary artery	Brachial plexus
Brachial artery	Median nerve
Radial artery	Median and radial nerves
Ulnar artery	Ulnar nerve
Femoral artery	Femoral nerve
Popliteal artery	Tibial nerve

Popliteal artery injuries can often be a result of knee dislocations, most of which will have spontaneously reduced. Patients showing complete ligamentous disruption of the knee on physical examination should be suspected of having a spontaneously reduced knee dislocation leaving little evidence of the original trauma, particularly in obtunded patients. Hemarthrosis may also be absent if the joint capsule is torn because blood can track into the fascial planes of the leg.

History

In patients who achieve and maintain hemodynamic stability, a more comprehensive history can be obtained. Important historical points to note include the exact time and mechanism of the injury. The time of injury is important because of the significant morbidity that results from prolonged warm ischemia time. The mechanism is of clinical and often forensic importance in that injuries are frequently inflicted during a criminal act or in the workplace. Various mechanisms of injury may mandate special reporting that can alter the patient's ultimate disposition. Certain types of injuries, such as crush or bite wounds, are particularly prone to complications. The occupation, avocation, and hand dominance of the patient are pertinent to determine the best approach to achieve maximum functionality. Comorbid medical conditions are also important. Patients who are immunocompromised because of diabetes mellitus, acquired immunodeficiency syndrome (AIDS), asplenia, cancer, or chronic steroid use are at increased risk for infection and impaired wound healing. Patients with preexisting vascular insufficiency have more tenuous perfusion, are more susceptible to ischemia from elevated compartment pressure, and have a higher incidence of complications. As with most aspects of trauma care, patients whose sensorium is altered by head injury or intoxication, patients with spinal cord injury who cannot perceive pain, and those with significant painful distracting injuries will not reliably be able to report pain or paresthesias suggesting vascular insufficiency, so extra vigilance should be exercised in these cases.

Evidence of abdominal injury raises concern for injury to the iliac vessels, and virtually all iliac artery and vein injuries have associated trauma to the small or large intestine, bladder, solid viscera, or bony pelvis. The common and external iliac arteries are injured with equal frequency and more often than the internal iliac vessels. Approximately 80% of iliac vessel injuries are caused by penetrating trauma, and the remainder are primarily associated with pelvic fractures. Trauma to the iliac veins is responsible for massive bleeding in displaced pelvic fractures and often requires angiographic embolization.

Physical Examination

Despite advances in technology, meticulous physical examination in combination with comparison of blood pressures in the affected and unaffected extremities remains the mainstay of diagnosis of vascular injury. Physical examination is directed at discovering evidence of local wound complications and distal ischemia suggestive of vascular injury. Pulses in the affected extremity are palpated to compare strength and

quality between the injured limb and its uninjured counterpart. Isolated detection of a diminished pulse distal to the site of injury merits further evaluation rather than immediate surgery because palpation of pulses is a relatively inaccurate means of predicting arterial injury. False-positive findings of a pulse deficit may occur because of shock, in which all pulses are diminished; congenital absence of a pulse in one extremity; preexisting vascular disease; operator technique; or arterial spasm or compression. False-negative findings can occur with transmission of the pulse through a "soft clot," past an intimal flap, or through collateral circulation. Distal pulses can persist despite significant arterial injury. Compression of an artery by casts, splints, or dressings may produce a pulseless extremity, and these should be removed if there is evidence of ischemia. Symptoms of limb ischemia may be apparent with absent radial and brachial pulses. However, pulses are only rarely completely absent, because collateral flow from the thyrocervical trunk may provide sufficient perfusion to avoid the symptoms and signs of ischemia. Finally, although the pulse may be absent, the extremity may be well perfused by collateral arterial supply, thus making immediate repair of the arterial injury less essential. Comparative palpation of the injured and unaffected limbs can also detect differences in skin temperature that may suggest hypoperfusion. Testing two-point discrimination on the injured and unaffected limbs may help to detect sensory deficits. Auscultation over the site of injury may reveal a bruit, which is present in more than half of patients with AVF. Repeated examination of any hematoma adjacent to a wound is indicated during the first 24 hours to determine whether it is expanding or pulsatile.

Neurologic deficits in the upper extremity occur in more than half of patients. The most severe of these injuries is damage to the brachial plexus, which occurs in nearly half of patients with blunt injury.

DIFFERENTIAL DIAGNOSES

In many cases, peripheral vascular injury will be readily apparent by external bleeding or hematoma formation. In other cases, vascular injury is suspected by the location or nature of the trauma the patient sustained. In all patients, vascular injury is a cue to search for associated injuries, such as bony injuries, injuries to proximate nerves, and soft tissue injuries due to either direct trauma or compression secondary to compartment syndrome. Conversely, some cases of vascular injury may not be obvious on initial examination and should be sought when evaluating patients with potential deep vein thromboses, crush injuries, and other presentations of acute extremity pain.

DIAGNOSTIC TESTING

Plain Radiography

Plain radiographs of the affected extremity are indicated to detect fractures, joint penetration, and foreign bodies. With gunshot wounds, the sum of the number of intact bullets seen on radiographs and the number of entrance and exit wounds in the body should be an even number. Rarely, bullets or shotgun pellets can deflect off bone and travel sufficiently far as to not be visible on the radiograph. Bullets or pellets can migrate distally and produce vascular occlusion or migrate proximally through the venous system to the heart. When there is concern for a missing projectile, broaden the radiographic search or consider a "through and through" penetrating injury in which the object passes through the extremity and exits the body.

Pulse Oximetry and Near-Infrared Spectroscopy

Pulse oximetry has been found to be a relatively insensitive means of identifying limb ischemia after trauma and should not be considered a discriminatory or useful test for vascular injury. However, measurement of tissue oxygenation by near-infrared spectroscopy (NIRS) to quantify muscle oxyhemoglobin has shown potential as a possible noninvasive and simple means of detecting diminished vascular perfusion; however, it is not yet used in common practice for this indication.[9]

Handheld Doppler

Absent or diminished pulses in an injured extremity should be evaluated using a handheld Doppler. Arterial injury is suggested by absent Doppler signal or by a change in the usual triphasic quality of the Doppler pulse to a biphasic or monophasic waveform, because the pulse is "damped" by partial occlusion.

Arterial Pressure Index and Ankle-Brachial Index

Measuring systolic blood pressure in the injured versus the uninjured extremity (arterial pressure index [API]) or measuring it in an injured leg at the ankle compared with brachial artery pressure (ankle-brachial index [ABI]) is an accurate means of screening for arterial injury. Systolic pressure is measured by inflating a standard blood pressure cuff proximal to the injury and recording handheld Doppler systolic pressure distal to the injury. The process is repeated on the uninjured limb (or the arm, if calculating an ABI), and a ratio of injured to uninjured systolic pressure is calculated. In general, a ratio less than 0.90 is considered abnormal and indicates need for further investigation. Clinical studies of API/ABI have shown promising results. In several studies, an API/ABI less than 0.90 yielded a sensitivity and specificity for the detection of vascular injury of more than 95%, with correspondingly high positive and negative predictive values.[10]

Patients with suspected vascular injury who have an API/ABI of 0.90 to 0.99 merit observation for 12 to 24 hours for repeated physical examination and API measurements to detect potentially evolving injury. Patients with normal physical examination findings and a completely normal (greater than or equal to 1.0) API/ABI can be safely discharged from the ED, provided that there are no other associated injuries requiring admission.

However, reliance on the API/ABI to screen for arterial injury is not always possible. Comparisons cannot be made when both limbs are injured or when severe soft tissue disruption precludes placement of a blood pressure tourniquet. Certain arteries (e.g., the profunda femoris, profunda brachii, and peroneal arteries) normally do not produce palpable pulses, and so API/ABI is of limited usefulness if injuries to these vessels are suspected. Shotgun wounds often are associated with normal API/ABI measurements despite multiple small arterial wounds; catheter-based angiography is the preferred diagnostic modality in this group.

Despite the limitations previously noted, API/ABI has proven effective in screening patients with proximity wounds in the ED setting. The vast majority of injuries missed by API/ABI heal spontaneously. Those that do not heal generally present within 3 months with signs of arterial injury and can be repaired electively.

Ultrasound

Bedside B-mode (real-time) ultrasound, particularly with color flow Doppler (see later), can reliably identify loss of arterial pulsation in major vessels (see also Chapter e3). However, B-mode ultrasound cannot visualize certain anatomic areas accurately (e.g., subclavian and iliac vessels) because of inadequate tissue windows, and it is unreliable in detecting a fresh, relatively nonechogenic thrombosis or hematoma. As blood liquefies within a hematoma, it becomes echolucent and more readily distinguishable from surrounding tissues.

Doppler ultrasound interprets sound moving toward or away from the transducer as flow. Venous flow is heard as a low-pitched hum, whereas arterial flow has a higher-pitched, triphasic quality. The

combination of B-mode and Doppler ultrasound is called *duplex ultrasound* and has enhanced accuracy in examining blood vessels. Duplex scans showing a focal increase in peak systolic velocity suggest partial obstruction of the vessel. However, duplex scanning is slightly less accurate for detecting injuries that do not decrease flow, such as small pseudoaneurysms, AVFs, and intimal flaps. In addition, it is technically limited in examining certain anatomic areas, such as the profunda femoris and profunda brachii arteries and the iliac and subclavian vessels. Duplex ultrasound findings may be subtle, and as with other applications of ultrasound, its accuracy is operator dependent. Despite these limitations, the sensitivity of duplex ultrasound in comparison with standard angiography ranges from 83% to 100%, with a specificity of 99% to 100% and an accuracy of 96% to 100%.[11]

Color flow Doppler converts Doppler echoes into quantitated visual signals. Flow toward the transducer is seen as red, and flow away from the transducer is seen as blue. The intensity of the color (the number of pixels on the screen) is proportional to flow through the vessel. Small prospective studies have indicated a high rate of accuracy in detecting arterial injury with color flow Doppler. Absence of flow is readily apparent, but subtle injuries, such as intimal flaps and small pseudoaneurysms, can be more difficult to identify than with CTA. The overall sensitivity of color flow Doppler in detecting arterial injury is 50% to 90%, with a specificity of 95% to 99%. The sensitivity for detecting injuries requiring surgical repair is greater than 90% (Figs. 40.6 and 40.7).[11]

Computed Tomography and Magnetic Resonance Imaging

With a few important exceptions, CTA has largely replaced catheter-based angiography for the detection of peripheral vascular injury in most trauma centers. Multidetector helical computed tomography (CT) scanners have proven very accurate for diagnosis of peripheral vascular injury in multiple series, with a sensitivity of 93% to 100% and specificity of 87% to 100% compared with catheter-based angiography.[12–14] The advantages of CTA over catheter-based angiography are that it is noninvasive, readily available, and less costly and provides information on other injuries in the region being studied. However, there are several

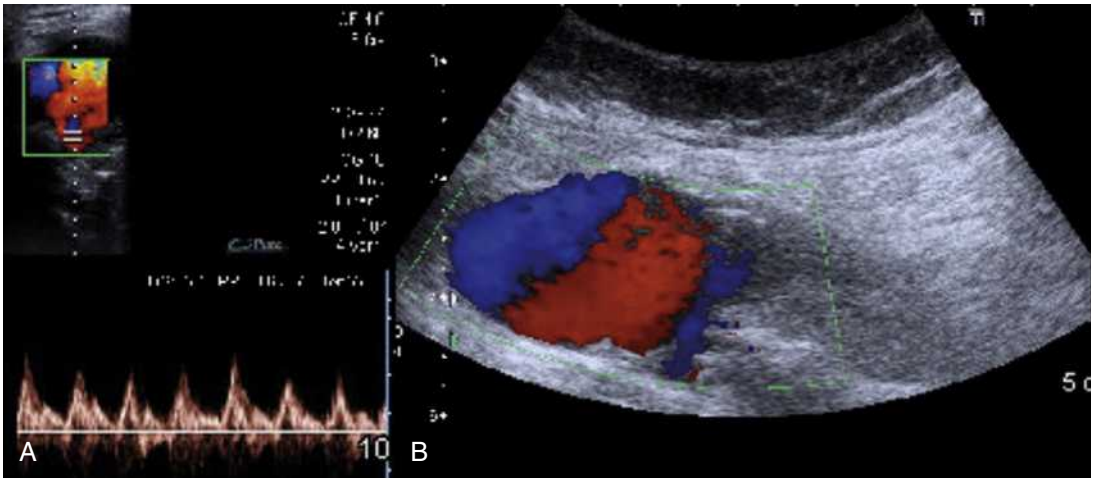

Fig. 40.6 Sonography of popliteal fossa with systolic bruit (A) and longitudinal color Doppler ultrasound (B) showing arterial blood. (From Tejero-Garcia S, Lirola Criado JF, Ast MP, et al: Popliteal pseudoaneurysm after unicompartmental knee replacement: a case report. *Knee.* 2014;21[2]:597–599.)

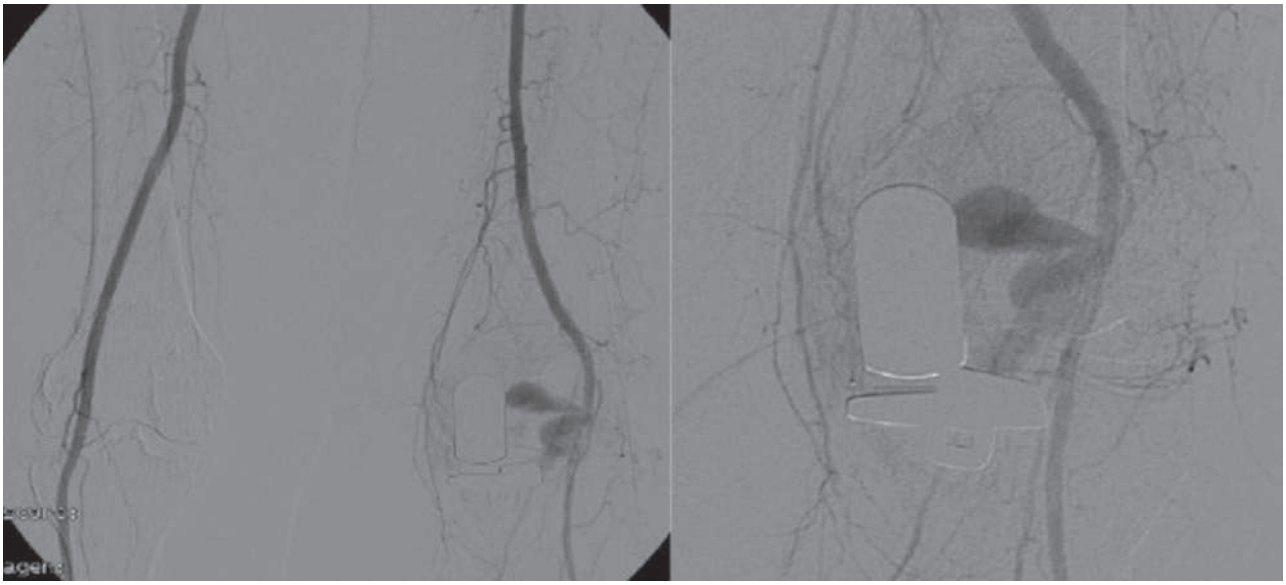

Fig. 40.7 Digital subtraction angiography of both popliteal arteries shows pseudoaneurysm on the *left (zoomed image on the right).* (From Tejero-Garcia S, Lirola Criado JF, Ast MP, et al: Popliteal pseudoaneurysm after unicompartmental knee replacement: a case report. *Knee.* 2014;21[2]:597–599.)

limitations to the use of CTA. Metallic artifact from bullets, orthopedic hardware, or other penetrating objects may obscure visualization of parts of a vessel, although with image reconstruction techniques, this problem can be largely overcome. Venous injuries may be missed depending on the phase of the contrast. The rapid image acquisition of current CT scanners makes timing of the contrast bolus more critical, and out-of-phase images may miss arterial injury. In practical terms, though, CTA is very useful in that it can be integrated into an overall plan for diagnostic imaging, including CT of the head and trunk, all of which can be accomplished rapidly.[12] Because of the enhanced detail, accuracy, and speed of image acquisition with 64 and greater slice CT scanners and the ability to perform three-dimensional reconstructions, this modality has become the standard imaging technique for suspected vascular injury. Magnetic resonance angiography (MRA) has been described and accurately detects vascular injuries but is not yet widely used. In most institutions, MRA is less readily available, more time consuming, and not appropriate for unstable patients.[12] MRI is also contraindicated in the presence of ferromagnetic foreign bodies.

Arteriography

Historically, catheter-based contrast angiography was used for diagnosing peripheral arterial injury. However, given the ready availability of CTA and additional steps necessary to obtain an angiography (transfer of the patient, activation of the angiography team, preparation of the angiography suite), CTA has replaced angiography as the initial diagnostic modality of choice in the ED.[12] Even those patients who may need intervention (embolization of pseudoaneurysms, endovascular stent insertion to bypass a dissection or AVF, and injection of thrombolytic agents to dissolve thrombus that are routinely performed via intra-arterial catheter) are best served by first obtaining a rapidly available CTA to establish the diagnosis.

Diagnosis of Specific Vascular Injuries

Although the aforementioned diagnostic strategies apply to vascular trauma overall, certain injuries bear particular mention.

For subclavian artery injury, the combination of physical examination and chest x-ray findings suggestive of subclavian injury (hemothorax, pneumothorax, apical pleural cap, or wide mediastinum) identifies nearly all injuries, and arteriography is not indicated in the absence of findings. When injury is suspected, and the patient is unstable, operative intervention is indicated. However, if the patient's clinical condition permits, angiography can confirm the diagnosis and can locate the injury precisely. APIs are not reliable with proximal thoracic outlet injuries because of collateral arterial flow. Ultrasound techniques are also relatively inaccurate in detecting subclavian injuries because of interference by overlying gas-filled lung tissue. Therefore, in cases in which the clinical diagnosis is equivocal (soft signs of injury or proximity wounds), arteriography (CTA or catheter based) is required to detect the injury.

No consensus has been reached on the diagnostic approach to detect popliteal artery injury resulting from documented or suspected knee dislocation. It is impractical to perform routine arteriography on every case of obvious or suspected knee dislocation. Although the exact diagnostic strategy is institution specific and dependent on available resources, our trauma center's approach is to perform a CTA in cases of high-energy mechanisms of blunt trauma (e.g., auto vs. pedestrian or MVC). For lower-energy blunt mechanisms, such as athletic injury, we perform serial clinical evaluations, including ABI. However, patients with *penetrating* trauma and more than one hard sign of popliteal artery injury can be taken directly to the operating room for repair, because delaying these cases to obtain a CTA is unnecessary for definitive care.

MANAGEMENT

Management of peripheral vascular injury is part of the total care of the trauma patient, including control of active hemorrhage by direct digital pressure. Blind clamping of a bleeding vessel is not recommended because of the risk of crushing adjacent nerves; however, clamping a clearly visible bleeding vessel can be effective. Tourniquet use for up to 6 hours is safe and effective, and it has been associated with increased survival in patients with major limb trauma. Tourniquets should be applied if direct pressure is insufficient to control bleeding and left in place until definitive surgical control can be achieved.[15] Few complications are associated with the use of tourniquets, and almost all of these are transient.[16] In cases in which proximal and distal control of large-vessel injuries cannot be readily achieved in the ED, insertion of a Foley catheter into the wound and inflation of the balloon with sterile water can temporarily tamponade the bleeding. Intravenous lines should not be started in the injured extremity, because they may be ineffective in delivering resuscitation fluid or medication and because extravasation from an injured vein may increase compartment pressure. Serial hemoglobin determinations may indicate unexpected blood loss from occult vascular injury. Patients with significant blood loss should have blood typed and crossmatched and may require immediate transfusion for stabilization. Patients with significant vascular injury often remain hypotensive despite crystalloid infusion and require further volume infusion or blood transfusion.

The issue of hypotensive resuscitation is controversial with regard to major vascular injuries. A tenuous clot can form in an injured artery and prevent further blood loss as long as the patient remains hypotensive. Once arterial pressure reaches a critical but variable point, the clot may be dislodged or expelled, and massive blood loss can ensue. Therefore, when an arterial injury is inaccessible for occlusion by direct pressure, the target blood pressure for resuscitation should be lowered to a systolic pressure of approximately 90 mm Hg. Overly rapid fluid administration in the field or in the ED can produce transient intravascular hypervolemia and may ultimately increase the rate of blood loss. Closely monitor vital signs and the total volume of fluid infused.

Once a vascular injury has been identified, a specific diagnostic and therapeutic strategy should be developed that is consistent with the severity of the injury, the presence of other injuries, and the resources available. In hospitals without the ability to perform vascular repair, transfer arrangements to a trauma center should be initiated early. In cases in which the transfer will involve a delay of several hours, cooling the ischemic limb will avoid exceeding the critical 6-hour cutoff for warm ischemia. To accomplish this, wrap the limb in towels, and apply ice in plastic bags around the limb, avoiding direct contact of the ice to the limb, which can result in frostbite.

Major Vascular Injuries

Major vascular injuries that compromise the viability of a limb should be repaired within 6 hours to avoid irreversible ischemic neuropathy and myonecrosis. Treatment of vascular injury has changed dramatically in the past 10 years. Endovascular treatment with self-expanding stents is currently the preferred technique for repair of these injuries in stable patients, and the majority of arterial repairs in the United States are now done with this technique.

Upper Extremity Arterial Injuries

For brachial artery injuries, limb salvage rates have improved to nearly 100% owing to efficient out-of-hospital transport, improved surgical techniques, and shorter time to first antibiotic dose. Repair is indicated in all cases because the amputation rate is high with ligation.

Injuries to forearm vessels detected by arteriography or ultrasound do not need to be repaired unless there are signs of ischemia in the hand; "hard signs" of arterial injury, such as an expanding hematoma, a pseudoaneurysm, or an AVF; or injury to both radial and ulnar arteries. However, some authors recommend repairing all these injuries because of the risk of intermittent claudication or cold intolerance in patients who have one artery ligated. Certain patients are almost exclusively dependent on the ulnar arterial supply to the hand because of an underdeveloped deep palmar arch. Clearly, ulnar artery injuries should be repaired in these patients. Ultimately, the decision to repair an arterial injury is in the domain of the vascular surgeon. Compartment syndrome in the forearm is common after repair of proximal arteries and veins and may require fasciotomy.[17]

Lower Extremity Arterial Injuries

In patients with severe injuries to the lower extremities, an initial "damage control" laparotomy with temporary vascular shunting of the iliac vessels is often necessary as resuscitation continues. Distal ischemic complications occur in approximately one-third of repaired iliac arteries, and subsequent amputations are required in up to 20% of cases.

Femoral artery injuries should be repaired as simple ligation of the common femoral artery and results in amputation of the lower extremity in 80% of cases.

Factors that place patients at higher risk of amputation include severe soft tissue injury of the extremity, the presence of multiple fractures, major venous repair, or delay in repair exceeding 6 hours of warm ischemia time. Because of the high incidence of compartment syndrome with lower leg injuries, fasciotomy is required in half of cases, and some centers routinely perform fasciotomy in all such cases.[17]

Late Complications of Arterial Injury

Despite timely optimal repair of arterial injuries, approximately one in five patients experiences delayed complications requiring further surgical intervention, including delayed amputation. The most common of such complications is delayed thrombosis, which often occurs after many months as stenosis at the repair site progresses. Other complications include intermittent claudication, chronic pain or edema of the limb, and aneurysm formation in the graft.

Venous Injuries

Venous injuries may be primarily ligated if the patient's condition makes them unable to tolerate a prolonged operative intervention. However, the current trend is to repair major venous injuries if possible, particularly in the lower extremity, because wound healing is improved and the incidence of compartment syndrome, venous thrombosis, pulmonary embolism, and chronic edema is decreased. Extensive venous collaterals in the upper extremity make surgical repair less compelling.

Minor Vascular Injuries

Increasingly, minor nonocclusive vascular injuries are being treated expectantly. Criteria for observation of vascular injuries include low-velocity missile wounds, intact distal circulation, absence of active hemorrhage, and minimal arterial wall disruption noted on angiography. Angiographic or CTA findings meeting these criteria include intimal flaps extending less than 5 mm and pseudoaneurysms smaller than 5 mm in diameter. Follow-up of these injuries with repeat angiography or ultrasound reveals that approximately 85% resolve spontaneously. Patients meeting these criteria can be monitored as outpatients for 3 months, with repeat physical examination and ultrasound to detect delayed complications. Most intimal flaps heal spontaneously, and asymptomatic injuries that do not disrupt perfusion of the limb can be treated conservatively with early administration of antiplatelet agents, such as clopidogrel or aspirin. However, almost all pseudoaneurysms ultimately require repair and, once discovered, should be repaired electively rather than undergoing continued observation. Failure to detect and repair occult arterial injuries in children often results in severe differential limb growth. Thus a more aggressive approach of repairing arterial injuries that cause a relatively minor decrease in blood flow to a child's growing limb may be justified.

Arterial Spasm

Isolated arterial spasm usually reverses with conservative treatment (topical warm saline or topical nitroglycerin paste), but prolonged spasm may require infusion of vasodilators, such as nitroglycerin, calcium channel blockers, alpha-blockers, nitroprusside, and specific prostaglandin inhibitors.

Antibiotics

Gram positive antibiotic coverage is needed for Type I and Type II fractures. Gram negative coverage is added for Type III open fractures. Appropriate antibiotic coverage (ideally administered within one hour of presentation) might include a first-generation cephalosporin (e.g., cefazolin 1 to 2 g intravenously preoperatively) and gentamicin 5 mg/kg. Alternative antibiotics include ceftriaxone and piperacillin/tazobactam.[18]

DISPOSITION

Patients with confirmed injury to major vessels, equivocal findings on diagnostic tests, or symptoms of limb ischemia should be admitted to the hospital or ED observation unit for further investigation and serial physical examinations. Frequent vascular and neurologic checks will be necessary in these patients, so step-down or intensive care unit levels of care may be necessary. Consultation with a vascular surgeon is indicated as soon as vascular injury is strongly suspected or the need for emergency operative repair established. Patients who are unstable because of vascular or other injuries may undergo further investigation or exploration in the operating room. If the treating hospital is incapable of performing vascular surgery or appropriate investigations, expedited transfer arrangements to a trauma center should be initiated. Obtaining angiograms for proximity wounds in centers that are incapable of acting on positive results is discouraged because this may delay definitive care beyond the safe limits of warm ischemia time.

CHAPTER 40: QUESTIONS AND ANSWERS

1. An 18-year-old man presents complaining of left lower leg pain. He was involved in a motor vehicle collision (MVC) 1 month earlier and required surgical repair of a left femur fracture. Which of the following is the *least* likely cause of the patient's symptoms?

a. Compartment syndrome
b. Intimal flap
c. Pseudoaneurysm
d. Thrombosis
e. Vessel stricture formation

Answer: a. Delayed thrombosis can occur months to years after injury if the injured vessel heals with stricture formation and decreased blood flow distally, followed by stasis and clot formation. Although flow is not altered by small intimal flaps and the associated soft tissue wounds often appear benign initially, they may become a nidus for thrombosis that can occur hours to months after the initial injury. The cavity of a pseudoaneurysm is in direct communication with the lumen of the vessel, so embolization of mural clots may produce distal arterial occlusion. Patients with pseudoaneurysm are commonly seen months to years later with symptoms of compression neuropathy or peripheral arterial embolism. The delayed presentation of this patient makes compartment syndrome the least likely cause of his leg pain.

2. A 45-year-old man complains of right leg pain and edema shortly after surgery for a midshaft femur fracture. Physical examination reveals decreased distal pulses in the extremity. What is the most important diagnosis to consider in this patient?

a. Anemia causing poor tissue oxygenation
b. Compartment syndrome
c. Intimal flap
d. Pseudoaneurysm
e. Vessel stricture

Answer: b. After restoration of arterial flow to a previously ischemic limb, a cascade of reperfusion injury has been identified that results from release of oxygen free radicals, lipid peroxidation, and influx of intracellular calcium. These mediators give rise to progressive cellular damage, edema, and necrosis, thereby propagating the vicious cycle that increases compartment pressure.

3. After vascular injury to an extremity, how many hours are generally required before irreversible damage occurs?

a. 2 hours
b. 6 hours
c. 10 hours
d. 12 hours
e. 24 hours

Answer: b. Although individuals may vary, 6 hours of complete warm ischemia is generally considered the point at which irreversible nerve and muscle damage begins to occur. After 6 hours of warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificially cooling the limb to just higher than freezing temperature will reduce the metabolic demands of ischemic tissues and greatly prolong the tissue's tolerance of ischemia to 24 hours or more.

4. A 25-year-old man who sustained a gunshot wound to the right leg has an ankle-brachial index (ABI) of 0.9. What is the most appropriate next step in this patient's management?

a. Admit for observation and repeat examinations.
b. Discharge the patient home with surgical follow-up.

c. Obtain an emergent computed tomography (CT) angiogram.
d. Obtain immediate vascular consultation.
e. Perform a Doppler ultrasound scan.

Answer: a. Patients with an ABI of 0.90 to 0.99 merit observation for 12 to 24 hours for repeat examinations and ABI measurements to detect evolving injury. In general, a ratio of less than 0.90 is considered abnormal and is an indication for further investigation, such as computed tomography angiography (CTA).

5. Which of the following is *least* likely to cause vascular injury to an extremity?
a. Close-range shotgun wound
b. Crush injury
c. Electrical injury
d. Gunshot wound from a long distance
e. Massive tissue avulsion

Answer: d. Close-range shotgun wounds can cause significant blunt trauma to vessels, as well as a higher rate of bone and nerve damage than gunshot wounds. An open avulsion injury to a limb is particularly severe because the skin is the final structure to be disrupted, and there is inevitable injury to deeper vessels and nerves. Vascular injury must be suspected in patients with massive soft tissue avulsion or crush injury, displaced long bone fractures, and electrical or lightning injuries.

41

General Principles of Orthopedic Injuries

Joel M. Geiderman and Sam Torbati

KEY CONCEPTS

- Many orthopedic injuries can be stabilized and treated definitively by the emergency clinician. Consultation with an orthopedist should be sought for the treatment of some long bone fractures, open fractures, injuries with joint violation, tendon injuries, and injuries with neurovascular compromise.
- A careful history and physical examination can predict radiographic findings in orthopedic injuries with a high degree of accuracy.
- Open fracture management should focus on the early administration of antibiotics, tetanus prophylaxis, dressing coverage of the wound, and splinting. Suggested therapy for open fractures includes a first-generation cephalosporin, with the addition of an aminoglycoside for type II or III fractures.
- Compartment syndrome is associated most commonly with a closed long bone fracture of the tibia but also is well described in the thigh, forearm, arm, hand, and foot and can occur with isolated soft tissue trauma. Clinical examination remains the diagnostic cornerstone of acute compartment syndrome, which may then be confirmed by compartment pressure measurement.
- Because of the anatomic location and blood supply distribution, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, and capitate are particularly prone to this complication.
- Fat embolism syndrome is a serious consequence of fractures, occurring most commonly after long bone leg fractures in young adults and after hip fractures in older patients. Acute respiratory distress syndrome is the most serious manifestation. Neurologic involvement, manifesting as restlessness, confusion, and deteriorating mental status, as well as thrombocytopenia resulting in a petechial rash are early signs.
- Patients should be evaluated for the ability to ambulate safely prior to discharge. The use of a walker or other device, if it can be used safely, is acceptable. It also must be assured that the patient or a caregiver can carry out essential activities of daily living.

OVERALL FOUNDATIONS

Background and Importance

Orthopedic emergencies and musculoskeletal complaints and conditions comprise approximately 20% of all emergency department (ED) visits.[1] Although rarely life-threatening, orthopedic injuries may threaten a limb or its function, and accurate early diagnosis and treatment can avert long-term complications. Outcomes, including preventable complications, may affect a person's quality of life. Many orthopedic injuries can and should be treated definitively by the emergency clinician. Consultation with an orthopedist should be sought for the treatment of most long bone fractures, open fractures, injuries with joint violation, tendon injuries, and injuries with neurovascular compromise.

When evaluating a potential orthopedic injury, the following basic general principles should be considered:

1. Most orthopedic injuries can be predicted by considering the chief complaint, age of the patient, mechanism of injury, and estimate of the amount of energy transferred during the injury.
2. A careful history and physical examination can predict radiographic findings with a high degree of accuracy. A presumptive diagnosis before a radiographic study may prompt the emergency clinician to order special views necessary to diagnose an injury correctly. Many fractures were accurately described even before the advent of radiology (Table 41.1).
3. If a fracture is suggested clinically, but radiographic films appear negative, the patient should be treated with immobilization as though a fracture were present. Similarly, certain soft tissue injuries require prompt identification and follow-up and should be immobilized despite normal radiographic findings. Computerized tomography (CT) or magnetic resonance imaging (MRI) may be helpful to better define these injuries if available.
4. Inadequate or suboptimal radiographic images should not be accepted and should be repeated.
5. When a fracture is suspected, radiographic studies should be performed before reductions are attempted in most instances, except when a delay could potentially be harmful to the patient or in some prehospital settings, such as when neurovascular compromise or ischemic skin is present.
6. Neurovascular status should be assessed and recorded prior to and following all reductions and after splint or cast application.
7. Orthopedic injuries should be described precisely and according to established conventions.
8. In a patient with multiple trauma, noncritical orthopedic injuries should be diagnosed and treated only after more threatening injuries have been addressed and the patient stabilized. Complex pelvic fractures that may lead to exsanguination are an exception.
9. Patients should receive explicit aftercare instructions before leaving the ED, covering areas such as monitoring for signs of

TABLE 41.1 Common Fracture Names and Their Origins

Fracture Eponym or Name	Description	Comment
Aviator	Vertical fracture of the neck of the talus with subtalar dislocation and backward displacement of the body	First described in flyers during World War I; arises from forced dorsiflexion of the foot in flying accidents and in traffic accidents after a head-on collision
Barton	Intraarticular fracture-dislocation of the wrist	Considered complicated and unstable; requires surgical reduction in most cases; described by Barton in 1838 before the advent of radiography
Dorsal Barton	Oblique intraarticular fracture of the dorsal rim of the distal radius with displacement of the carpus along with the fracture fragment	Results from high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in dorsiflexion at the moment of impact
Volar Barton	Wedge-shaped articular fragment sheared off the volar surface of the radius (volar rim fracture), displaced volarly along with the carpus	Similar mechanism as dorsal Barton but with wrist in volar flexion at time of injury; also referred to as reverse Barton's fracture; much rarer than dorsal Barton fracture
Bennett	Oblique fracture through base of the first metacarpal, with dislocation of the radial portion of the articular surface	Usually produced by direct force applied to the end of the metacarpal; dorsal capsular structures disrupted by the dislocation; marked tenderness along medial base of thumb
Bosworth	Fracture-dislocation of the ankle resulting in the fibula being entrapped behind the tibia	Rare injury, produced by severe external rotation force applied to the foot; physical examination reveals foot severely externally rotated in relation to the tibia
Boxer	Fracture of the neck of the ring or small finger metacarpal	Results from striking a clenched fist into an unyielding object, usually during an altercation, or against a wall, out of frustration or anger
Chance	Vertebral fracture, usually lumbar, involving the posterior spinous process, pedicles, and vertebral body	Caused by simultaneous flexion and distraction forces on the spinal column, usually associated with use of lap seat belts; anterior column fails in tension, along with the middle and posterior columns; may be misdiagnosed as a compression fracture
Chauffeur	Solitary fracture of radial styloid	Occurs from tension forces sustained during ulnar deviation and supination of the wrist; name derived from occurrence in chauffeurs who suffered violent, direct blows to the radius incurred while turning the crank on a car, only to have it snap back, during previous eras
Clay shoveler	Fracture of the tip of the spinous process of the sixth or seventh cervical vertebra	First described in Australian clay shovelers who sustained a fracture of the spinous process by traction as they lifted heavy loads of clay
Colles	Fracture of the distal radius with dorsal displacement and volar angulation, with or without an ulnar styloid fracture	Most common wrist fracture in adults, especially in older adults; results from fall on an outstretched hand; also known as silver fork deformity, which accurately describes the gross appearance in the lateral view; first described by Colles in 1814, before the advent of radiography
Cotton	Trimalleolar fracture	Fracture of the lateral malleolus, fracture of the posterior malleolus, and either a fracture of the medial malleolus or disruption of the deltoid ligament, with visible widening of the mortise on ankle radiograph
Dashboard fracture	Fracture of the posterior rim of the acetabulum	Named for mechanism of injury—a seated passenger striking the knee on a dashboard, driving the head of the femur into the acetabulum
Dupuytren	Fracture-dislocation of the ankle	Results from a similar mechanism as the Maisonneuve fracture (i.e., external rotation of the ankle), resulting in deltoid ligament rupture or medial malleolus fracture, diastasis of the inferior tibiofibular joint, and indirect fracture of the fibular shaft; Maisonneuve was a student of Dupuytren
Essex-Lopresti	Fracture of radial head with dislocation of the distal radioulnar joint	Results from longitudinal (axial) compression of the forearm
Galeazzi	Fracture of the shaft of the radius with dislocation of the distal radioulnar joint; ligaments of inferior radioulnar joint ruptured, head of ulna displaced from ulnar notch of the radius	Results from fall on outstretched hand, with the wrist in extension and the forearm forcibly pronated; inherently unstable, with tendency to redisplace after reduction
Hangman	Fracture-dislocation of atlas and axis, specifically of pars interarticularis of C2 and disruption of C2–3 junction; separation occurs between second and third vertebral bodies from anterior to posterior side	Results from extreme hyperextension during abrupt deceleration; most common cause is the forehead striking the windshield of a car during a collision; a bit of a misnomer in that hanging usually produces death by strangulation rather than cord damage
Hume	Fracture of the proximal ulna associated with forward dislocation of the head of the radius	Essentially high Monteggia injury
Jefferson	Burst fracture of ring of C1, or atlas	Axial loading results in a shattering of the ring of the atlas; decompressive type of injury; associated with disruption of transverse ligament; unstable injury

Continued

TABLE 41.1 Common Fracture Names and Their Origins—cont'd

Fracture Eponym or Name	Description	Comment
Jones	Transverse fracture of the fifth metatarsal base, occurring at least 15 mm distal to the proximal end of the bone, distal to the insertion of the peroneus brevis	Should not be confused with the more common avulsion fracture of fifth metatarsal styloid, produced by avulsion at the insertion of the peroneus brevis; Jones described the fracture that bears his name in 1902, after sustaining the injury himself while dancing.
Le Fort	Maxillary fracture	Types I, II, and III (see Chapter 34)
Le Fort-Wagstaffe	Avulsion fracture of the anterior cortex of the lateral malleolus	Rare pull-off injury of the fibular attachment of the anterior tibiofibular ligament
Lisfranc	Fracture located around the tarsometatarsal (Lisfranc) joint, usually associated with dislocation of this joint	Lisfranc, a field surgeon in Napoleon's army, described an amputation performed through the tarsometatarsal joint in a soldier who caught his foot in a stirrup when he fell off his horse; since then, the joint has borne his name.
Maisonneuve	Fracture of proximal third of fibula associated with rupture of the deltoid ligament or fracture of the medial malleolus and disruption of the syndesmosis	Results from external rotation of the ankle with transmission of forces through syndesmosis; proximally, the force is relieved by fracture of the fibula; described experimentally in 1840, before radiography
Malgaigne	Fracture of the ilium near the sacroiliac joint with displacement of the symphysis, or a dislocation of the sacroiliac joint with fracture of both ipsilateral pubic rami	Resultant pelvic injury is unstable; described by Malgaigne, based on clinical findings, in 1847
March	Fatigue, or stress, fracture of the metatarsal	Arises from long marches or other repetitive use trauma (e.g., marathon running) or, less commonly, from single stumbling movements
Monteggia	Fracture of the junction of the proximal and middle thirds of the ulna associated with anterior dislocation of the radial head	Usually caused by fall on outstretched hand along with forced pronation of forearm or by a direct blow on the posterior aspect of the ulna; reported by Monteggia in 1814
Nightstick	Fracture of ulna, radius, or both	Name derived from a citizen's attempt to protect himself from a police officer's baton or "nightstick" by offering the forearm
Piedmont	Closed fracture of the radius at the middle third–distal third junction, without associated ulnar fracture	Named for a series of cases presented at the Piedmont Orthopaedic Society of Durham, North Carolina
Pott	Definitions vary (see comment); usually a bimalleolar fracture or fracture of the distal fibula, 4–7 cm above the lateral malleolus	The exact fracture Pott described in 1769 is uncertain; clearly, it referred to a fracture of the lower fibula, usually associated with other fractures or dislocations about the ankle.
Rolando	Intraarticular fracture at base of the first metacarpal; frequently Y- or T-shaped, or may be severely comminuted	Produced by an axial load with the metacarpal in partial flexion; worse prognosis than a Bennett fracture and, fortunately, rarer
Salter-Harris	Epiphyseal fracture occurring in children or adolescents	Graded I–V, depending on degree of involvement and/or displacement of epiphysis and metaphysis (see text dealing with Salter-Harris fractures and Table 41.2)
Smith	Extraarticular fracture of the distal radius with volar displacement of distal fragment	Reverse of the Colles fracture but much more uncommon; sometimes referred to as a garden spade deformity; usually results from fall with force to back of hand; first described by Smith in 1847
Stener	Avulsion of the ulnar corner of the base of the proximal phalanx of the thumb	Bony equivalent of rupture of the ulnar collateral ligament, or so-called gamekeeper's thumb
Teardrop	Wedge-shaped fracture of the anteroinferior portion of the vertebral body, displaced anteriorly	Commonly involves a ligamentous injury; may produce neurologic injury
Thurston Holland fragment	Triangular metaphyseal fragment that accompanies the epiphysis in Salter-Harris type II fractures	Described by Thurston Holland in 1929; the name is commonly hyphenated, although technically it should not be
Tillaux	Isolated avulsion fracture of the anterolateral aspect of the distal tibial epiphysis	Occurs in older adolescents (12–15 years) after the medial parts of the epiphyseal plates close but before the lateral part closes; external rotation force places stress on anterior talofibular ligament; described by Tillaux in 1872

neurovascular compromise, increasing compartment pressure, cast care, wound care, weightbearing, crutch use, the use of ice and elevation, and a plan and timing for follow-up.

10. Patients must be checked for the ability to ambulate safely before discharge from the ED and should not be discharged unless safe transportation and home care can be established. Also assure that they or a caregiver can carry out essential activities of daily living on their behalf.

FRACTURES

Foundations

Anatomic Location of a Fracture: Nomenclature

Describing orthopedic injuries with precise language according to established convention enables accurate and clear communication with other providers and consultants. Terms commonly used to describe a fracture are listed in Box 41.1. A fracture is a break in the continuity

BOX 41.1 Fracture Description

of bone, which may be more subtle in children. Clinically, a history of trauma, loss of function, pain, tenderness, swelling, abnormal motion, and deformity all suggest a fracture.

Anatomic Descriptors

Description of a fracture should begin by stating whether the fracture is closed or open. In a closed fracture, the skin and soft tissue overlying the fracture site are intact. The fracture is considered open if it is, or has been, exposed to the outside environment in any manner, which may not be immediately obvious. Occasionally, it is difficult to determine whether a small wound in proximity to a fracture communicates with that fracture. Probing such a wound with a blunt sterile swab to establish a relationship may not be safe or accurate and should be avoided. If doubt exists, an open fracture should be assumed to be present and treated as such.

The exact anatomic location, including the name of the bone, left or right, and standard reference points along the bone (e.g., the humeral neck or posterior tibial tubercle) should be noted. Long bones can be divided into thirds—proximal, middle, or distal—and these thirds, or the junction of any two of them (e.g., the junction of the middle and distal thirds of the tibia), are often used to describe fractures. The most descriptive language possible should be used. It is better to say "closed fracture of the right ulnar styloid" than "closed fracture of the right distal ulna" because the former conveys more precise anatomic information and will help guide optimal treatment.

An additional modifier describes the direction of the fracture line in relation to the long axis of the bone in question. A *transverse* fracture occurs at a right angle to the long axis of the bone (Fig. 41.1A) whereas an *oblique* fracture runs oblique to the long axis of the bone (see Fig. 41.1B). A *spiral* fracture results from a rotational force, a torque, and encircles the shaft of a long bone in a spiral fashion (see Fig. 41C). The terms oblique and spiral are sometimes confused but can be important since the latter may have significance when child abuse is being considered as a mechanism of injury. A fracture with more than two fragments is termed *comminuted* (see Fig. 41.1D).

The position and alignment of the fracture fragments (i.e., their relationship to one another) should be described. Fragments are described relative to their normal position, and any deviation from normal is termed *displacement*. By convention, the position of the distal fragment is described relative to the proximal portion. Displacement may be described as a quantitative measurement (i.e., in millimeters) or as an approximate percentage of the bone width. It also may be described qualitatively as non, minimal, moderate, or severe. Fig. 41.2 shows dorsal displacement of the fractured radius, and Fig. 41.3 shows lateral, or *valgus*, displacement of the distal tibia and fibula.

Fig. 41.2 Dorsal Displacement of Distal Radius.

Alignment refers to the relationship of the longitudinal axis of one fragment to another; deviation from the normal alignment is termed *angulation.* The direction of angulation is determined by the direction of the apex of an angle formed by the two fracture fragments (Fig 41.4). The term *valgus* denotes a deformity in which the apex of the deformity points toward the midline. Conversely, the term *varus* denotes a deformity in which the apex of the angulation points away from the midline. The relative position or angulation of the distal fragment of a fracture may also be described with terms such as *radial* or *ulnar, dorsal* or *volar, anterior* or *posterior,* and *lateral* or *medial.* For the forearms and hands, the anatomical position (palms up) should be used, along with radial and ulnar rather than medial and lateral to describe the direction of displacement. One should also be aware of rotational deformity, present when the distal fragment of a fracture is rotated to some degree along the axis of the bone itself. Especially in the digits of the hand, when the finger is flexed, clinically significant radial or ulnar deviation may be present that are not seen on radiographs (see Chapter 42).

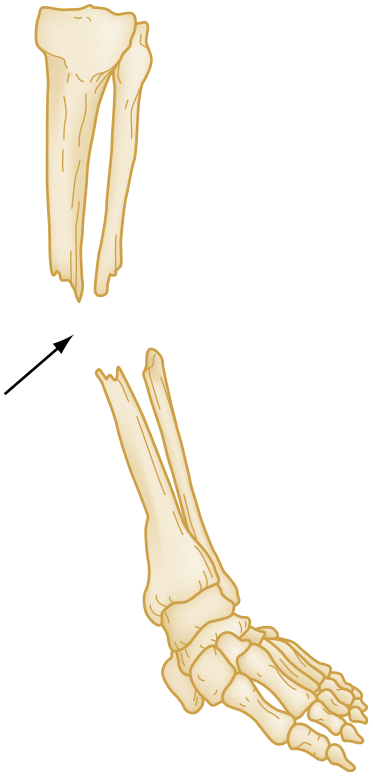

Fig. 41.3 Valgus Displacement of the Distal Tibia and Fibula. The distal segment is angled away from the midline of the body. The *arrow* shows the location of the fracture and the valgus displacement of the distal segment.

Descriptive Modifiers

A fracture is termed *complete* if it interrupts both cortices of the bone on orthogonal radiographic views and termed *incomplete* if one cortex remains intact. It should be noted whether a fracture extends into and involves an articular surface. Frequently, the percentage of articular surface involved can only be estimated; in some cases, the estimated percentage that is involved dictates the need to perform a surgical intervention. In general, it is important that the articular surface be restored to anatomic integrity to prevent consequent posttraumatic arthritis or disability.

The term *avulsion fracture* refers to a bone fragment that is pulled away from its normal position by the forceful contraction of a muscle (Fig. 41.5A) or the resistance of a tendon or ligament to a force in the opposite direction (see Fig. 41.5B). The term *impaction* refers to the forceful collapse of one fragment of bone into or onto another. In the proximal humerus, this collapse typically occurs in a telescoping manner, particularly in older patients, whose bones are osteoporotic and brittle. In the tibial plateau, impaction occurs frequently in the form of a depression (Fig. 41.6A and B) and, in the vertebral bodies, impaction frequently occurs in the form of compression resulting in a significant loss of bone height in some cases (see Fig. 41.6C).

A fracture that occurs through abnormal or diseased bone is termed *pathologic.* A pathologic fracture is suggested whenever a fracture occurs from seemingly trivial trauma. Diseases that cause structural weakness predisposing to injury include primary malignancy or malignant metastatic lesions, bone cysts, enchondromas, and giant cell tumors. In addition, metabolic and genetic disorders such as osteomalacia, scurvy, rickets, vitamin D deficiency, Paget disease, and osteogenesis imperfecta can alter bone density, making them susceptible to fracture. The term *pathologic* is also often applied to fractures through osteopenic bone when demineralization is a result of disuse, as in polio. In contrast, fractures through osteoporotic bone of older adults usually are not described as pathologic; these are more accurately referred to as geriatric or insufficiency fractures. When fractures occur in normal bones and a history of supposed trivial trauma or a suspicious mechanism is elicited, interpersonal violence or abuse should be suspected, and safety of the patient assured.

Repeated low-intensity forces may lead to resorption of normal bone, resulting in a stress fracture. Other terms for this condition are *fatigue fracture* and *march fracture* (see Table 41.1). Most stress fractures occur in the lower extremities and affect individuals involved in activities such as long-distance running, basketball, aerobics, and dancing. There is often a history of functional pain leading up to the fracture.

TABLE 41.2 Salter-Harris Classification

Type	Description	Diagram
I	Fracture extends through the epiphyseal plate, resulting in displacement of the epiphysis; this may appear merely as widening of the radiolucent area representing the growth plate.	II	As above; in addition, a triangular segment of metaphysis is fractured.	
III	Fracture line runs from the joint surface through epiphyseal plate and epiphysis.	IV	Fracture line occurs as in type III but also passes through adjacent metaphysis.	
V	This is a crush injury of the epiphysis; it may be difficult to determine by radiographic examination.	
Extrinsic factors such as training regimens, type of equipment used, nutrition habits, as well as intrinsic factors such as anatomic variation, muscle endurance, and hormonal factors, have all been associated with stress fractures. The tibia, fibula, metatarsals, navicular, cuneiform, calcaneus, femoral neck, or femoral shaft may be involved. These injuries may not be recognizable on initial plain films. Management therefore should be based on the clinical diagnosis.

Fracture Eponyms and Mechanistic Names

Many fractures were described before the advent of radiography and are described shorthand by an eponym or other name rather than by the exact bony injury. These eponyms and mechanistic names reflect the storied history of medicine and orthopedic care and are still commonly used to describe specific orthopedic injuries (see Table 41.1).

Epiphyseal Fractures

Fractures involving the epiphyses in children and adolescents are described according to the Salter-Harris classification (Table 41.2). The clinical features of fractures in children are further discussed in Chapter 170.

Clinical Features of Fractures

Fracture Healing

The goal of fracture reduction is to realign major bony fragments so that union can take place, and normal function is restored. In the initial stage of healing, a hematoma caused by the rupture of a vessel crossing the fracture line forms a hematoma. This hematoma eventually resorbs and provides the first continuity between the fragments. This *procallus* provides no structural rigidity for bearing stress but, with calcification and remodeling, callus is formed on the periosteal and endosteal surfaces of the bone, acting as a biologic splint. Over several months to a year, the callus normally completely ossifies, remodels, and becomes indistinguishable from mature bone.

Radiographic studies conducted 10 to 14 days after injury further reveal the fracture line as it becomes more visible due to localized bone resorption and hyperemia during the inflammatory phase. After 2 to 4 weeks, soft tissue swelling has regressed, and callus first becomes visible, initially in a mottled pattern and then taking on a dense appearance. Callus then undergoes organization, with peripheral margins becoming smooth as physically unstressed portions are resorbed.

In a healthy adult, the entire process from injury to consolidation takes approximately 2 months for the humerus and about 4 months for a large bone such as the femur. The rate of fracture healing is affected by the type of bone (cancellous bone heals faster than cortical bone), degree of fracture and opposition, systemic states, such as hyperthyroidism, use of corticosteroids, smoking, or illness requiring immobilization. Oblique fractures tend to heal more quickly than transverse fractures because of the greater amount of surface contact and a buttressing effect. Appropriately timed weightbearing can increase the rate of ossification of callus, whereas premature or excessive weightbearing can create a nonunion.

The presence of abundant bridging callus that is beginning to organize radiographically is usually associated with clinical union. If there is any suggestion of movement at the fracture site noted on clinical examination, union is regarded as inadequate. Several terms are used to denote abnormal healing. *Delayed union* is union that takes longer than usual for a particular fracture location; *malunion* occurs when a residual deformity exists; and *nonunion* is the failure of a fracture to unite. When nonunion results in a false joint, it is termed a *pseudarthrosis.*

If there is clinical evidence of stability, such as pain-free weightbearing, and radiographs demonstrate bridging bone at the cortices, a patient may resume activities of daily living with the injured extremity, even if the original fracture remains visible. The process of complete radiographic consolidation or healing can take several additional months.

Complications of Fractures

Infection (Osteomyelitis)

A fracture that communicates with the surface of the skin is termed an *open fracture.* Open fractures are treated as true, time-dependent orthopedic emergencies because of the risk of bone infection, or *osteomyelitis.* The high morbidity associated with osteomyelitis dictates that therapy be

BOX 41.2 Classification and Emergency Management of Open Fractures

Grades

Grade I: Wound less than 1 cm long, punctured from below

Grade II: Laceration 5 cm long; no contamination or crush; no excessive soft tissue loss, flaps, or avulsion

Grade III: Large laceration, associated contamination or crush; frequently includes a segmental fracture

- IIIA: Involves extensive soft tissue stripping of bone
- IIIB: Periosteal stripping has occurred
- IIIC: Major vascular injury present

Management

1. Control hemorrhage in field with sterile pressure dressing after carefully removing gross debris (e.g., wood, clothing, leaves).
2. Splint without reduction, unless vascular compromise is present.
3. Irrigate with saline, cover with saline-soaked sponges after arrival in the emergency department.
4. Begin IV antibiotic prophylaxis, usually a first-generation cephalosporin for grade I, with the addition of an aminoglycoside for grades II and III.
5. Administration of tetanus prophylaxis, including tetanus immune globulin, for large crush wounds.

initiated expeditiously, including parenteral administration of antibiotics as early as possible, coverage with a moist dressing, and emergent washout of debris. The Gustilo-Anderson classification is commonly used to describe the various types of open fractures (Box 41.2).

Suggested antibiotic therapy currently includes a first-generation cephalosporin, such as cefazolin, 2 g IV every 8 hours, for all open fractures, with the addition of an aminoglycoside, such as gentamicin, 5 mg/kg once daily, for type II or III fractures. Alternatively, a beta-lactam with both gram positive and negative coverage (e.g., ceftriaxone or piperacillin-tazobactam) may provide equivalent benefit. For patients with farm-related injuries or those with potential fecal contamination, ampicillin or penicillin should be added to the treatment regimen to empirically cover for clostridial contamination. Early versus delayed debridement of open fractures and the subsequent effect on rates of infection has been a source of debate.[2] Historic guidelines recommending debridement of open fracture wounds within 6 hours of injury were based on animal experiments conducted in the 1890s. The timing of debridement—less than 6 hours versus more than 6 hours after injury—has not been proven to change outcome, but general practice is to undertake debridement and irrigation of the wound within the first 24 hours of injury. Regardless, the goals of open fracture management in the ED should focus on early administration of antibiotics, tetanus prophylaxis, dressing coverage of the wound, and splinting of the extremity.

Open distal tuft fractures of the fingers and toes are a notable exception to the previous recommendation. These are common when the phalanx of a finger or toe is subject to crush injury (e.g., by a closing door) and there is a skin wound overlying a fractured bone. Treatment of these injuries can be provided by the emergency clinician without the need for immediate consultation. Vigorous irrigation and debridement are adequate primary treatment for these injuries, provided digital arteries are intact. Infections of the tuft region are rare.

Hemorrhage

Because of the rich blood supply to the skeleton, fractures can result in large amounts of blood loss, shock, and even death from exsanguination. In particular, certain pelvic fractures can cause major blood loss because adequate tamponade is not possible. In adults, blood loss can range from 100 mL from a forearm fracture to 3 L from a pelvic fracture (Table 41.3). Such hemorrhage can be controlled in part by early stabilization of the injured area through splinting, a binder, or skeletal traction. Definitive treatment options include embolization by an interventional radiologist or by emergent surgical intervention (see Chapter 46).

TABLE 41.3 Blood Loss Associated With Fracture in Adults

Fracture Site	Amount of Blood Loss (mL)
Radius and ulna	150–250
Humerus	250
Tibia and fibula	500
Femur	1000
Pelvis	1500–3000

Vascular Injuries

Vascular injuries are characteristically associated with certain fractures and may be limb threatening. Fractures and dislocations at the femorotibial articulation of the knee result from tremendous force, which may injure the popliteal artery and lead to the need for amputation (see Chapter 48). Fracture of the femoral neck requires emergent fixation regardless of the need for reduction to protect the blood supply to the femoral head and prevent aseptic necrosis. In the extremities, assessment of vascular injuries may be challenging. The initial survey should note the presence or absence of pulses and the state of capillary filling. If an end artery is completely disrupted, the tissue distal to the injury may exhibit the classic five Ps: pain and paresthesias (in the conscious patient), followed by pallor, pulselessness, and paralysis. Incomplete and subclinical injuries occasionally occur that initially may be asymptomatic and undetectable. In an unconscious, multiple trauma injured patient, major vascular injuries may not be obvious and may be overlooked. The mechanism of injury and anatomy dictate the need to assess the possibility of an injured vessel. If pulses cannot be palpated, a Doppler stethoscope should be used to detect blood flow. Even the presence of pulses may be misleading however, because pulses may be normal in some patients with significant arterial injuries. When pulses are present, but the mechanism of injury suggests the possibility of a vascular injury, additional diagnostic studies or surgical exploration may be necessary. If a limb is clearly not perfused, operative vascular exploration and repair should be undertaken promptly. Late complications of undiagnosed vascular injuries include thrombosis, arteriovenous fistulae, aneurysm, false aneurysm, and tissue ischemia with limb dysfunction. Delay of vascular injury repair is a risk factor for consequent amputation. The evaluation of peripheral vascular injuries is further discussed in Chapter 40.

Nerve Injuries

Nerves can be injured by blunt or penetrating orthopedic trauma:

- Neurapraxia is the contusion or traction injury of an otherwise intact nerve, with temporary disruption of the ability to transmit impulses. Paralysis, if present, is transient, and sensory loss is slight. Normal function usually returns to a neurapraxic nerve in weeks to months.
- Axonotmesis is the result of a crush or traction with more severe injury. There is complete interruption of the nerve axon and its myelin sheath, but the mesenchymal structures including perineurium and epineurium are either completely or partially intact. Because the Schwann tubes remain in continuity, spontaneous healing is possible, but delayed.
- Neurotmesis is the severing of a nerve along with its surrounding stroma, usually requiring surgical repair.

When the nerve is completely severed, all functions are absent, including superficial sensation to touch, pain, and temperature; deep sensation to muscle and joint movements; deep pressure, and vibration;

TABLE 41.4 Nerve Injuries Accompanying Orthopedic Injuries

Orthopedic Injury	Nerve Affected
Distal radius	Median nerve
Elbow injury	Median or ulnar nerve
Shoulder dislocation	Axillary nerve
Sacral fracture	Cauda equina nerve
Acetabulum fracture	Sciatic nerve
Hip dislocation	Femoral nerve
Femoral shaft fracture	Peroneal nerve
Knee dislocation	Tibial or peroneal nerve
Lateral tibial plateau fracture	Peroneal nerve

TABLE 41.5 Life-Threatening or Limb-Threatening Emergencies

Condition	Possible Adverse Outcome
Open fracture	Osteomyelitis
Fracture or dislocation with major vascular disruption (especially popliteal)	Amputation
Major pelvic fracture	Exsanguination
Hip dislocation	Avascular necrosis of femoral head
Compartment syndrome	Ischemic contracture; amputation; myoglobinuria, renal failure

motor supply and deep tendon reflexes to distally innervated muscle groups; and response to electrical stimulation. For less severe injuries, any subjective change in sensation should be noted. Light touch is a good screening test. Two-point discrimination is a more sensitive examination and should be used routinely in evaluating digital nerves. The discrimination on the injured digit is then compared with the uninjured ones. A normal two-point discrimination value at the fingertip of an adult is 4 mm, or discrimination may be compared to a non-injured digit. Evaluation of the innervation of the hand is further discussed in Chapter 42.

The injured nerve, patient age, site, and delay between injury and repair have all been shown to influence prognosis after microsurgical repair. Due to proximity, specific nerve injuries characteristically accompany certain fractures (Table 41.4). For example, in the upper extremity, a distal radius fracture caused by a high-energy insult can be associated with acute dysfunction of the median nerve. Deteriorating or lost neurologic function may necessitate temporary or definitive stabilization of a fracture.

Compartment Syndrome

Compartment syndrome is an acute, emergent complication that should be considered whenever significant pain and paresthesias occur in an extremity following a fracture or crush injury within an enclosed osseofascial space (Table 41.5). Pain is typically severe and out of proportion to the apparent underlying injury. A sense of tenseness may be detected on physical examination. The immediate threat is to the viability of nerve and muscle tissue within the involved compartment, but infection, gangrene, myoglobinuria, and renal failure also may ensue if the diagnosis is not made in a timely fashion. Compartment syndrome is usually associated with a closed long bone fracture of the tibia, but it also is well described in the thigh, forearm, arm, hand, and foot. In addition, compartment syndrome can occur with isolated soft tissue trauma and even with open fractures. It also has been described in a host of unusual situations, including prolonged procedures in the lithotomy position, the tuck position (knees tucked to the chest) for lumbar surgery, coma, spontaneous hemorrhage, extravasation of intravenous injections, and application of excessive traction in treatment of a fracture.

BOX 41.3 Causes of Compartment Syndrome

Increased Compartment Content

- Bleeding
  - Major vascular injury
  - Coagulation disorder
  - Anticoagulant therapy
- Increased capillary filtration
  - Reperfusion after ischemia
    - Arterial bypass grafting
    - Embolectomy
    - Ergotamine ingestion
    - Cardiac catheterization
    - Lying on limb
  - Trauma
    - Fracture
    - Convulsion
  - Intensive use of muscle
    - Exercise
    - Seizures
    - Eclampsia
    - Tetany
  - Burns
    - Thermal
    - Electrical
  - Intraarterial drug injection
  - Orthopedic surgery
    - Tibial osteotomy
    - Hauser procedure
    - Reduction and internal fixation of fractures
- Increased capillary pressure
  - Intensive use of muscles
  - Venous obstruction
    - Phlegmasia cerulea dolens (i.e., acute inflammation and edema of the legs)
    - Ill-fitting leg brace
    - Venous ligation
  - Diminished serum osmolarity (i.e., nephrotic syndrome)

Decreased Compartment Volume

- Closure of fascial defects
- Excessive traction on fractured limbs

Miscellaneous

- Infiltrated infusion
- Pressure transfusion
- Leaky dialysis cannula
- Muscle hypertrophy
- Popliteal cyst

External Pressure

- Tight casts, dressings, or air splints
- Lying on limb

Pathophysiology. Increased pressure in a closed, non-expandable compartment essentially represents a mismatch between the volume of that space and its contents. As such, it may arise from one of three circumstances: (1) increased compartment contents; (2) decreased compartment volume; or (3) external pressure (Box 41.3). As tissue

pressure increases, so does venous pressure, resulting in compromise of the local circulation and tissue hypoxia. This process is believed to occur at pressures that are above normal diastolic pressure but below systemic arterial pressure because of a reduced arteriovenous gradient at the tissue level. The body responds by releasing histamine in an attempt to dilate capillaries and increase blood flow to the affected area. Histamine also increases capillary membrane permeability, resulting in a leak of proteins and fluid into the surrounding tissue, further increasing compartment pressure in a vicious cycle.

As tissue pressure continues to increase, venous blood flow is impaired as capillary perfusion pressure is exceeded. Finally, arterial capillary blood flow falls to a point at which basic cellular metabolic needs are no longer met, leading to ischemic necrosis of muscles and nerves within the compartment and severe pain. An important concept in the management of compartment syndrome is that because local venous pressure cannot be significantly below local tissue pressure, and because elevation of a dependent limb decreases local arterial pressure by approximately 0.8 mm Hg for each 1 cm of limb elevation, elevation of a limb with resultant reduction in the local arteriovenous gradient is counterproductive and may actually exacerbate compartment syndrome. Vascular spasm seems to play a minimal role in the development of compartment syndrome.

Normal compartment pressure is 0 mm Hg. Microcirculation generally is impaired when tissue pressures reach 30 mm Hg or more; however, some patients can tolerate much higher compartment pressures without the development of compartment syndrome. Controversy exists over attempts to define compartment syndromes on the basis of specific tissue pressure. The tolerance to tissue ischemia varies among individuals because of shock, compensatory hypertension, altered tone in resistance vessels, and preexisting vascular disease. Inadequate perfusion and relative ischemia begin when tissue pressure within a closed compartment increases to within 20 mm Hg of a patient's diastolic pressure or, more accurately, within 30 mm Hg of the mean arterial pressure. When tissue pressure equals or exceeds the patient's diastolic blood pressure, tissue perfusion effectively ceases. The development of muscle ischemia depends not only on the magnitude but also on the duration of elevated pressure. Intra-compartmental pressures do not measure muscle and nerve ischemia but rather suggest the existence of the proper parameters needed for compartment syndrome. When establishing the diagnosis, clinical judgment should prevail.

Anatomic considerations and risk factors. Compartment syndrome theoretically can develop in any location where neuromuscular tissue is contained within a limited or confined space. The condition has been reported in the leg, thigh, buttock, arm, forearm, and hand (Box 41.4). By virtue of its location and higher likelihood of sustaining high-energy trauma, the leg, particularly the anterior compartment, is most commonly involved. Higher rates of compartment syndrome are seen with open fractures than with closed fractures, despite the fascial rents that accompany open fractures. The higher energy of injury observed with open fractures, with resultant tissue trauma, swelling, and bleeding, may account for this observation.

Most patients with compartment syndrome have an associated long bone fracture, and fractures of the tibial shaft are particularly likely to cause increased compartment pressure. Up to one-third of patients, however, have a crush or soft tissue injury without fracture. Compartment syndrome is more likely in patients with bleeding disorders or those on anticoagulation therapy.

Clinical presentation. Compartment syndrome is a clinical diagnosis. In a conscious and fully oriented patient, pain that is disproportionate to the apparent injury or physical findings is a hallmark finding in compartment syndrome.[3] Pain often is characterized as deep, burning, and unrelenting and is difficult to localize. The need for increasing amounts of analgesics should not lead the emergency clinician to the conclusion that the patient is drug-seeking; rather, it should serve as a prompt that compartment syndrome may be developing or is present.

Pain on passive stretching of the muscle groups in the suggestive compartment is an important finding. In addition, active flexion of involved muscles may produce pain. Other reliable suggestive signs and symptoms are hypoesthesia and paresthesia in the distribution of nerves crossing the compartment or tenderness, tenseness, or sensation of tightness of the compartment.

Although it is classically taught that the five Ps—pain, pallor, pulselessness, paresthesias, and paralysis—are signs and symptoms of compartment syndrome, this is generally not true. Rather, these are the symptoms and signs of acute disruption of arterial flow. Skin color, temperature, capillary refill, and distal pulses *all* are unreliable monitors for compartment syndrome because the pressure necessary to produce compartment syndrome is well below arterial pressure. Pallor and loss of pulses are late and ominous signs. Diminished pulses suggest concomitant pathologic conditions responsible for reduced arterial flow. Subjective complaints are an important indicator of compartment syndrome. Patients who are not fully alert or cooperative should be fully assessed for clinical signs of compartment syndrome.

Diagnostic testing. Clinical examination remains the diagnostic cornerstone of acute compartment syndrome, which can then be confirmed by the measurement of compartment pressure. The two most common methods of measuring compartment pressures are the slit catheter techniques and side port needle. The Stryker Intra-Compartmental Pressure Monitor (Stryker, Kalamazoo, MI) system is a commercially available hand-held digital device that is easy to use with minimal training (Fig. 41.7). The monitor should be set at zero on the plane in which it will be inserted to account for the effects of gravity. It is paramount that the appropriate compartment be measured; consultation with an anatomy reference is recommended. Compartment pressures of less than 30 mm Hg generally do not produce compartment syndrome. When intra-compartmental pressures exceed 30 mm Hg, or when the difference between diastolic

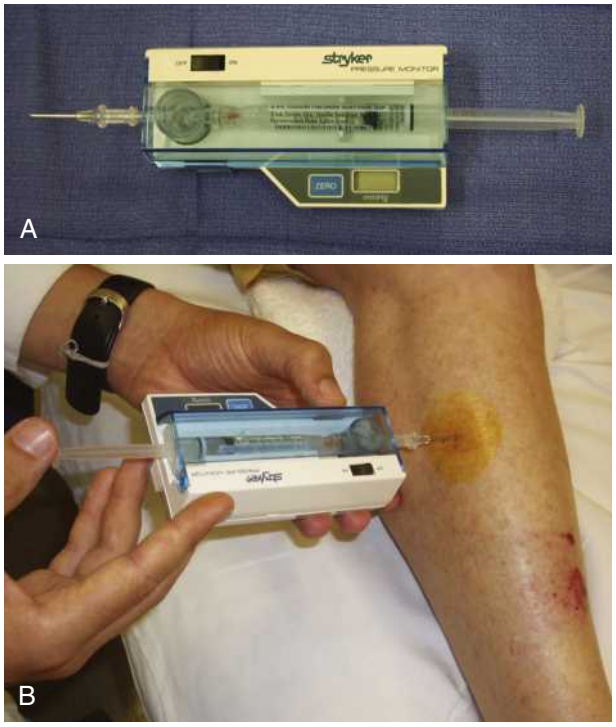

Fig. 41.7 (A) Hand-held device for measuring compartment pressure. (B) Device is inserted perpendicular to skin.

blood pressure and compartment pressure (perfusion pressure, also known as the ΔP) is less than 30 mm Hg, an emergent fasciotomy may be indicated. Serial or continuous pressure measurements should be performed in cases that are not clear-cut. A rising or sustained elevated compartment pressure is superior to a single measurement as an indicator of acute compartment syndrome or the need for fasciotomy. A hand-held Doppler stethoscope is not useful in evaluating these patients because arterial blood flow may still be detected, even in the presence of a significant compartment syndrome.

Treatment, complications, and disposition of compartment syndrome. Complete fasciotomy is the only treatment that can reliably normalize elevated compartment pressure. Surgery should be performed as quickly as possible. Delaying fasciotomy often results in irreversible myonecrosis and nerve damage. While the patient is awaiting definitive treatment, the affected part should not be elevated above the level of the heart because this maneuver does not improve venous outflow and reduces arterial inflow. Slight dependency (e.g., in reverse Trendelenburg position) has been suggested to maximize arterial flow to the extremity.

Because tissue compartments are more pliable soon after injury, the rate of extremity swelling is greater in the immediate postinjury period and tends to peak at 36 to 48 hours after injury. Although compartment syndrome usually appears within 36 hours of injury, cases have been reported more than 2 weeks following injury. Extremity swelling decreases over a similar duration. Rhabdomyolysis as demonstrated by elevated creatinine kinase, hyperkalemia, and myoglobinuria may occur and should be managed with fluid resuscitation to avoid subsequent renal failure. Lactic acid also is released from necrotic muscle tissue and its elevation in the serum may serve as a clue to the diagnosis.[4] Other complications include infection and tissue loss, necessitating amputation.

Short of amputation, delayed treatment often results in loss of nerve and muscle function and eventual contracture formation. The magnitude of these injuries is illustrated by the fact that in a 2017 national closed claims study, the mean indemnity award for compartment syndrome resulting from trauma was $987,716 USD. Delay in diagnosis was alleged 88% of the time. Thus, when the diagnosis of compartment syndrome is confirmed or highly suspected, surgical consultation and fasciotomy should be done without delay.[5]

Avascular Necrosis

Because of the anatomy of their limited blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, lunate, and capitate are particularly prone to this complication. These injuries are described in subsequent chapters.

Fat Embolism Syndrome

Fat embolism refers to the presence of fat globules in the lung parenchyma and peripheral circulation after a long bone fracture or major trauma. The phenomenon of fat embolization is probably more common than recognized as a subclinical event after long bone fracture.

Fat embolism syndrome (FES) is a serious manifestation of fat embolism, occurring most commonly after long bone fractures (usually tibia and femur) in young adults or after hip fractures in older patients. Symptoms usually appear 1 to 2 days after an acute injury or after intramedullary surgical nailing. Respiratory distress and hypoxemia are the earliest, most common manifestations. Acute respiratory distress syndrome (ARDS) may occur and is the usual cause of death. Neurologic involvement, presenting as restlessness, confusion, or deteriorating mental status, is an early sign, as are thrombocytopenia resulting in a petechial rash. Fever, tachycardia, jaundice, retinal changes, and renal involvement may occur. Fat is seen in the urine in 50% of patients within 3 days of injury. On computed tomography (CT) scan of the chest, common features are ground glass opacities and consolidation.[6] The incidence of full-blown FES varies from 1% to 2% in patients with isolated long bone fractures to 5% to 10% in patients with multiple fractures. Most patients with uncomplicated fat emboli recover without severe sequelae. Once FES appears however, the mortality rate is 10% to 20%. Management of FES is primarily supportive, usually in an intensive care unit often necessitating intubation and assisted mechanical ventilation.

Fracture Blisters

Fracture blisters are tense blisters or bullae that accompany high-energy injuries, with significant soft tissue swelling. They can occur anywhere but are most common in areas with thin soft tissue envelopes. The ankle, elbow, foot, and knee (in that order) are the most common sites; all these contain fewer hair follicles and sweat glands to anchor together the epidermal-dermal junction than other limb locations. Fracture blisters are believed, in many cases, to occur in the setting of increased underlying tissue pressure and may be a harbinger of compartment syndrome.

Early fracture reduction and splinting with expedited surgical intervention reduces the incidence of fracture blister formation. In addition, the presence of a fracture blister requires an alteration of the surgical approach or delay in surgery. We discourage incisions through a fracture blister because such incisions often lead to increased infection and skin breakdown. Early surgery after high-energy injuries might reduce the incidence of this complication. Once present, intact blisters should be covered with povidone-iodine solution and a sterile dressing. Unroofing the blister and applying coverage with silver sulfadiazine paste has been advocated by some to decrease the incidence of complications and to improve cosmesis but not in the presence of full thickness (blood-filled) blisters or diabetes mellitus.

BOX 41.5 Complications of Fractures

Avascular necrosis compartment syndrome
Complex regional pain syndrome
Fat embolism syndrome
Fracture blisters
Hemorrhage
Nerve injuries
Vascular injuries

Complications of Prolonged Immobility and Hospitalization

Contractures
Decubitus ulcers
Deep venous thrombosis

Pneumonia
Psychosis
Pulmonary embolism
Stress ulcers
Urinary tract infection
Wound infection

Complications of Immobilization and Hospitalization

Fractures frequently result in long periods of immobilization. Immobility may lead to multiple medical problems, especially in older patients, including pneumonia, deep venous thrombophlebitis, pulmonary embolism, catheter associated urinary tract infection, wound infection, nosocomial infection, decubitus ulcers, muscle atrophy, stress ulcers, gastrointestinal hemorrhage, and psychiatric disorders, especially psychosis or delirium (Box 41.5). In the geriatric population, surgery within 24 hours of admission has been shown to reduce delirium and improve 30-day mortality.[7] Early ambulation is a major goal of optimal orthopedic care.

Damage Control Orthopedic Surgery

Over the past few decades, the management of the multiply injured trauma patient has changed considerably. Historically, patients with multiple injuries were treated nonoperatively because it was believed they were too critically ill to tolerate surgery. In the 1970s, literature began to appear suggesting increased adverse outcomes as a result of prolonged bed rest. The notion of early total care of the polytrauma patient led to the advent of early fracture stabilization and subsequently, fixation techniques evolved. In 1993, the successful use of an abbreviated operation in patients with penetrating abdominal trauma to avoid the lethal triad of hypothermia, acidosis, and coagulopathy was reported, and the term *damage control* was introduced. In the polytrauma patient, similar principles were found to be applicable in the management of pelvic and long bone fractures.

The overall approach to all major fractures gradually shifted to early temporary fracture stabilization, resuscitation of the patient to a stable physiologic state, and definitive fixation at a later time once the patient is hemodynamically stable.[8] Temporary fracture stabilization is usually accomplished by the application of external fixation devices to aid in hemorrhage control and tissue oxygenation. The timing and optimal type of fracture surgery in the multiply injured trauma patient are still subjects of ongoing research. The role of the emergency medicine clinician is to facilitate stabilization, transfer to the operating room or angiography suite, or if necessary, to an outside tertiary care facility, and pre-operative preparation of the patient.

Differential Diagnoses

Pain and swelling of an extremity can occur after trauma with fracture as well subluxation, dislocation, sprain, strain, contusion, and thrombophlebitis. Severe pain alone or in combination with swelling may be present without trauma in arterial or venous occlusion, compartment syndrome, or with deep seated necrotizing fasciitis.

Diagnostic Testing

Plain Radiography

Conventional radiography is the mainstay for diagnosing fractures. In addition to confirming or excluding fractures, it can identify other pathologic conditions. Foreign bodies, air, and gas may also be detected. Conventional radiographic evaluation of long bones includes at least two orthogonal views (usually PA and lateral); an oblique view is part of the standard series in certain locations such as the phalanges and ankle. If fracture is suspected despite negative radiographs, additional oblique views should be obtained. A fracture line is most visible when it is parallel to the x-ray beam and is invisible when it is exactly 90 degrees to the beam. For this reason, for ribs, because of their curvature, multiple views must be obtained. To identify the extent of the fracture accurately, the entire bone should be visualized.

Each image should be examined to ensure that proper technique has been used and that no important area is omitted from the image. Emergency clinicians should review all films they order, even when the radiologist has already read it. Overexposed images may fail to reveal an abnormality. Although some fine detail is lost on portable images, these are acceptable if the patient is unstable or cannot tolerate transport to the x-ray suite and movement on and off the x-ray table, or for post-procedural films that are mainly concerned with acceptable positioning. Even with optimal technique, some fractures are not visible initially and do not appear until the margins of the fracture absorb. Absorption widens the radiolucent line, and a defect appears in 10 to 14 days. At that time, new bone produced beneath the periosteum at the margins of the fracture accentuates the fracture. Accordingly, if a fracture is suggested but is not visible at the initial visit, the injury should be treated as a fracture, reexamined clinically and radiographically in 10 to 14 days. The patient should be informed of the rationale for this regimen.

Comparison views with the contralateral bone may be useful in selected situations. It is reasonable to use comparison views in cases in which radiographs are inconclusive and when confusion arises specifically out of the need to distinguish between a possible fracture and normal developmental anatomy. Comparison views sometimes are helpful in adults when there is a question regarding the presence of accessory ossicles or non-fused bones (e.g., bipartite patella), because these anomalies are usually bilateral. They may at times be helpful in assessing fracture lines versus growth plates in pediatric patients (see Chapter 170). Consultation with orthopedic reference texts may be helpful. The bleeding that inevitably accompanies fractures may produce soft tissue swelling, which may impinge on or obliterate overlying muscle planes. Fat pads, such as in the elbow, may be displaced. Another useful sign is the fat-fluid level or *lipohemarthrosis* that results because fat is less dense than blood and layers out on top of it. This is most often seen in the knee joint and is only visible if the cross-table technique is used.

The bones themselves should be examined systematically. Normal adult bones possess a smooth contour. A distinct angle is highly suggestive of a fracture. In an adult, a lucent line that interrupts the smooth contour and usually extends to the opposite side represents a typical fracture. Nutrient arteries may be confused with fractures but have different radiographic characteristics: they are fine, sharply marginated, and extend obliquely through the cortex and are less radiolucent than

fractures. In addition, they do not extend to the opposite side of the bone. Pseudofractures can be created by soft tissue folds, bandages, monitor wires, or other overlying material or by a radiographic artifact called the "Mach effect," which occurs at the margin of areas of differing radiographic densities. If a lucency extends beyond the bone, the line is highly unlikely to represent a fracture.

Anomalous bones and calcified soft tissue likewise may be mistaken for fractures. Avulsions and small fracture fragments have an irregular surface that lacks well-corticated margins, with a defect in the adjacent bone, whereas anomalous ossification centers (accessory ossicles) and sesamoids are characterized by smooth cortical margins. Radiologic and orthopedic reference texts are useful in identifying and confirming these anomalies because they tend to occur in predictable locations. Compression fractures are suggested or represented by increased density rather than by a radiographic lucency (commonly occurring in the spine or proximal humerus). Finally, there is an adage that the most commonly missed fracture is the second fracture. One should be diligent in searching for additional fractures after discovering the first fracture in a patient. In particular, certain paired fractures should be sought, such as the distal tibia and proximal fibula, the *os calcis* and the lumbar spine, or in ring structures such as the mandible and pelvis.

Special Imaging Techniques

Computed tomography. Although conventional radiography remains the initial imaging study of choice for skeletal trauma, CT offers a more detailed and diagnostically sensitive evaluation of displacement, alignment, fragmentation of fractures, or joint penetration. CT should be considered when the clinical evidence does not correlate with the findings of routine radiography. Two-dimensional multiplanar reconstruction in any chosen plane, and three-dimensional surface rendering techniques provide images with higher quality, even in the presence of metallic implants or fixation devices which can be eliminated by advanced scanners equipped with special programs. Three-dimensional CT reconstructions are also sometimes useful for surgical planning.

CT is commonly used in blunt trauma to rule out a cervical spine fracture when plain films are equivocal, especially when there is underlying degenerative disease or in the elderly, and also in noncompressive vertebral fractures to assess the number of fragments and their spatial relationship to the spinal canal. CT is also used frequently to define the integrity of articular surfaces in the acetabulum, knee, wrist, or ankle and in certain Salter-Harris type fractures. In the multiple trauma patient requiring thoracic, abdominal, and pelvic CT imaging to rule out visceral injury, radiologic windows may be adjusted to also acquire diagnostic bone images of the thoracolumbar spine and bony pelvis structures.

Magnetic resonance imaging. MRI constitutes the most advanced noninvasive examination of orthopedic structures, delineating lesions of bone, cartilage, ligaments, and other structures, such as menisci, disks, and epiphyseal structures. It is rarely the test of choice for fractures, an exception being occult fracture of the hip.[9–11] MRI is expensive and time-consuming and should be reserved in the ED for cases in which the diagnosis is unclear, and specific findings would alter the treatment urgently. If not, it can be scheduled at a later time if deemed necessary.

Ultrasound imaging. Point of care ultrasound can be an effective tool for the diagnosis of fractures when conventional radiography is unavailable, such as in conflict settings or during mass casualty incidents.[12] Point of care ultrasonography can sometimes visualize fractures as an interruption of the linear bony cortex and may be clinically correlated during the physical examination of the affected area. The efficacy of ultrasound may be limited by the proficiency of the operator, the ability to control ambient light, and the quality of the machine. Plain radiography is the preferred initial diagnostic modality in the ED.

Laboratory Testing

Most fractures can be managed without the need for laboratory tests. C-reactive protein, sedimentation rate, and CBC may be useful in evaluating for complications such as osteomyelitis. A urinalysis and creatinine kinase may be useful in evaluation of compartment syndrome. When major bleeding is a concern, CBC and coagulation studies are indicated. Emergency clinicians should assure that patients in need of urgent surgery have routine pre-operative laboratory tests obtained so as not to contribute to a delay with surgical interventions.

Management

Field Care

Splinting and bandaging. Suspected fractures should be splinted in the field to limit damage to muscles, nerves, vessels, and skin and to prevent a closed injury from being converted to an open fracture during transport. In addition, splinting may relieve the pain associated with movement of the fracture. Numerous commercial devices are available, and most ambulances carry an assortment of immobilization devices (Fig. 41.8). Field personnel should splint suspected fractures before the patient is moved. Analgesics should be given according to need in keeping with local protocols. Severely angulated long bone fractures should be reduced in the field before they are splinted. Splints should be applied in such a way as to immobilize the joints above and below the fracture site to avoid motion of the involved bone. The skin should be padded to avoid local necrosis, and the splint should be secured by use of a circumferential wrapping material. This material should allow for some expansion and should not be applied in a constricting manner.

Standard ambulance equipment includes long and short backboards, cervical collars, sandbags, and extremity splints. A half-ring traction splint also is essential. Cardboard splints are acceptable and have the advantage of being able to be packed with ice packs. Inflatable air splints are favored by some because they are convenient, easy to apply, transparent, radiolucent and can tamponade low-pressure bleeding. If used, inflatable splints should be inflated only to the point that still permits splint indentation by gentle finger pressure.

Emergency Department Care

In the ED, the indications for initial splinting are the same as in the field. Splints applied in the field should be checked and, if properly applied, generally need not be changed. An exception to this rule is that if Hare traction was applied in the field and alternate traction is available, the former should be carefully removed in the ED because it may angulate femur fractures and result it decubitus ulcers over the ischium. Most splints can be left in place during initial clinical and radiographic evaluation. In some cases, a splint is all that is needed for definitive treatment. The following is an inventory of orthopedic devices available in most EDs.

Upper Extremity

Sling-and-swathe bandages. Sling-and-swathe bandages are useful in immobilizing the shoulder, humerus, and elbow. They are commonly used after reduction of dislocated shoulders and to treat impacted fractures of the humeral neck. The affected axilla should be padded and powdered with talc to avoid skin maceration. A commercial shoulder immobilizer also is available and is useful after reduction of a shoulder dislocation. Its advantages are ease of application and ease of removal and reapplication by the patient for bathing. Although they may aid

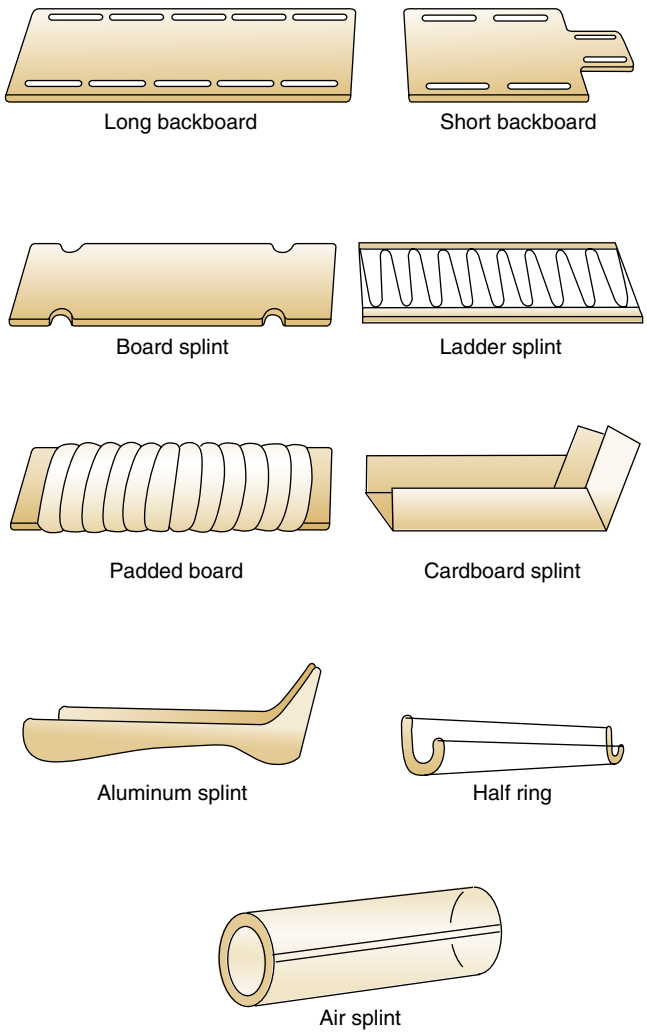

Fig. 41.8 Commercial Splints.

in healing, they are primarily placed for comfort and to decrease the incidence of recurrent injury.

Clavicle fractures. A simple sling of the arm on the affected side is sufficient to support the clavicle, improving healing immobilization and relieving pain. Figure-of-eight clavicular splints, once commonly used for clavicle fractures are no longer recommended because they are uncomfortable and provide no additional benefit.

Plaster and fiberglass splints. Well-fitting, customized plaster splints can be fashioned easily to immobilize the elbow, forearm, wrist, and hand. The advantage of these splints is the ability to mold them to a concise size and shape (e.g., along the ulnar side of the forearm and hand to immobilize a midshaft fourth or fifth metacarpal fracture, the so-called "gutter" splint). Several commercially available products consist of multiple layers of plaster or fiberglass strips, inside a covering of foam and flannel, on a continuous roll that can be applied to any length. The material is dipped in water and while the splint is still wet, a bandage is wrapped over it, and the splint is molded and held in the desired position as the plaster or fiberglass resin hardens. Cutting the fiberglass and plaster splints produces an exothermic reaction. To avoid burns, lukewarm water should be used to wet the splinting material and adequate skin padding applied.

Casts

Plaster casts perform a function similar to splints in that they provide stability and pain relief. Casts are not mandatory for all fractures and, in situations in which they are, application is usually not an immediate necessity. Because they are circumferential, casts provide more effective immobilization of a fracture, but they require more skill and time to apply. Swelling and subsequent pressure under the cast are highest during the first 24 hours after injury. Complications of casting include compartment syndrome, thermal injury, pressure sores, bacterial and fungal infections (especially if a wound is present under the casted area), and pruritic dermatitis. Plaster is applied as strips or rolls of cloth impregnated with a hemihydrate of calcium sulfate. When this cloth is dipped in lukewarm water, a creamy paste is formed that can be molded into a cast. As described previously, an exothermic reaction takes place that causes the plaster to harden and can burn the skin. Factors that have been shown experimentally to increase skin temperatures during plaster application are water temperatures greater than 24°C (75°F), cast thickness greater than eight sheets, and inadequate ventilation of the newly applied cast. Immersing the plaster in water for too short a time or squeezing too much water out can also lead to the generation of excess heat. To avoid pressure on the skin and over bony prominences, stockinette and layers of cotton sheet wadding are first snugly applied. Padding that migrates under a formed cast can be uncomfortable and result in pressure sores. Of note, padding alone does not prevent burns.

Variations of the basic cast exist. A window may be placed in the cast, and the cutout area may be used for access to skin wounds that require care or observation during immobilization. Walking heels may be worked onto a lower extremity cast and should be placed in the center of the foot. Synthetic fiberglass casts are lightweight, durable, and water-resistant. In addition, their setting temperatures are significantly lower, and they are less likely to produce burns. However, they are more expensive then plaster casting material, so may not be available in all settings.

Patients with casts may visit the ED for complaints related to their casts; these usually are pain, local irritation, swelling, or numbness of the distal part. A cast that is too tight results in swelling, pain, coolness, and change in skin color of the distal parts. Pain also may be caused by the initial orthopedic injury, by local pressure, a developing compartment syndrome, or wound infection. When a patient complains of pain, it is prudent to bivalve the cast and inspect the extremity. This is done by cutting the plaster and padding on each side and removing half the cast at a time, with the other half used as a mold to keep the extremity immobile. Afterward, the bivalved cast can be held together with bias-cut stockinette or elastic wrap until a new cast is applied. If relieving external pressure does not alleviate symptoms, the diagnosis of compartment syndrome should be considered. Casts may obscure open wounds, wound infections, and can be sources of sepsis or tetanus.

The need for a follow-up cast assessment 1 to 2 days after initial application is generally recommended depending on the location and type of fracture, the condition of the skin, reliability of the patient, and ease of access to alternative follow-up care.

Forearm and Wrist Splints

Numerous preformed Velcro splints are available for splinting fractures of the distal forearm and wrist. They are lightweight, form-fitting, and easy to apply and are easily removed by the patient (Fig. 41.9). Athletic taping can sometimes be used, such as in the management of a minor fifth metacarpal fracture.[13]

Lower Extremity

Splinting methods for various lower extremity fractures, including hip, femoral shaft, knee, and lower leg, are described in the respective chapters. Casts are applied as described previously. Commercially available knee immobilizers can be used after acute injuries to provide firm but nonrigid stabilization of the knee. The device is a foam cylinder with

medial and lateral aluminum stays, attached by Velcro straps, and spanning the upper thigh to upper ankle. This device is commonly used after trauma to allow the knee to rest until a more detailed physical examination or diagnostic study can be performed a few days later.

Fig. 41.9 Wrist Splints.

Ankle. Immobilization of the ankle can be accomplished by numerous methods. Plaster or fiberglass splints can be used temporarily for the treatment of nondisplaced ankle fractures or severe sprains. Plaster splints and casts are described previously. Most ankle injuries should be splinted with the patient's ankle in neutral position. Injuries to the Achilles tendon, plantaris muscle, or gastrocnemius muscle initially should be treated with the foot held in slight equinus (plantar flexion) for comfort. The toes should be free to move distal to the metatarsophalangeal joints, and the proximal border should end below the tibial tubercle to avoid pressure on the peroneal nerve.

Taping or adhesive strapping is an alternative method of ankle immobilization that provides good support and limitation of motion (Fig. 41.10). Taping tends to lose its protective properties with cyclic loading and sweating. This technique is commonly used by trainers in sports activities, who can reapply it as necessary. The method is lightweight and not bulky, and a shoe can be worn over the material. The use of tape is sometimes associated with dermatologic complications, including itching or contact dermatitis, owing to adhesion of the tape to the skin. For moderate to severe lateral ankle sprains, a commercial mechanical support composed of molded plastic with Velcro straps is more effective than elastic bandaging alone (Fig. 41.11). Another common commercially available device is the controlled ankle motion (CAM) boot. These boots are adjustable and removable and allow bathing but should not be used when strict weight bearing is needed.

The treatment of ankle sprains is further discussed in Chapter 49.

Thermal Therapy

Some confusion exists as to the role of cold versus heat therapy in the treatment of acute orthopedic injuries. Part of this confusion arises because heat may be more soothing to the patient. Icing or cooling is commonly recommended and used for acute orthopedic injuries to help reduce acute pain. In addition to a local anesthetic effect, cold

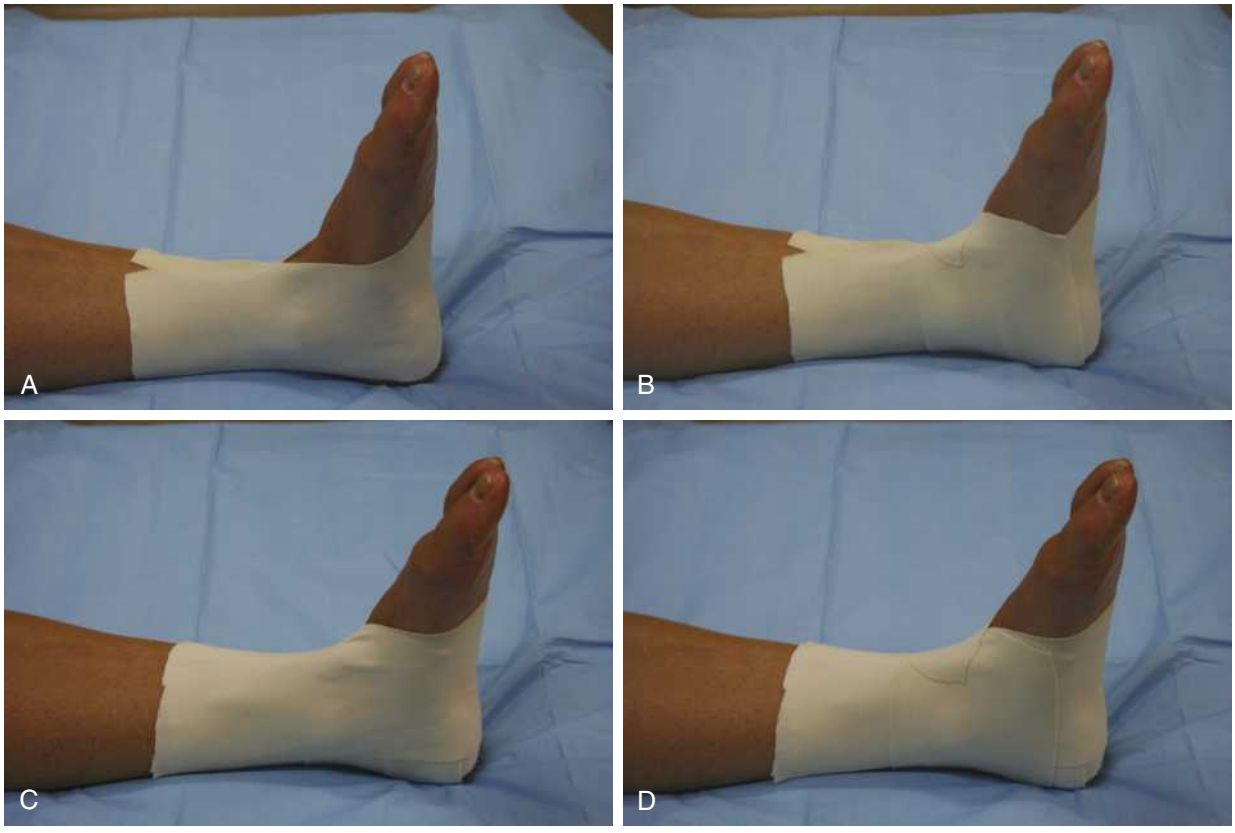

Fig. 41.10 (A–D) Application of adhesive strips to immobilize the ankle.

Fig. 41.11 Air Cast Ankle Support. (A) Lateral view. (B) Anterior view.

causes vasoconstriction, believed to limit blood flow and hemorrhage into the traumatized area. Metabolic requirements are reduced in cooled tissues, as is histamine, and less capillary breakdown occurs as a result. The sooner postinjury ice therapy is initiated, the more beneficial the reduction in metabolism will be. Reduced blood flow also should limit edema formation, and lower extravascular fluid pressure allows for better lymphatic drainage of injured areas. Generally, if ice is to be applied, it is recommended that an insulating layer be placed between the ice and skin, and that icing be continued for no longer than 30 minutes at a time, with the skin allowed to rewarm completely between applications. Ice therapy is most likely to be beneficial in the first 48 hours after injury.

Absolute contraindications to cold therapy include severe cold allergy (with hives and joint pain) and Raynaud disease. Relative contraindications include some rheumatoid conditions and paroxysmal cold hemoglobinuria, with renal dysfunction and secondary hypertension. Rare complications of cold therapy include skin burns and nerve damage, especially in athletic patients with more serious injuries. Anesthetic skin in a paralyzed or comatose patient is at greater risk with ice therapy.

Heat increases blood flow and initially increases the inflammatory response and edema. Warm tissues and cells have a higher metabolic rate and increased requirements for nutrients and oxygen. Patients seen 48 to 72 hours after injury with significant bruising may benefit from the application of heat in addition to elevation to help resolve the hematoma.

Disposition

Most fractures can be safely discharged for outpatient follow-up care, or surgery if indicated in the next 3 to 7 days. Significant fractures should be reduced to diminish pain and to avoid neurovascular compromise. Discharged patients should be given a short course of analgesics, as needed. Acute pain usually subsides in a few days as the fracture hematoma is absorbed and the swelling diminishes. It has been demonstrated that many patients can be managed with non-opioid medications.[14–17] Patients who are at risk for loss of function, who cannot ambulate safely, or whose analgesic needs cannot be met should be admitted. Patients who cannot perform activities of daily living (e.g., toileting and feeding) must have arrangements made for assistance with these activities, or else be admitted to a facility that can provide the care.

SUBLUXATION AND DISLOCATIONS

Foundations

Abnormal forces applied to joints may result in the loss of continuity between two articulating surfaces. Partial loss of continuity is termed *subluxation,* and complete loss is termed *dislocation*. In general, dislocations are named for the major joint involved, as in a dislocated shoulder or hip. In three-bone joints, the injury is named for the joint involved if the disturbance involves the two major bones or, if the lesser bone is involved, the disturbance is named for that bone. Separation of the femur from the tibia is termed *dislocation of the knee,* whereas displacement of the patella from its normal articulation is termed *dislocation of the patella* (Fig. 41.12). At the elbow, separation of the olecranon from the humerus is termed a *dislocation of the elbow,* whereas separation of the radius from the humerus is termed *radial head dislocation.*

Dislocations and subluxations should be described according to the direction of the distal segment relative to the proximal segment or of the displaced bone relative to the normal structures. The injury shown in Fig. 41.13 is termed *dorsal dislocation of the interphalangeal joint of the thumb.* Disruption of articulation also may occur in combination with a fracture. The term *fracture-dislocation* is used to describe this combination. If the overlying skin is broken in any way, dislocations, subluxations, or fracture-dislocations are described as open and constitute the same emergency treatment as an open fracture with contamination being a major concern.

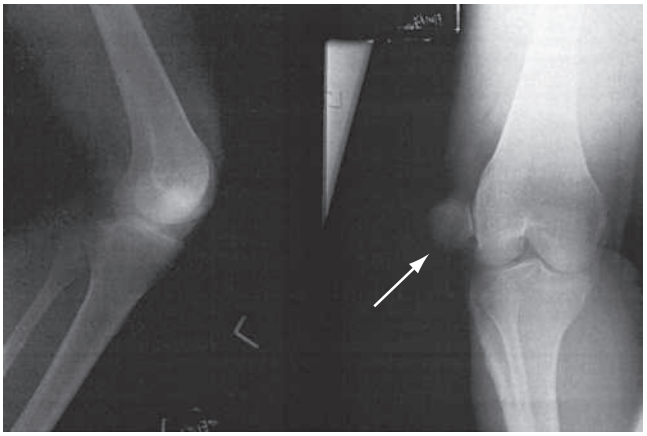

Fig. 41.12 Dislocation of the Patella. The *arrow* indicates the patella.

Clinical Features

In most cases of dislocation, severe to excruciating pain is present because the highly innervated joint capsule is stretched or torn. Attempted movement of the joint exacerbates the pain. This useful sign is lost in an obtunded, intoxicated, or unconscious patient and may result in a missed diagnosis if a careful examination is not performed. Some dislocations, such as anterior shoulder dislocation, cause an obvious deformity, whereas others, such as posterior shoulder dislocation, may be subtle. Swelling of soft tissues also may obscure the diagnosis, such as in the tarsal-metatarsal region. Gentle passive testing of range of motion should be performed but never forced. Assessment for neurovascular function is similar to that for fractures. Certain dislocations (e.g., the knee) are so commonly associated with vascular injuries that a meticulous assessment of blood flow is important in evaluating these injuries, including CT angiography.

Differential Diagnoses

Differential diagnoses of dislocation are usually comprised of an associated fracture (i.e., fracture/dislocation). In addition, acute neurovascular and tendon injuries may be mistakenly diagnosed as a dislocation or subluxation.

Diagnostic Testing

Plain radiographic studies detect most dislocations. In some locations, such as the shoulder, extra views are necessary to determine the type of dislocation (e.g., anterior versus posterior). Occasionally, when the diagnosis of dislocation is unclear, supplemental CT scanning can be helpful. Radiographs should be performed before and after attempts at reduction of first-time or complicated dislocations unless there is acute neurovascular compromise. This imaging not only confirms the diagnosis but ensures that associated fractures are documented before treatment is undertaken.

Management

Methods of reducing specific joints are reviewed in subsequent chapters, but a few basic principles apply. In general, a joint should be reduced as soon as possible. Over time, swelling and muscle spasm make reduction more difficult. Also, pain is not adequately relieved until the dislocation is reduced. In the hip, early reduction is mandatory to restore vascular supply and avert the complication of avascular necrosis. The general principle of reducing a dislocation is to stabilize the proximal bone and re-create and reverse the mechanism of injury, pulling the proximal end of the dislocated bone out and away from whatever is trapping it in its resting position. This technique helps prevent interposition of soft tissues in the joint that can preclude reduction. As this maneuver is accomplished, the disarticulated surface is manipulated back or may snap back spontaneously toward its normal anatomic position. Large joint relocation may require procedural sedation with parenteral analgesia. An ultrasound-guided regional nerve block can facilitate large joint relocations and is useful in some cases if available.[18] Smaller joints may require local anesthesia or, on occasion, no anesthesia. Some joints cannot be reduced in the ED because the opposing muscles are contracting too forcefully, and general anesthesia is necessary to overcome these forces. Mechanical obstruction by a bony fragment or torn piece of cartilage, tendon, or joint capsule usually requires surgical intervention for reduction to be accomplished.

Disposition

Most patients with dislocations that have been reduced can be discharged after a period of observation if sedation has been used. Patients should usually be referred for orthopedic follow up in 1 to 2 weeks. Patients with refractory unreduced joints should be admitted for surgery as should patients in whom vascular injury is suspected.

SOFT TISSUE INJURIES

Sprains

Foundations

Sprains are ligamentous injuries resulting from an abnormal motion of a joint with various degrees of tearing of the fibrous structure. While sprains may be graded according to the severity of pathologic findings, clinically, the grades may be less distinct but are classified as follows:

- A first-degree sprain is a minor tearing of ligamentous fibers, with resultant mild microscopic or obvious hemorrhage and swelling. Minimal point tenderness is usually elicited. Stressing the ligament produces some pain, but there is no opening or abnormal joint motion.
- A second-degree sprain is a partial tear of a ligament, i.e., more fibers are torn than in the first-degree injury. Clinical findings include tenderness, moderate hemorrhage and swelling, painful motion, abnormal motion, or loss of function. In some cases, there will be radiographic findings. In some joints there is a tendency toward persistent instability, loss of proprioception, and recurrence. Prevention of these complications is a major goal of treatment.
- A third-degree sprain denotes the complete tearing of a ligament. Signs include a further exaggeration of the signs mentioned for second-degree sprain. In addition, stressing the joint, when possible and not limited by pain or swelling, reveals grossly abnormal joint motion. In some cases, such as a third-degree acromioclavicular separation, there will be both clinical and radiographic findings.

Evacuation of a hemarthrosis and intraarticular analgesia may be used to allow a more complete diagnosis of some injuries. Chronic joint instability may result if severe ligamentous injuries are not properly treated.

Clinical Features

The clinical presentation of an extremity sprain may be indistinguishable from that of a fracture. The injury commonly occurs during vigorous athletic activity but may occur when there is other stress on the joint in an abnormal or exaggerated direction, such as stepping off the curb, or dancing. The patient may complain of hearing a snap at the moment of injury and conclude that a fracture is present. Patients may report "seeing stars" or "almost passing out" at the moment of injury and may still be in extreme pain, appearing pale and diaphoretic if seen shortly afterward. Analgesia should be provided promptly to these

patients. Evaluation should include a careful history of the sequence of events at the time of injury and attempting to ascertain the position of the extremity and the forces applied to it. Examination of the joint should include attempting to stress it to show abnormal motion. If radiographs are planned to rule out a fracture, or if excessive pain is produced by mild attempts to apply stress, it is probably better to delay stressing the joint until films have verified the absence of a significant fracture.

Differential Diagnoses

Fractures, sprains, and dislocations can present similarly. These injuries may be present concomitantly.

Diagnostic Testing

Plain radiography. Plain radiography is indicated in some, but not all, cases of suspected sprain to rule out a fracture. From a medical standpoint, validated clinical decision rules exclude the need for routine radiography in some situations. In these scenarios, shared decision making with the patient is a useful strategy to avoid unnecessary radiographic imaging.

Radiographic stress views of joints are occasionally used to evaluate the degree of ligamentous injury when other methods are not available.[1] The value of stress views is limited because pain may not allow sufficient stress to be applied, and there is a possibility of further injuring an already traumatized structure. Stress views should not be used until a fracture has been ruled out so as not to displace a fracture, especially if it involves an active growth plate in a pediatric patient.

Magnetic resonance imaging. MRI is generally not indicated acutely but may be indicated in follow up when significant ligamentous injuries that may require surgery are suspected. This is especially important in the knee when significant pain, hemarthrosis, and disability are present. Avulsion fractures may occur concomitantly with sprains. In children, epiphyseal fractures occur more commonly than ligamentous disruption because of the relative ligamentous strength compared with the ease of disrupting the epiphyses. MRI may be indicated in the follow-up evaluation of some of these injuries.

Management

Specific management of sprains varies depending on the location and severity of the injury. In general, initial measures should include the traditional recommendations of ice, elevation, and analgesia. Nonsteroidal antiinflammatory drugs (NSAIDs) are effective analgesics in many patients and may contribute to a more rapid decrease in swelling, increased exercise endurance, and earlier return to work and normal daily activities.

Immobilization provides protection and comfort in the initial management of most injuries. The method chosen depends on the location and specific recommendations are in the chapters that follow. Because the severity of injury is sometimes difficult to establish at the first visit, it is reasonable to immobilize the affected joint for the first 48 to 72 hours, after which the extent of injury can be better determined. At that time, early mobilization is often desirable, particularly in lateral ankle injuries, because this leads to earlier return to work and athletic activities and better preservation of proprioceptive and neuromuscular function. For lower extremity injuries, protected weightbearing with crutches provides patients with comfort and avoids motion of the impaired part. In older patients, safe ambulation sometimes cannot be accomplished, and a short hospitalization or respite in an acute rehabilitation or skilled nursing facility may be necessary. Surgical management is indicated for some specific injuries in certain patients. These are also addressed in the chapters that follow.

Disposition

Generally, for complete or nearly complete ligamentous disruption, urgent orthopedic consultation should be pursued within 5 to 7 days postinjury, when acute swelling has subsided, to determine whether surgical repair might be needed. When surgery is not indicated, physical therapy and rehabilitative exercises are sometimes prescribed at these visits and can be continued for several weeks. Because ligaments are relatively avascular, healing is slow, and patients with significant sprains should be informed of this. Sprains should be diagnosed as precisely as possible and should not be trivialized. If radiographs have ruled out fracture of an affected extremity, the patient should not be told that the injury "is only a sprain." This can be misleading, creating false expectations regarding recovery and may lead to missed occult fractures or epiphyseal injuries.

STRAINS

Foundations

A strain is an injury to a musculotendinous unit resulting from violent contraction or excessive forcible stretch. The term *pulled muscle* sometimes is used interchangeably with muscle strain. These injuries are graded in a manner similar to sprains.

- A first-degree strain is a minor tearing of the musculotendinous unit, characterized by minor swelling, local tenderness, and minimal restriction of movement.
- A second-degree strain increases fibrous tearing along a continuum but without complete disruption of the musculotendinous unit. Swelling, ecchymosis, and loss of strength are more marked.
- A third-degree strain is a complete disruption of the musculotendinous unit with resultant separation of muscle from muscle, muscle from tendon, or tendon from bone.

An accompanying avulsion fracture may be present on radiographs in second- or third-degree injuries.

Clinical Features

Signs and symptoms include pain, ecchymosis, swelling, and loss of function. A force applied to the muscle, passive stretching, or active contraction produces sharp pain at the site of injury, even as the injured muscle may be relatively comfortable at rest. A palpable defect sometimes is present at the site of a complete rupture, which usually involves the region of the muscle-tendon junction, or a bunching up of the muscle may be appreciated and is common with bicep tendon injuries.

In athletes, generation of tremendous contraction forces coupled with excessive forcible stretching (while the body may be accelerating or with sudden forced planting) results in severe strains. Involvement of almost any muscle group is possible, and the onset of such injuries is usually acute. Sudden generation of forces, of which the thighs are capable, results in second-degree strain of the hamstrings, quadriceps, or thigh abductor muscles. Rapid forcible contraction of the calf (e.g., in a tennis player) may result in a third-degree gastrocnemius or plantaris tear, whereas pushing off to jump is a common cause of Achilles tendon rupture in a basketball player. A sudden violent attempt at lifting by an older individual can result in a complete biceps brachii disruption.

Among nonathletes, strains commonly are seen in patients who have overstressed a muscle group or tried to generate repeated force in an unconditioned muscle. Examples are the weekend gardener or mover who experiences low back strain on Monday morning, the aerobics student who strains the rectus muscles, and the amateur weightlifter with pectoralis strain. These are usually first-degree injuries, and the onset is slow.

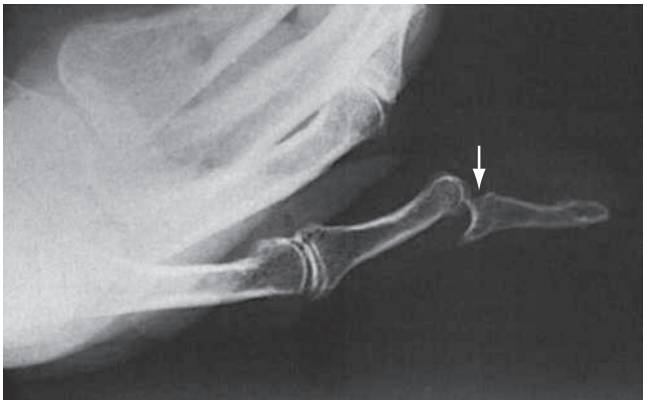

Fig. 41.13 Dorsal dislocation of the distal phalanx of the thumb *(arrow)*.

Differential Diagnosis

Fractures and sprains can mimic strains that occur in proximity to joints. These injuries may be present concomitantly.

Diagnostic Testing

Plain radiography is used in cases in which the possibility of a fracture is present, either by itself or in association with a strain. Ultrasound can be useful to diagnose complete tendon rupture. MRI is often used to diagnose rotator cuff tears, tendon ruptures, and muscle tears, but as mentioned, this modality often requires scheduling and is not always available or indicated in the ED. MRI can generally be safely delayed until a follow up visit outside of the ED.

Management

Treatment depends on location and the degrees of disruption and functional loss. Most first-degree injuries respond to rest, application of ice and, for some patients, analgesics for a few days post-injury. NSAIDs are commonly recommended. Second-degree strains are treated similarly, with protection against aggravating activity required for longer periods. Third-degree strains receive similar initial treatment in the ED plus early outpatient orthopedic consultation. Some of these injuries are amenable to surgical repair, whereas others may be treated with immobilization. The muscle affected, age, occupation, and activity level of the patient all are factors in deciding whether surgical intervention is appropriate. Early mobilization is an important tenet in the treatment of muscle strains; its timing may be based on the ability to stretch the injured muscle as much as the uninjured contralateral muscle and the use of the injured muscle without pain during basic movements.

Disposition

Strains can be referred and treated on an outpatient basis by either an orthopedist or at the direction of a primary care physician.

Tendinitis and Tendinosis

Foundations

Tendinitis is classically described as an inflammatory condition characterized by pain at tendinous insertions into bone, occurring in the setting of overuse. It is now believed that the pathophysiology of this condition is more complex than mere overuse, with the roles of load and use affecting the cell-matrix interaction. Contributing factors are those associated with aging, decreased blood supply and decreased tensile strength, muscle weakness and imbalance, insufficient flexibility as well as male gender, obesity (in weight-bearing joints), smoking, malalignments, training errors, and improper equipment. In addition, certain systemic diseases, including diabetes mellitus, chronic renal failure, rheumatoid arthritis, and systemic lupus erythematosus, steroid therapy, and fluoroquinolone use are associated with the development of tendinopathies.

The histopathology of tendinitis is characterized by the following: degeneration and disorganization of collagen fibers; infiltration by macrophages, plasma cells, and lymphocytes rather than leukocytes; and increased vascularity. Inflammatory changes are not a principal finding in tendinitis. This evolving understanding of tendinitis may allow for more logical treatment of these injuries aimed at the underlying pathophysiology. It also has led some to propose that chronic painful conditions of the tendon should be referred to as *tendinosis* rather than tendinitis or by other terms previously used to describe this condition, including the alternately spelled *tendonitis,* "degenerative changes of the tendon," and chronic tendinopathy. In this chapter, we use the terms tendinitis and tendinosis interchangeably.

Common sites for tendinitis are the rotator cuff of the shoulder, Achilles tendon, radial aspect of the wrist (de Quervain's tenosynovitis), and insertion of the hand extensors on the lateral humeral epicondyle (tennis elbow). Also commonly involved in athletes are the patellar tendon, particularly for those engaged in jumping sports; biceps femoris; semitendinosus and semimembranosus (hamstring syndrome); posterior tibial tendon (shin splint syndrome); and iliotibial band. It is also common in wrist flexors (e.g., medial epicondylar involvement is seen in little league pitchers and golfers). In some locations, most commonly the shoulder, calcium deposition occurs along the course of the tendon, resulting in a painful condition termed *calcific tendinitis.* This condition also may occur in the wrist, hand, neck, hip, knee, ankle, foot, and mandible.

Clinical Features

Physical examination reveals pain with motion and limitation of function and may include point tenderness and palpable crepitus over the involved tendon with motion. In general, a clinical test can be performed by forcible flexion of the involved muscle while keeping the point of insertion fixed or by operating the involved muscle against resistance. Either test should intensify the discomfort.

Differential Diagnosis

Avulsion fractures, sprains, and strains may mimic tendinitis.

Diagnostic testing

Radiographs are usually negative. A small fleck of bone suggests an avulsion, or the surface of the bone at the attachment may be irregular, indicating periostitis. Calcium deposits may occur along the course of the tendon due to calcific tendonitis and should not be confused with an avulsion fracture.

Management

Peritendinous local infiltration of anesthetics and corticosteroids may be useful in some anatomical locations but should not be repeated frequently because overuse may be associated with tendon rupture. Injection therapy is especially useful in calcific tendinitis demonstrated in the shoulder. Injection of steroids directly into the Achilles tendon should be avoided in the ED because of reports of partial or complete rupture after a single injection.

The classic approach to instances of tendinitis not amenable to injection therapy consists of rest, ice, and NSAIDs initially, followed by rehabilitation, physical therapy, training, and control of force loads (including weight loss), to prevent recurrences. NSAIDs may be useful

for a brief period as an analgesic but they have not been demonstrated to significantly alter the pathophysiology of this condition. They therefore should not be ordered for patients at significant risk for complications, including the elderly, diabetics, or those with or at risk for renal impairment. Arthroscopic or open surgery may be indicated in some cases of calcific tendinitis, not responsive to conservative therapy.

Disposition

Tendinitis is an outpatient condition. Persistent cases should be referred to the primary care clinician, a rheumatologist, or a musculoskeletal specialist.

Bursitis

Foundations

Bursitis is a painful inflammation of the bursa that may be traumatic, infectious, or related to systemic illness. Commonly involved sites include the olecranon, greater trochanter of the femur, and prepatellar or anserine bursae around the knee.

Clinical Features

Physical findings are tenderness and swelling over the involved bursa. In the olecranon, swelling will be prominent. Severe tenderness is a common feature and a hallmark over the greater trochanter of the femur. When accompanied by warmth and overlying erythema, common in the olecranon, an infection may or may not be present.

Diagnostic Modalities

Radiographs may rarely be useful in establishing the diagnosis, but their greatest usefulness is in ruling out other conditions. Advanced imaging is generally not indicated. If infection is suspected, aspiration of the bursa with gram stain and culture is indicated if the bursa is accessible and can be entered safely.

Management

Bursitis benefits from immobilization by resting the inflamed part and thus treating associated pain. If infection is suggested, aspiration of accessible bursal fluid, and Gram staining and culture are recommended, assuming aspiration can avoid any overlying cellulitis. If the bursa cannot be entered without avoiding an area of suspected cellulitis, it is usually better to wait. Otherwise, treatment is conservative and is similar to that for tendinitis, with rest, ice, NSAIDs, and the addition of antibiotics if there is a suggestion of cellulitis.

Disposition

Most patients can be treated as outpatients. When gross infection is present, especially when there is extension manifest by cellulitis, a short admission for intravenous antibiotics in addition to immobilization and elevation is indicated.

Other Soft Tissue Conditions

Other soft tissue injuries (e.g., inflammatory conditions, infections, bites, burns, repaired injuries of muscle bellies or tendons) may present to the ED as orthopedic conditions. Such complaints need to be carefully evaluated based on history and physical findings. Plain radiography may be helpful, along with specific blood tests or advanced imaging rarely. These conditions all generally benefit from immobilization. Splints also can be used to improve function, such as with wrist drop that accompanies radial nerve palsy. When an extremity is immobilized, it is important to stress elevation of the affected part to avoid edema formation and promote healing. The various immobilization devices are described previously.

CHAPTER 41: QUESTIONS AND ANSWERS

1. A 40-year-old diabetic woman is brought to the emergency department (ED) after crashing her car into a tree at moderate to high speed. She has a minimally displaced trimalleolar fracture and no other injuries after full body scanning and evaluation by the trauma team. While awaiting admission to the floor she develops blood-filled fracture blisters over the anterior ankle. What is the next step?

a. Debride blisters and apply silver sulfadiazine cream
b. Arrange for urgent surgery within 8 hours
c. Cover with sterile dressing and elevate foot and ankle
d. Measure the compartment pressure in the ankle

Answer: c. Fracture blisters sometimes follow high-energy injuries, especially when the overlying skin is thin and there are few hair follicles or sweat glands. Debridement and application of silver sulfadiazine is sometimes used when blood is not present. It is contraindicated in the presence of diabetes. Conservative treatment with a sterile dressing is recommended and surgery through the involved area should be delayed.

2. A patient presents with severe pain in the leg despite the removal of a cast 3 days after suffering a closed tibia fracture. Which of the following requires an emergent fasciotomy?

a. A high clinical suspicion based on extreme pain and tenseness in the compartment
b. The absence of pulses detected with a hand-held Doppler stethoscope
c. Tissue pressure less than the diastolic pressure
d. Tissue pressure of 20 mm Hg

Answer: a. Compartment syndrome cannot be diagnosed on the basis of specific tissue pressure. The tolerance to tissue ischemia varies among individuals because of shock, compensatory hypertension, altered tone in resistance vessels, and other unknown factors. Inadequate perfusion and relative ischemia begin when the tissue pressure within a closed compartment increases to within 20 mm Hg of a patient's diastolic pressure or, more accurately, within 30 mm Hg of the mean arterial pressure. When tissue pressure equals or exceeds the patient's diastolic pressure, tissue perfusion effectively ceases. Clinical judgment is paramount. Delayed diagnosis and fasciotomy frequently result in high damage claim awards.

3. An intoxicated alcoholic man is brought into the ED after being found on a bench and is found to have a wrist drop. Which is the likely cause of the wrist drop?

A. Axonotmesis
B. Neurotmesis
C. Neuropraxia
D. Increased compartment pressure

Answer: c. The patient likely has a contusion of the radial nerve; axonotmesis and neurotmesis involve more severe injury such as crushing or severing. Isolated neurologic dysfunction is not a feature of compartment syndrome.

41.4.)A 60-year-old woman presents to the emergency department (ED) with a closed deformity to the wrist as shown in the figure (show old figure 42.4 in text). In discussing this injury to a consultant, which is the best description?

a. Compound fracture of the wrist
b. Severely angulated fracture of the wrist
c. Fracture of the distal radius with dorsal displacement and volar angulation
d. Fracture of the distal radius with severe anterior displacement

Answer: c. Fractures should be described using the most precise language possible. The injury is a closed injury, so it is not compound. Fracture displacement in the forearm or wrist should be described as volar and dorsal, and occasionally as radial or ulnar (as the forearm is viewed in the anatomic position). Descriptions should convey as much information as possible.

5. A 50-year-old nonprofessional weightlifter presents after sudden pain in the upper arm described as a "pop." There is bunching up of the biceps muscle and bruising at its insertion. Which drug class is commonly associated with this condition?

a. Nonsteroidal antiinflammatory drugs (NSAIDs)
b. Angiotensin converting enzyme inhibitors
c. Fluoroquinolones
d. Statins

Answer: c. The patient appears to have rupture of the biceps brachialis tendon. Tendinopathy is associated with use of fluoroquinolones but not NSAID use, hypertension, or hyperlipidemia.

42

Hand Injuries

Benjamin Schoener and Mary Jo Wagner

KEY CONCEPTS

- For general testing of the motor nerve function of the hand, have the patient make an "OK" sign with their thumb and index finger (testing the median nerve), while spreading/abducting the third, fourth, and fifth fingers (ulnar nerve) and dorsiflexing the wrist (radial nerve).
- For general sensory exam, test two-point discrimination on the finger tufts of the index finger (median nerve), the little finger (ulnar nerve), and the dorsum of the first webspace (radial nerve).
- The most important treatment for the majority of hand injuries is applying an appropriate splint. The neutral position for general fractures of the hand or fingers is achieved by placing a volar splint ideally with the wrist at 20 to 30 degrees extension, MCP at 70 to 90 degrees flexion, and the PIP and DIP kept in extension. This is also known as intrinsic plus position.
- The most common extensor tendon injury is a terminal tendon disruption from sudden flexion of the extended DIP joint resulting in a *mallet injury.*
- A flexor tendon injury should be considered when an injured finger does not assume its naturally flexed position on *cascade sign* testing.
- Traditionally, patients with acute open wounds on the hand have been treated prophylactically with antibiotics, but there is little scientific data supporting the clinical efficacy of this practice.
- For a stable finger tuft with a subungual hematoma without external disruption of the nail plate, trephination without antibiotics is the only treatment needed.
- Small tuft avulsions defined as less than 1 cm^3 can be treated conservatively, while larger amputations should have emergent consultation with a hand surgeon for consideration for flap coverage or reimplantation. The presence of exposed bone or tendon indicates the need for surgical intervention.
- Most hand infections are based on skin flora; treatment for outpatient injuries are oral first-generation cephalosporins. With the growing emergence of community-acquired MRSA, antibiotics such as doxycycline, TMP-SMX, or clindamycin should be considered. For inpatient injuries, IV first-generation cephalosporins or vancomycin is recommended.
- The four classic Kanavel findings for infectious flexor tenosynovitis are fusiform swelling of the digit, tenderness along the tendon sheath, digit held in flexion at rest, and pain with passive extension of the digit.

FOUNDATIONS: A GENERAL APPROACH TO HAND INJURIES

Complaints regarding the hand present frequently to the emergency department with evaluation and management challenges due to the complex anatomy and function of the hand. Careful review of hand injuries is needed to identify simple wounds, injuries that can be initially managed but need further treatment, or time-sensitive emergencies. The disposition of the patient may involve simple follow-up or consideration for the need for specialized consultants.

The initial evaluation of a patient presenting with a hand injury should include a focused, but thorough, history and physical exam. The patient's age, mechanism of injury, time of injury, other acute or distracting injuries, hand dominance, occupation, and any prior hand injuries or impairments should be queried. For penetrating injuries, tetanus immunization status should be assessed, and for patients who may require surgical management, the timing of the last solid or liquid ingestion or nil per os (NPO) status should be assessed. For nontraumatic hand complaints, the presence of contracture, timing of symptoms, pain, aggravating or alleviating factors, presence of symptoms in other extremities, as well as functional impairment are additional key components of the history.

The hand should be completely exposed and examined, including all components as listed in Box 42.1. Inspection to identify deformity, discoloration, swelling, ecchymoses, laceration, or signs of open fracture should occur. Angular deformities are best evaluated with the fingers in full extension. Rotational deformities are best evaluated with the fingers in flexion. Severe hand injuries create the appearance of significant tissue loss or destruction which should not distract the provider from providing basic or advanced trauma care.

A neurovascular assessment should be performed and documented using the Allen test, capillary refill, and two-point discrimination. The point of maximal tenderness should be noted. Tendon, ligament, and joint capsule integrity should be examined with special testing performed where it is relevant to the patient's injury or complaint. Wound exploration may be necessary to assess for foreign bodies, gross contamination, or structural injury. Proper analgesia and regional blocks should be considered prior to wound exploration, which should be performed with sterile technique.

Radiographic imaging is the most widely available and used imaging modality for the hand. It is essential to obtain sufficient views to adequately assess the areas of injury. A standard x-ray series of the hand should include a posterior-anterior (PA), lateral (90 degrees to the PA), and generally, at least one oblique film. The ideal x-ray film should have no overlapping of bones, allowing for proper evaluation of each joint space, radiopaque foreign bodies, dislocations, and fractures. If possible, all rings, jewelry, and watches should be removed before imaging. Comparison of films performed on the uninjured side may assist in pediatric patients with developing growth plates.

Ultrasound imaging has also been shown to be a useful, though inferior, bedside modality for detecting fractures of the hand. A recent meta-analysis of 8 randomized control trials (RCTs) and prospective studies found a pooled sensitivity and specificity of 91% and 96% respectively in identifying fractures of the phalanx and metacarpals using x-ray as the gold standard.[1] Another blinded study looking at point-of-care ultrasound (POCUS) performed by emergency medicine

(EM) physicians, found a lower sensitivity of 79% and specificity of 90% for phalanx fractures.[2] Ultrasound is also helpful in evaluation of the soft tissue and for detection of foreign bodies.

CT and MRI are rarely used for evaluation in the acute setting, although they are occasionally used for evaluation of complex fractures or if there is a high clinical suspicion of fracture with negative x-ray imaging. MRI has the added ability to visualize the ligaments, tendons, and soft tissues. It is an effective imaging modality for investigating suspected osteomyelitis, avascular necrosis, and bone tumors.

BOX 42.1 General Hand Exam

I. Inspection
  A. Skin
    - Wounds
    - Erythema
    - Pallor (arterial compromise)
    - Cyanosis
  B. Edema
  C. Deformity
    - Rotation
    - Angulation
    - Cascade sign

II. Range of Motion
  A. Active
  B. Passive

III. Palpation
  A. Warmth
  B. Joint effusion
  C. Tenderness
  D. Masses (i.e., nodules, ganglions)

IV. Neurovascular Exam
  A. Motor
    - Median N.—Flexion of thumb and index finger ("OK sign")
    - Radial N.—Extension of thumb against resistance
    - Ulnar N.—Abduct fingers against resistance
  B. Sensation
    - Two-point discrimination
  C. Vascular
    - Allen test
    - Capillary refill at nail beds

Anatomy

Surface Anatomy and Skin

To understand the surface anatomy of the hand, it is important to be familiar with certain landmarks and associated terminology. The posterior surface of the hand is referred to as the dorsal surface, and the palmar surface of the hand is referred to as the volar surface. The radial border of the hand is that which borders the thumb, and the ulnar border of the hand is that which borders the little finger (Fig. 42.1).

The skin on the dorsal surface of the hand is generally thin and mobile compared to the volar surface. Unlike the volar surface, the dorsal surface is more prone to swelling. Also unique to the dorsal surface is the presence of hair follicles and the presence of the nail bed at the distal phalanges.

The volar surface of the hand is thick and stable. It is layered with subcutaneous fat and a thick dermis designed in a series of transverse folds or creases. This allows for sufficient padding and firmness with gripping. The folds are anchored directly to fascia in areas without underlying fatty tissue. This allows for easier flexion and limits the development of inflammation and edema. A collection of underlying muscles that respectively form the thenar eminence and the hypothenar eminence at the radial border and the ulnar border are also identifiable on the volar surface of the hand.

Fingertip and Nail. The fingertip is the area distal to the DIP and insertion of the flexor digitorum profundus (FDP) and extensor tendons. The volar surface is well-innervated, vascularized, and padded with adipose tissue. This area, which is anchored to the distal phalanx, is also known as the *pulp*.

The fingernails are specialized structures of keratinized epithelium that protect the distal phalanges. Underneath the nail, also known as the nail plate, is the nail bed which is comprised of skin (Fig. 42.2).

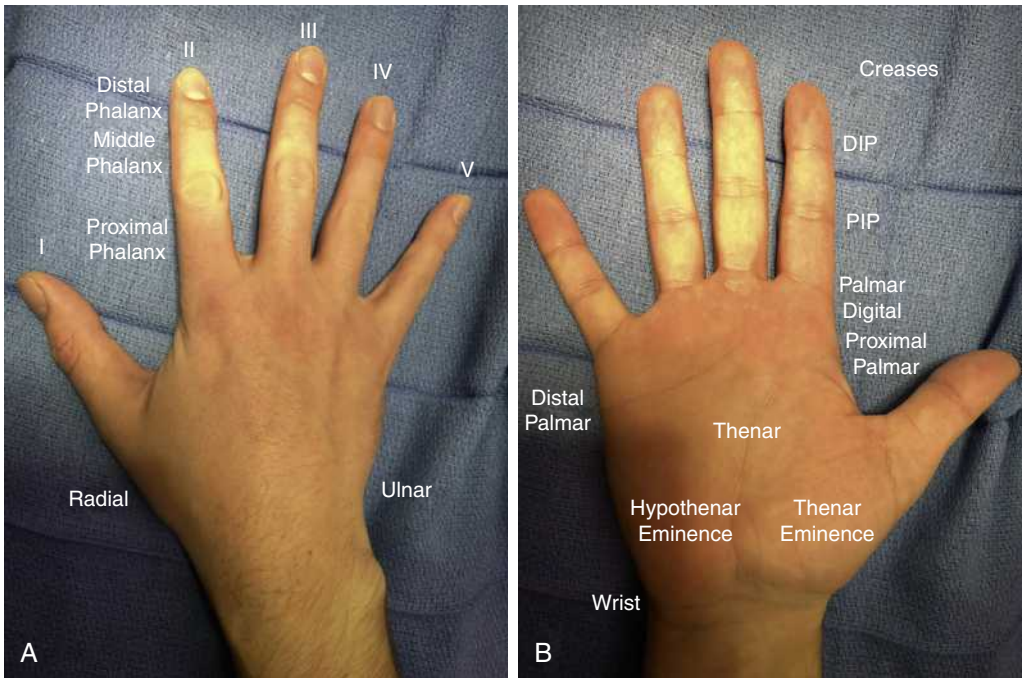

Fig. 42.1 (A) Dorsal and (B) volar views of the hand with digits I–V, palmar creases, and surface anatomy labeled (Courtesy of Benjamin Schoener, MD and Harrison Zeitler, MD; Central Michigan University COM)

The distal part of the nail is known as the nail body and the proximal portion of the nail is the nail root. The point of division is at the distal lunula, visible on exam as the white crescent-shaped area of the nail bed. The lunula represents the distal end of the germinal matrix, which is responsible for generation of the nail plate, which grows distally along the nail bed. Damage to the germinal matrix may lead to permanent damage of the nail plate. The insertion of the extensor tendons is found as distal as the lunula with a similar location for insertion of the flexor digitorum profundus (FDP), so damage to this area can result in tendon dysfunction. The small area of skin covering the proximal nail is known as the eponychium or cuticle. The hyponychium is skin underlying the distal nail plate. The paronychium refers to the skin overlying the lateral portions of the nail plate.

Examination of the nail bed by checking for capillary refill is important when assessing a patient's perfusion status. Additionally, the nail itself should be assessed for clubbing, spooning, splinter hemorrhages, discoloration, and thickness.

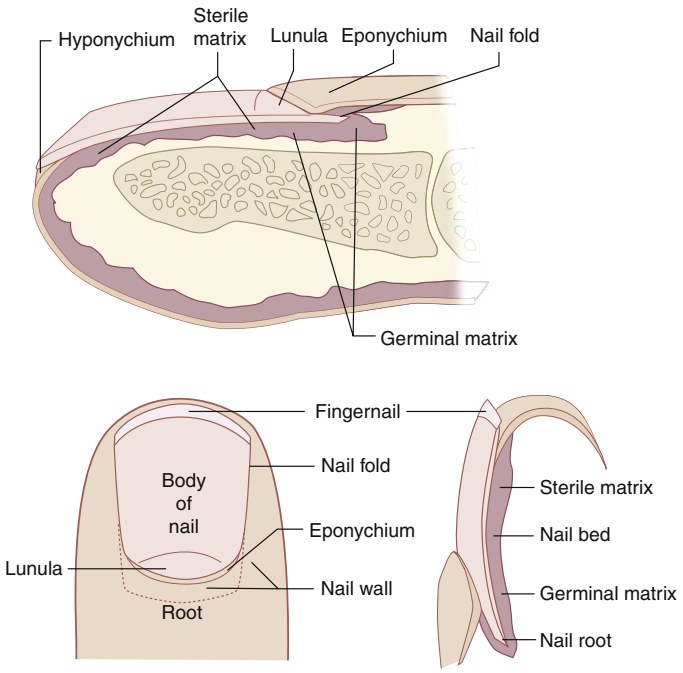

Fig. 42.2 Fingernail with labeled anatomy. (From: Buttaravoli P, Leffler, Stephen M. *Minor Emergencies*, ed 3. Philadelphia: Elsevier Saunders; 2012:535-538.)

Skeletal Anatomy and Ligaments

The hand is comprised of five digits: four fingers and one thumb. Each digit is numbered from I to V with digit I being the thumb and digit V being the little finger. The fingers contain a distal, middle, and proximal phalanx, while the thumb only has a proximal phalanx and a distal phalanx. The joints of the hand from proximal to distal include the carpometacarpal (CMC), metacarpophalangeal (MCP), proximal interphalangeal (PIP), and the distal interphalangeal joints (DIP) (Fig. 42.3). Proximal to the metacarpals are the 8 carpal bones which are tightly bound by ligaments which creates a concave formation on the volar surface. This is held together by the flexor retinaculum, a strong fibrous band, which forms the carpal tunnel, containing the median nerve and flexor tendons passing from the forearm. The boundaries of the carpal tunnel include the flexor retinaculum volarly and the carpal bones medially and laterally.

Bone development in the hand differs from other long bones. The thumb metacarpal epiphysis and phalangeal epiphyses are located at the proximal end. The finger metacarpal epiphyses are located at the distal end. The ossification centers of the phalanges and metacarpals appear at 10 to 36 months of age and usually fuse by age 14 to 16 years, with females having ossification earlier than males in general. The

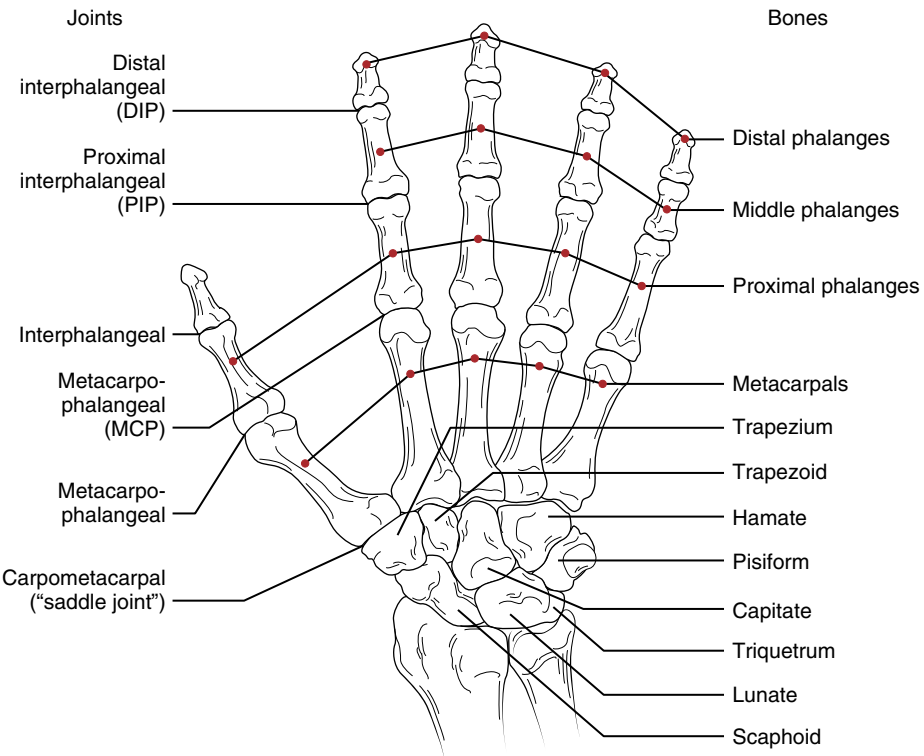

Fig. 42.3 Anatomy of the bones and joints of the hand. (Trott AT. *Wounds and Lacerations: Emergency Care and Closure*. Philadelphia: Elsevier Saunders; 2012:161-191.)

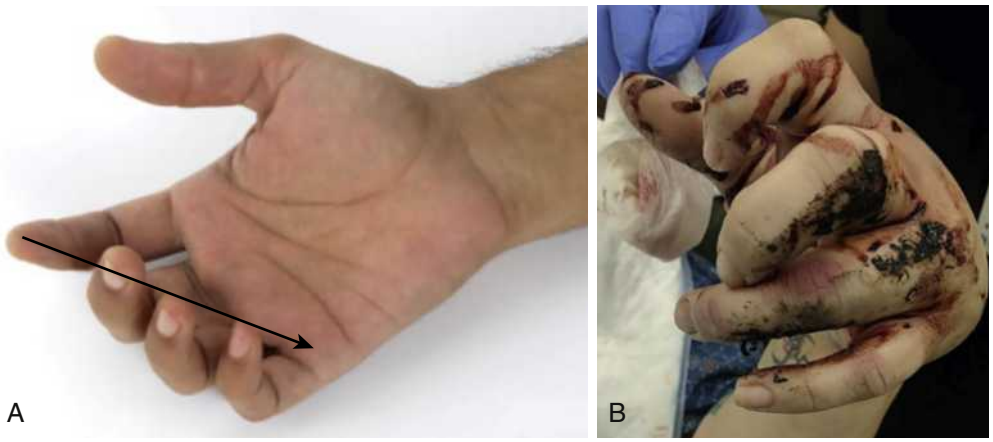

Fig. 42.4 Cascade of the hand. (A) Demonstration of cascade testing where the hand is positioned with the palm upward. Notice the gradual increase in flexion from radial to volar for joints of the hand. (B) Abnormal cascade in a patient following a crush injury. There is overlap of digits with a rotational deformity. (From: [A] Odak S, Bhalaik V. Assessment of the acutely injured hand. *Orthop Trauma.* 2014;28(4):199-204; [B] Courtesy of Tiffany Weiss-Feldkamp, DO and David Kramp, MD; Central Michigan University COM)

ossification center of the middle finger generally develops first and the fifth generally develops last.

The DIP and PIP joints of the fingers are uniaxial hinge joints that move along a sagittal plane. The DIP joint can flex to a maximum of 90 degrees whereas the PIP joint can flex up to 105 degrees from full extension. The DIP and PIP joints are structurally identical in that they both have a bicondylar configuration with a tongue-in-groove insertion of the distal phalanx. This configuration on both sides of the joint, in addition to collateral ligaments (also known as retinacular ligaments), is responsible for lateral stability and resisting of lateral, oblique, and rotatory forces. To provide additional stability, a fibrocartilaginous volar plate forms the anterior surface of the IP joint. The volar plate, along with a pair of check ligaments, serves to reinforce the joint capsule and limit hyperextension.

To evaluate any rotational deformities of the fingers in flexion, the *cascade sign* test may be used (Fig. 42.4). With the patient's elbow flexed to 90 degrees and the forearm supinated, the patient closes his or her hand with the thumb remaining open. Normally, the fingers should come together over the thenar and hypothenar eminences and point toward the scaphoid region. However, if there is overlap of the fingers or they are askew, this is a positive cascade sign, indicating rotational deformity often associated with metacarpal or phalangeal fractures.

In contrast to the IP joints, the MCP joints are less stable. They are formed by a rounded head of the metacarpal bone inserting into the concave surface of the proximal phalanx. This facilitates an efficient grasp by allowing for some rotational movement and side-to-side mobility. The MCP joints also contain a volar plate and collateral ligaments, though the volar plates of the MCP joints, unlike the IP joints, are interconnected by a deep transverse ligament. Additionally, the arc of rotation of the MCP joint depends on the degree of flexion of the proximal phalanx. As the MCP joint is flexed from 0 to 90 degrees, the collateral ligaments transition from a relaxed to a tight functional state. The integrity of the collateral ligaments should be tested when the MCP joint is fully flexed, where there should be no ability to abduct or adduct the phalanx. This is in contrast to the extended state, where limited side-to-side mobility is possible.

The functional anatomy of the MCP joint also illustrates the importance of splinting the joint in flexion to avoid shortening and subsequent stiffening of the collateral ligaments. Functional positioning is essential for proper splinting of the hand (Fig. 42.5).

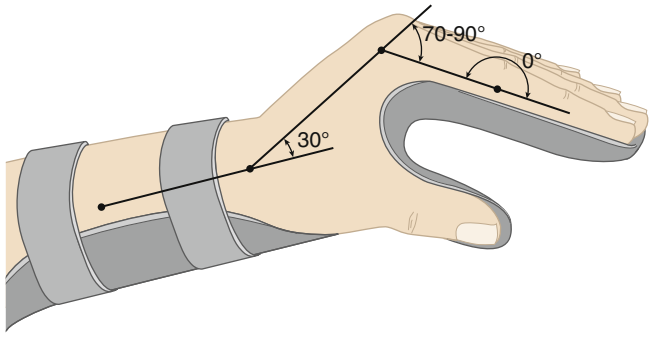

Fig. 42.5 Functional position of the hand with the wrist at 30 degrees extension, the MCP joint at 70-90 degrees flexion, and the PIP and DIP joints fully extended. (From: Yang G, McGlinn EP, Chung KC. Management of the stiff finger: evidence and outcomes. *Clin Plast Surg.* 2014;41(3):501-512.)

The arrangement of the metacarpals creates three arches: the proximal (carpal) and distal (metacarpal) transverse arches and the longitudinal arch (Fig. 42.6). The articulations between the carpal and metacarpals for the second and third digits are essentially fixed, making them relatively immobile in comparison to the articulations of the fourth and fifth digits, which have 15 and 25 degrees of movement, respectively. This variability creates a transverse and longitudinal concavity when the thumb is adducted against the index finger.

The joints of the hand should be properly examined for erythema, pallor, and swelling. They should also be examined for excessive warmth to assess for inflammatory arthritis. Cool or discolored digits may indicate vascular pathology or Raynaud phenomenon. Both passive and active range of motion of the joints should be assessed (Box 42.2). Crepitus may be present with a joint effusion or inflammatory arthritis. Clicking or snapping may indicate that tendonitis is present.

Musculature and Tendons

The muscles of the hand are divided into two groups: intrinsic and extrinsic. The intrinsic hand muscles contain origins and insertions within the hand itself, whereas the extrinsic hand muscles include origins proximal to the hand with tendon insertions within the hand.

Intrinsic Musculature. The intrinsic hand muscles include the muscles of the thenar and hypothenar eminences as well as the adductor

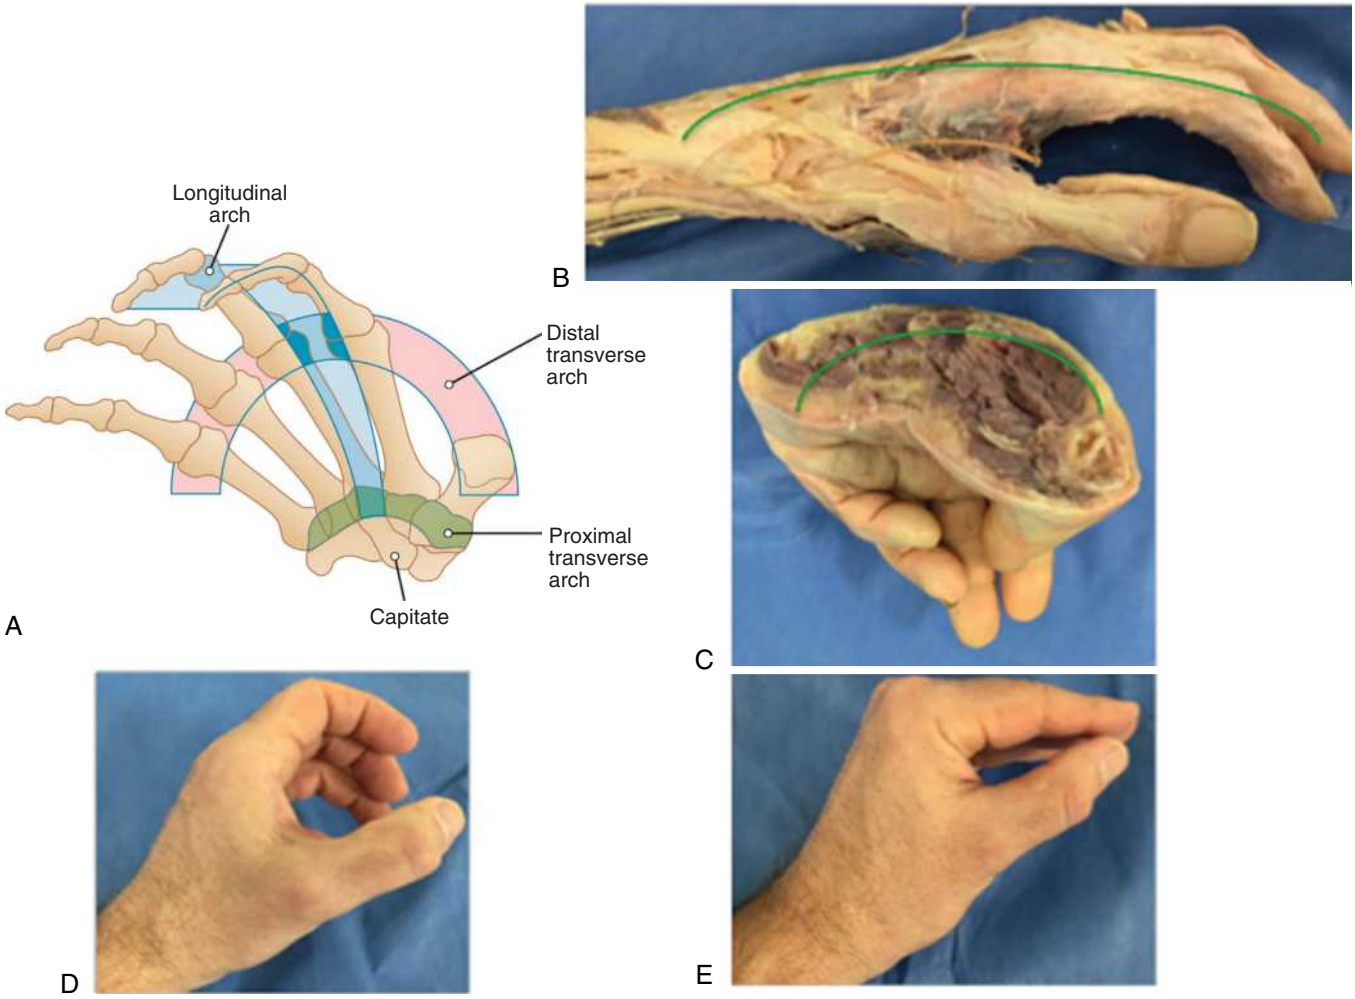

Fig. 42.6 (A) The longitudinal and transverse arches of the hand and their relationship to the metacarpals. (C) Proximal transverse arch. (D & E) Articulations of the thumb are unique and contribute to the intrinsic arches to create an array of grasp positions. (A from Erickson M, et al. Anatomy and kinesiology of the hand. In: *Rehabilitation of the Hand and Upper Extremity*. Jan 1, 2021. (c) 2021. Fig. 1.3; B–E courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

BOX 42.2 Maximum Joint Range of Motion

I. Fingers
- MCP: 0 to 90 degrees flexion
- PIP: 0 to 110 degrees flexion
- DIP: 0 to 85 degrees flexion

II. Thumb
- MCP: 10 degrees hyperextension to 70 degrees flexion
- IP: 15 degrees hyperextension to 90 degrees flexion

pollicis, lumbricals, and interossei. These muscles are innervated by the median and ulnar nerves.

The muscles of the thenar eminence cover the metacarpal of the thumb and include the abductor pollicis brevis, flexor pollicis brevis, and the opponens pollicis. The names of these muscles describe their function and they are controlled by the recurrent branch of the median nerve. The muscles are easily palpable over the volar surface of the hand proximal to the MCP joint of the thumb.

Another muscle in this location, the adductor pollicis, arises from the capitate and bases of the second and third metacarpals. Unlike other muscles in this location, it is innervated by the ulnar nerve and functions to adduct the thumb and rotate it medially. The adductor pollicis, as well as ulnar nerve function, can be tested by asking the patient to hold a piece of paper between the thumb and index finger. If when the examiner attempts to pull the paper out of the patient's hand, the patient is unable to hold on, or there is flexion of the thumb at the IP joint, this indicates weakness of the adductor pollicis muscle. This is also known as the *Froment paper sign* (Fig. 42.7). The patient flexes his or her thumb because the median nerve–innervated flexor pollicis longus tendon takes over to allow the thumb to grasp the paper when the adductor pollicis is weak.

The muscles of the hypothenar eminence include the opponens digiti minimi, flexor digiti minimi, and abductor digiti minimi. All three muscles aid in movement of the little finger and are innervated by the ulnar nerve. Strength of these muscles may be evaluated by having the patient hold a piece of paper between the thumb and little finger or by having the patient attempt to abduct the little finger against resistance.

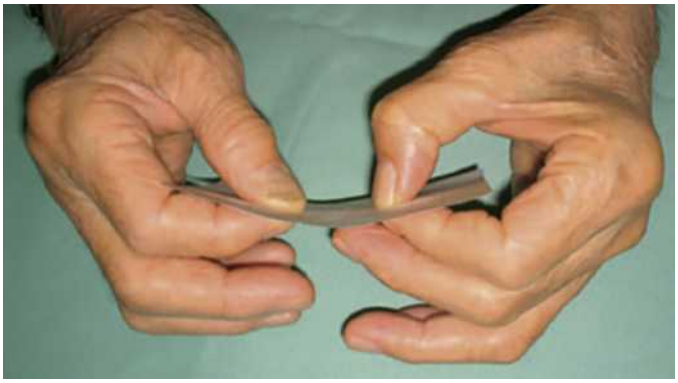

Fig. 42.7 Froment sign demonstrated in a patient with left ulnar nerve weakness. The patient attempts to hold onto the paper with the thumb IP joint in flexion and the MCP joint in hyperextension. (Kakinoki R. Examination of the upper extremity. In: *Plastic Surgery: Vol 6: Hand and Upper Extremity*, ed 4. London: Elsevier; 2017:49-70.)

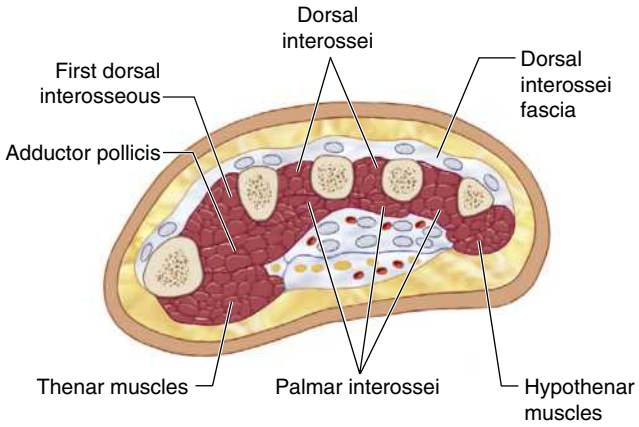

Fig. 42.8 Cross-sectional view of the compartments of the hand. (Lin PY, Sebastin SJ, Chung KC. Fasciotomy of the upper limb. In: Chung KC, ed. *Operative Techniques: Hand and Wrist Surgery*, ed 2. Philadelphia: Elsevier Saunders; 2012.)

The lumbricals originate from tendons of the flexor digitorum profundus (FDP) and insert at the extensor hood and the base of the proximal phalanx. They function to flex the MCP joints and extend the IP joints. The ulnar two lumbricals are innervated by the ulnar nerve and the radial two lumbricals are innervated by the median nerve.

The interossei muscles are divided into dorsal and palmar interossei. The four dorsal interossei are located in the intermetacarpal spaces and function to abduct the fingers. The three palmar interossei are also located in the intermetacarpal spaces and insert at the base of the second, fourth, and fifth proximal phalanx. They function to adduct the fingers. All interossei are innervated by the deep branch of the ulnar nerve.

Extrinsic Musculature. The extrinsic hand muscles are those that originate proximal to the wrist and insert within the hand. Most extrinsic hand muscles originate in the forearm. The dorsal forearm contains extensor muscles of the wrist and fingers as well as abductors of the thumb. The volar forearm contains flexor muscles of the wrist, thumb, and other fingers.

Extensor Muscles and Tendons. The extensors tendons pass through the dorsum of the wrist at 6 different compartments and are innervated by the radial nerve (Fig. 42.8). Compartment 1 is located most radial and contains the abductor pollicis longus and extensor pollicis brevis tendons which form the lateral border of the anatomical snuffbox. Both muscles are innervated by the posterior interosseus nerve, a branch of the radial nerve. Compartment 3 contains the extensor pollicis longus tendon, which forms the medial border of the anatomical snuffbox. The tendons forming the borders of the anatomical snuffbox are easily palpable and often visible when the thumb is held in abduction and extension. Compartment 2 contains the extensor carpi radialis longus and extensor carpi radialis brevis tendons, which insert at the base of the second and third metacarpals, respectively. Both muscles act to extend and abduct the hand at the wrist.

Compartment 4 contains the extensor indicis and extensor digitorum communis (EDC) tendons. The extensor indicis proprius (EIP) inserts into the extensor hood, which is a dorsal aponeurosis of the index finger. The EDC tendons similarly insert into the extensor hood of the middle and distal phalanges of the second, third, fourth, and fifth fingers. The muscles of compartment 4 function to extend the 4 digits and the hand, though primarily at the MCP joint. Extensions of tendons from the extrinsic and intrinsic muscles form an extensor complex on the dorsum of the fingers. Extensions from the lumbrical and interosseus muscles connect with extensions of the extensor digitorum tendons to form the extensor hood (expansion). The expansion divides into three bands—two lateral bands and a central tendon (central slip). The three bands are held together by the transverse retinacular ligament preventing volar displacement of the lateral bands which would result in PIP flexion as seen in the *boutonnière deformity* (Fig. 42.9).

Compartment 5 contains the extensor digiti minimi (EDM) tendon which inserts at the extensor expansion at the base of the fifth digit and extends it at all joints. Compartment 6 contains the extensor carpi ulnaris (ECU) tendon which inserts at the fifth metacarpal and functions to extend and adduct the wrist.

Of relevance to identifying and diagnosing an extensor tendon injury are the zones of the extensor tendons. This will be discussed in depth under extensor tendon injuries.

Flexor Muscles and Tendons. The anterior forearm contains muscles responsible for flexion of the wrist, hand, and digits and can be divided into an anterior compartment and posterior compartment.

The flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), and palmaris longus (PL) tendons are responsible for flexion of the hand at the wrist. The flexor carpi radialis (FCR) inserts at the base of the second and third metacarpals and is controlled by the median nerve. In addition to flexion of the wrist, it is responsible for abduction of the hand at the wrist. The flexor carpi ulnaris (FCU) inserts at the hook of the hamate and base of the fifth metacarpal. It is controlled by branches of the ulnar nerve and is responsible for flexion and adduction of the hand at the wrist. The palmaris longus muscle inserts at the palmar aponeurosis and flexor retinaculum. It is controlled by the median nerve and is responsible for wrist flexion. It can be visible and palpable when one flexes the wrist and touches the pads of the fourth finger and thumb together. Of note, it is innately absent in approximately 25% of patients.[3] Both the palmaris longus and flexor carpi ulnaris (FCU) partially insert at the flexor retinaculum, a fibrous band covering the carpal bones and forming the roof of the carpal tunnel.

The flexor digitorum profundus (FDP), flexor digitorum superficialis (FDS), and flexor pollicis longus (FPL) are responsible for flexion of the digits and enter the hand via the carpal tunnel. All three muscles are innervated by the median nerve or one of its branches with the exception that movement of the fourth and fifth digits via the FDP is controlled by the ulnar nerve. The FDP originates over the proximal body of the ulna and fans out into 4 tendons which insert at the base of the distal phalanges. The FDP primarily functions to flex the fingers at both interphalangeal joints. The flexor digitorum superficialis (FDS) lies superficial to the FDP in the forearm and similarly fans into 4 tendons, though these insert at the base of the intermediate phalanges of digits 2 through 5. The FDS primarily functions to flex the PIP joints.

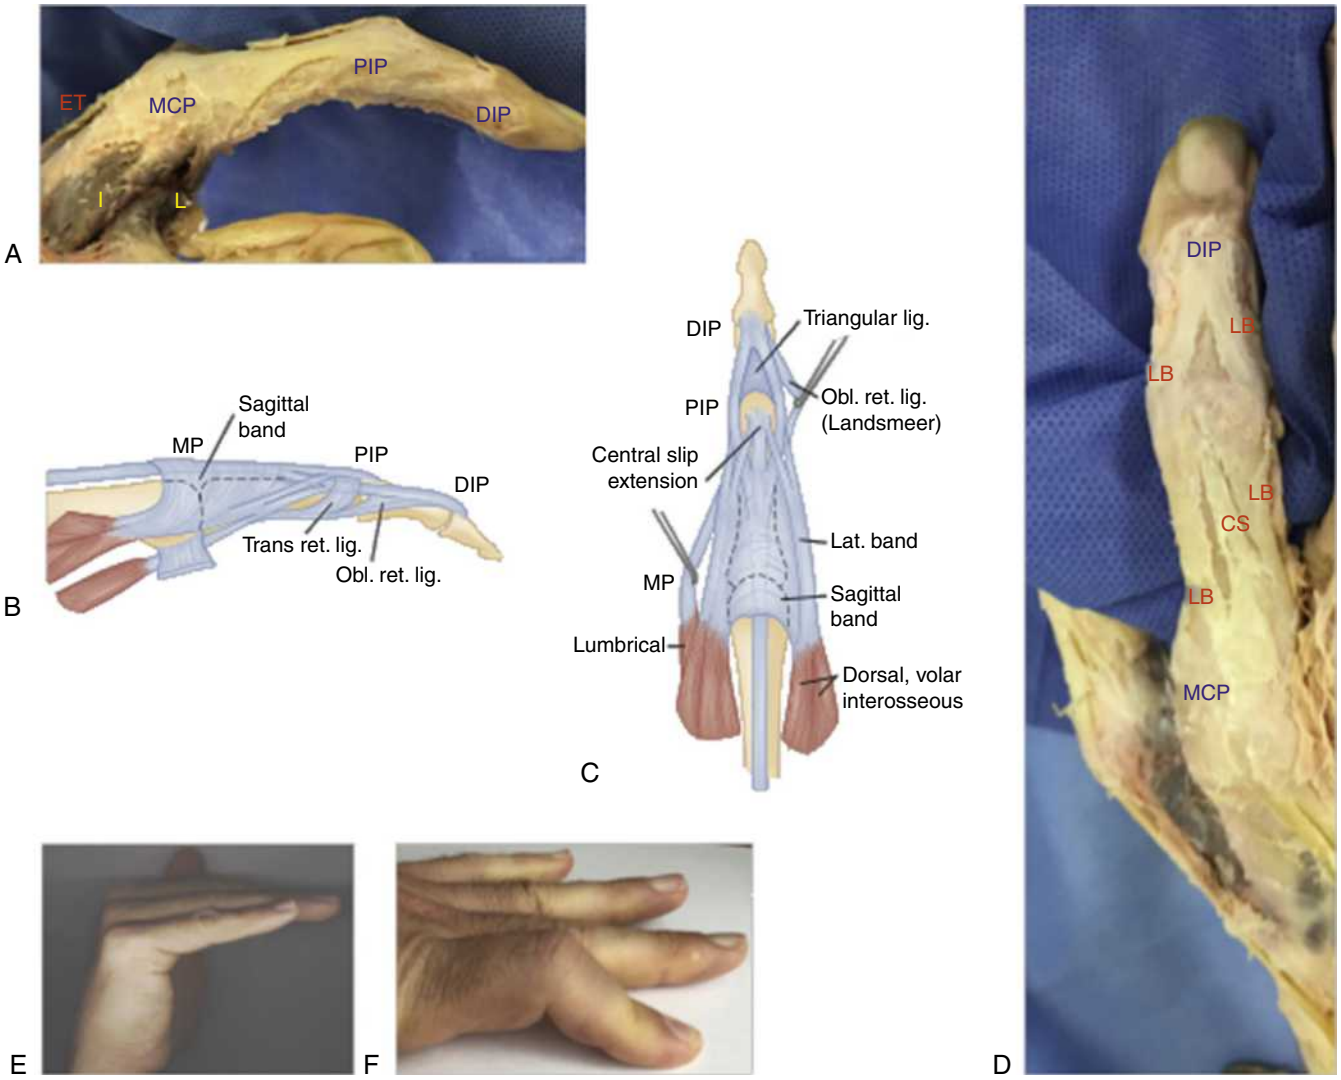

Fig. 42.9 Finger extensor complex. (A and B) The extensor hood is formed by a sagittal band originating from metacarpal ligaments and volar plate. The intrinsic tendons lumbrical (L) and interosseous (I) muscles insert into the extensor mechanism along the proximal dorsal phalanx. (C and D) The extension complex at the PIP joint contains a central slip (CS), which inserts on the dorsal base of the middle phalanx and two lateral bands (LB). The lateral bands insert at the dorsal base of the distal phalanx, extending beyond the distal interphalangeal (DIP) joint. (E and F) The PIP extension mechanism over the PIP joint is maintained by the transverse and triangular ligaments, preventing the lateral bands from migrating anteriorly, which would result in paradoxical PIP joint flexion. (F) Demonstration of boutonnière deformity where the PIP joint of the index finger is paradoxically flexed with DIP extension. (A, D–F: Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; B, C: from: Doyle JR. Extensor tendons—acute injuries. In Green DP, ed. *Operative Hand Surgery*. New York: Churchill Livingstone; 1998:1928.)

To test for FDS integrity, the examiner should flex the associated finger against resistance at the PIP while holding the other fingers in extension to control for FDP action (Fig. 42.10). The flexor pollicis longus functions to flex the thumb and inserts at the base of its distal phalanx (Table 42.1).

Digital Flexor Sheath. The digital flexor sheath of the hand is a closed system of synovial membranes that is divided into membranous and retinacular components. The membranous portion contains interdigitations between the retinacular tissue and tendons. Of note, the synovial sheaths of the flexor tendons are avascular systems and thus are more prone to infection. Extensor tendons, which do not have similar sheaths, are less likely to develop infectious tenosynovitis (Fig. 42.11).

The retinacular component is also described as the "pulley system" that overlies the synovial sheath which consists of the palmar aponeurosis (PA) pulley, 3 cruciform pulleys, and 5 annular pulleys. Of note, the thumb flexor tendon sheath has its own pulley system (Fig. 42.12). The overall function of the pulley system is to maintain tendons in axis with flexion of the MCP and ICPs, thereby preventing "bowstringing." The A2 and A4 pulleys are the most essential to preserve.

Blood Supply

Arterial Supply. The radial and ulnar arteries are primarily responsible for blood supply to the hand. The radial artery courses through the anatomical snuffbox where it branches into the deep palmar arch and the superficial palmar arch. The princeps pollicis

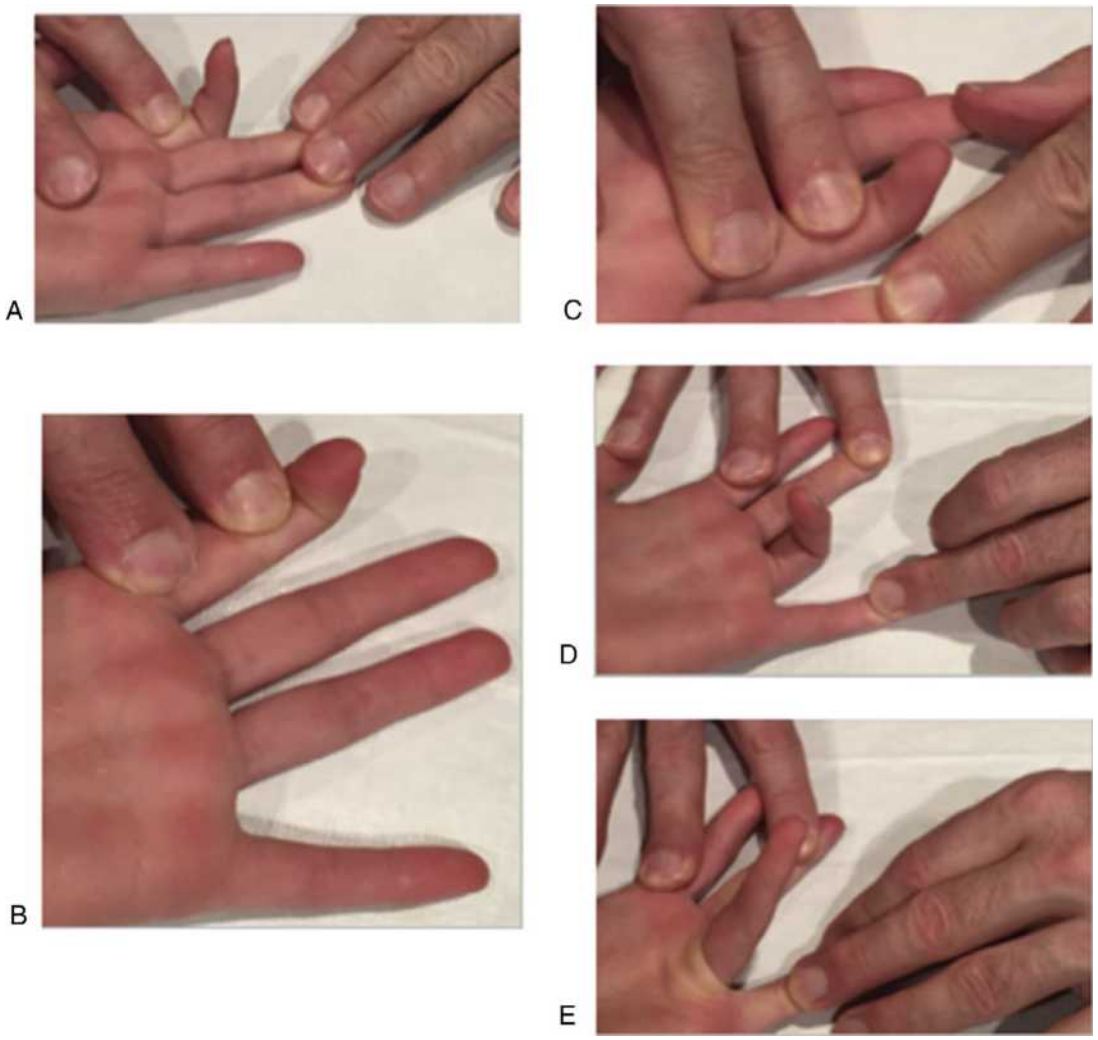

Fig. 42.10 Demonstration of individual testing of flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) tendon integrity (A) The index finger FDS tendon is examined by asking the patient to flex the corresponding proximal interphalangeal (PIP) joint while the adjacent digits are held in extension by the examiner. (B) FDP integrity is assessed by asking the patient to flex the distal interphalangeal (DIP) joints of each digit individually while the corresponding PIP joints are stabilized in extension by the examiner. (C–E) The ring finger's flexor digitorum profundus (FDP), FDS, and lumbrical functions are tested individually. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

TABLE 42.1 Flexor Tendons of the Hand

Flexor Tendon	Insertion	Innervation	Function/Physical Examination
Flexor Carpi Radialis	Second and third metacarpal bases	Median N.	Flexion and radial deviation at the wrist
Flexor Carpi Ulnaris	Hook of hamate and base of fifth metacarpal	Ulnar N. Branches	Flexion and ulnar deviation at the wrist
Palmaris Longus	Palmar aponeurosis and flexor retinaculum	Median N.	Flexion at wrist, palpable tendon if present
Flexor Digitorum Profundus (FDP)	Base of distal phalanges	Median N. and Ulnar N.	Flexion of MCP, DIP, and PIP joints (Isolated examination by flexing DIP with other joints held in extension)
Flexor Digitorum Superficialis (FDS)	Base of proximal phalanges	Median N.	Flexion of MCP and PIP joints (Examine by flexing PIP with MCP held in neutral position)
Flexor Pollicis Longus	Base of distal phalanx of thumb	Median N.	Flexion at MCP and IP joints of thumb

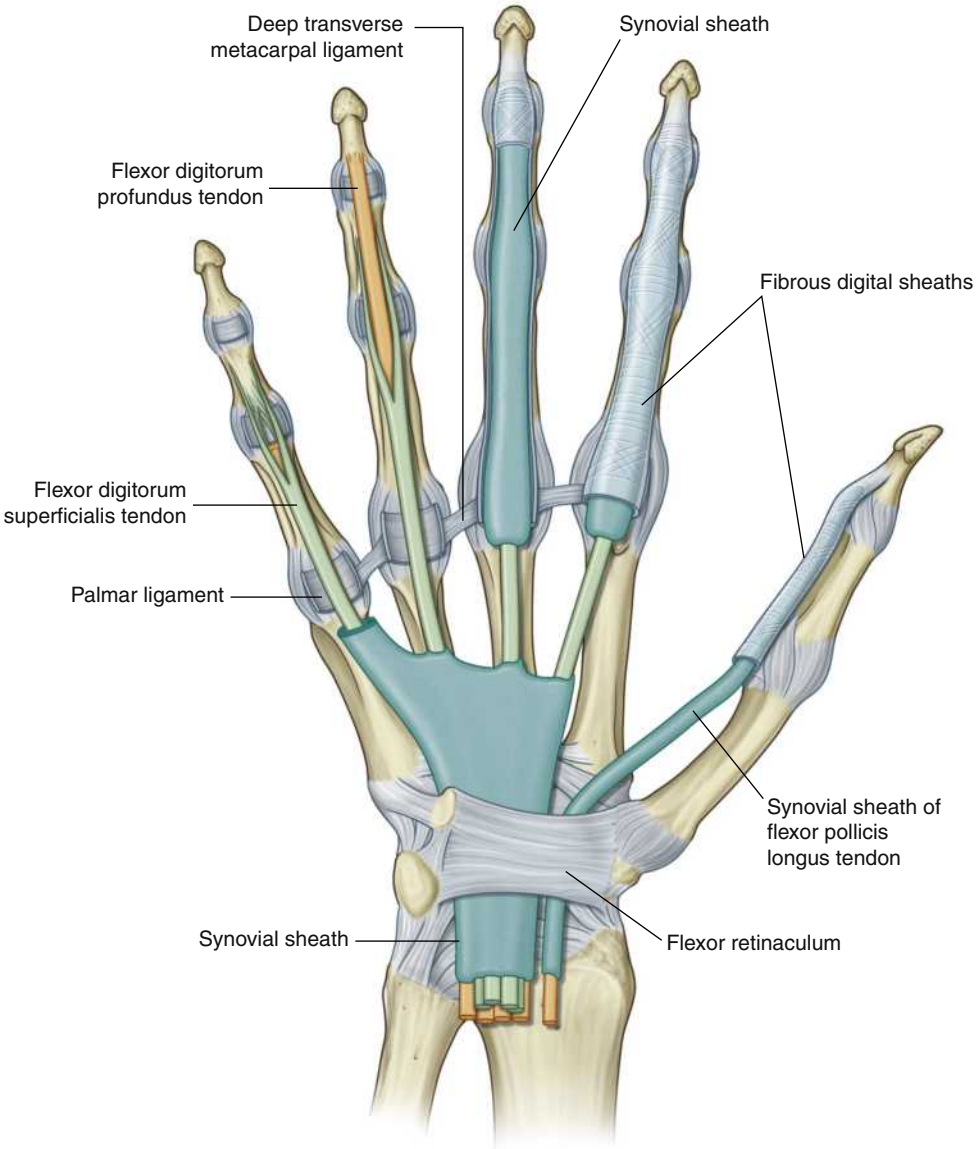

Fig. 42.11 The synovial sheaths of the hand and their relationship to the flexor tendons. (Drake RL, Vogl AW, Mitchell A. Upper limb. In: *Gray's Anatomy for Students,* ed 4. Philadelphia: Elsevier; 2020:671-821.)

artery and the radialis indicis artery arise from the deep palmar arch. The deep palmar arch of the radial artery continues to loop deep within the volar surface of the hand and anastomoses with the ulnar artery. The superficial palmar arch of the radial artery courses superficially over the metacarpals where it also anastomoses with the ulnar artery. In doing so, the superficial palmar arch gives rise to the palmar digital arteries which further branch to supply the fingers distally from the radial and ulnar aspects of each digit (Fig. 42.13).

The ulnar artery enters the hand superficial to the flexor retinaculum through the wrist via the Guyon canal, a space created by the pisiform and palmar carpal ligament. Immediately distal to the Guyon canal, the ulnar artery branches into the large superficial palmar arch. These arches form collaterals with the deep palmar arches of the radial artery and perfuse every digit in almost all patients. The collateral arterial system within the hand and digits allow for continued perfusion if either the radial or ulnar arterial flow is impaired. Testing for perfusion via the radial and ulnar arteries individually can be accomplished through the *Allen test* (Fig. 42.14).

There are times when an Allen test cannot be performed due to the patient's level of consciousness or due to other injuries. In those situations, simple palpation or use of Doppler ultrasound to assess blood flow to the hand through the radial and ulnar arteries at the wrist will suffice. It is important to make sure backflow through the palmar arch does not give the examiner a false-positive result of a patent artery. Thus, the ulnar artery should be compressed at the wrist when checking the patency of the radial artery when the Allen test cannot be done. Additionally, there may be significant arterial injury in the absence of heavy bleeding as the injured vessel may become compressed by surrounding edematous tissue.

Venous and Lymphatic System

The deep veins of the hand travel in a neurovascular bundle along with the arteries of the hand. The dorsum of the hand contains the lymphatic system within the loose subcutaneous tissue. The lymphatics eventually drain into the forearm via the cephalic and basilic veins. The presence of lymphatics and loose subcutaneous tissue results in greater swelling on the dorsum (versus volar) aspect of the hand with infections.

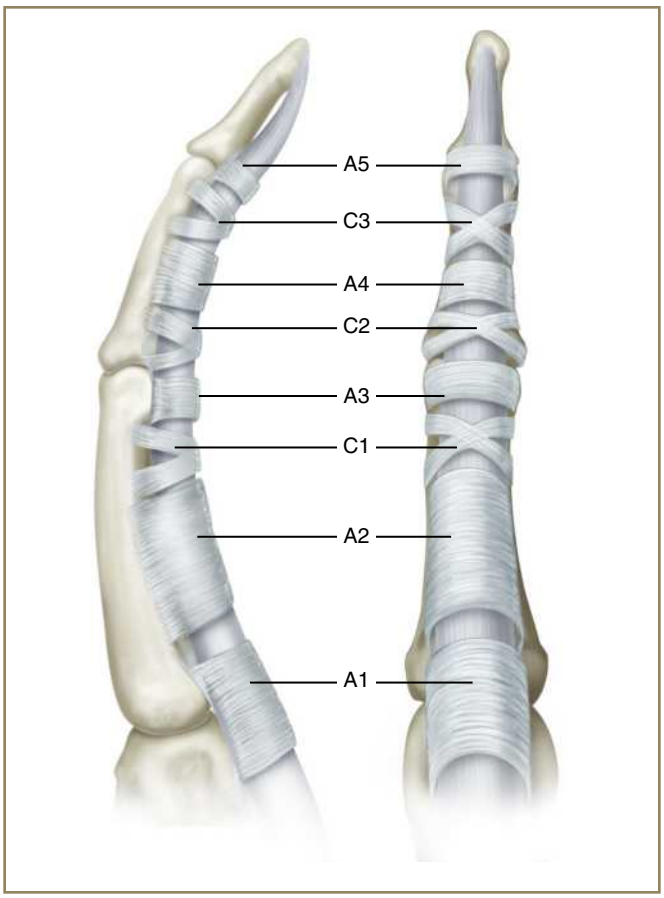

Fig. 42.12 Normal anatomy of the flexor pulley system with lateral and volar views. A2 and A4 are the narrowest points. (From: Morrison WB, Sanders TG. *Problem Solving in Musculoskeletal Imaging*. Philadelphia: Mosby; 2008:484.)

Innervation and Sensory Systems

The median nerve enters the hand via the carpal tunnel. It is responsible for sensation of the radial two-thirds of the volar surface of the hand as well as the flexor surface of fingers 1 through 3 and the radial half of the fourth (ring) finger (Fig. 42.15). The motor branch of the median nerve innervates five intrinsic muscles of the hand including the thenar muscles and two of the lumbricals. The extrinsic muscles of the hand innervated by the median nerve include the flexor tendons to the radial three digits and FCR.

The ulnar nerve supplies sensation to the ulnar one-third of the hand at both the volar and dorsal surfaces. It is also responsible for sensation of the fifth finger and the ulnar half of the fourth finger. The ulnar nerve is responsible for the extrinsic motor function of the flexor carpi ulnaris (FCU) and the flexor digitorum profundus (FDP) tendons of the fourth and fifth digits. It also innervates the remaining intrinsic muscles of the hand and divides into a volar and dorsal branch at the wrist. The volar branch, along with the ulnar artery, enters the palm through the Guyon canal. It is responsible for movement of muscles of the hypothenar eminence, interosseus muscles, and the lumbricals of the fourth and fifth fingers. The deep branch innervates the adductor pollicis. The ulnar nerve's motor innervation of the fourth and fifth digits is largely responsible for grip power and injury can significantly alter normal use of the hand.

The radial nerve contains superficial and deep branches and provides sensation to the radial two-thirds of the hand on the dorsal surface excluding the fingertips. There are no motor function branches for the radial nerve within the hand, though its innervation of the dorsal forearm leads to hand function including extension of the wrist (extensor carpi radialis longus) as well as other extensor tendons (extensor digitorum communis, extensor digiti quinti proprius, extensor pollicis longus and brevis).

The median, ulnar, and radial nerves each give rise to common digital nerves which further divide into lateral and medial branches on respective sides of each digit (Fig. 42.16). There are four individual digital nerves supplying sensation to each digit. The dorsal branch of these nerves run along the dorsal edge of the line made by the flexor crease to the tip of the finger.

Sensation of the hand should be tested in all hand injuries, particularly in patients with suspected nerve injury. Two-point discrimination is most precise in testing for sensation at the digits and may be tested by using the blunt ends of a paperclip (Fig. 42.17). Sensation is deemed intact if a patient is able to distinguish between one and two points to a distance of 5 mm.

For rapid examination of the motor and sensory functions of the hand, a few simple tests can be performed. One simple test for motor function of the radial, ulnar, and median nerve is to have the patient make an "OK" sign with their thumb and index finger (testing the median nerve), while dorsiflexing the wrist (radial nerve) and spreading/abducting the third, fourth, and fifth fingers (ulnar nerve). For general sensory examination, a clinician can test the finger tufts of the index finger (median nerve), the little finger (ulnar nerve), and the dorsum of the proximal phalanx of the thumb (radial nerve) with two-point discrimination. Simply being able to differentiate between sharp and dull is often enough to assess sensation. This can be done expeditiously at the bedside by using a broken tongue blade or 18-gauge needle.

If there is any concern about the function or sensation, more specific testing should be focused on a specific nerve and digit. It is important to identify where the nerves are injured. For example, if the ulnar nerve is severed in the forearm, the extrinsic muscles will not function and the fourth and fifth fingers will not flex. If tendons are lacerated in the hand, there may be similar dysfunctional results.

Regional Blocks

Digital Block

The digital block is commonly used for wound repair or incision and drainage of the affected finger. The volar and dorsal nerves of the finger course along the lateral edges of the fingers and allow for easy access to regional anesthesia (Fig. 42.18). Lidocaine 1% or 2% is commonly used for digital blocks, though bupivacaine may be used if a longer period of anesthesia is desired. Despite the lack of evidence, many people advocate against the use of epinephrine in anesthetic preparations given the theoretical potential for vascular compromise secondary to arterial constriction. However, a previous prospective study of over 3000 patients and a recent meta-analysis found no harm in the use of epinephrine for digital blocks in healthy patients.[4] Lidocaine with epinephrine has the added benefit of a longer period of anesthesia and potentiating hemostasis. Lidocaine with epinephrine should be used at the physician's discretion, though we uphold its safety in patients without severe vascular disease based on the current literature.

There are multiple ways to perform a digital block, though a common method is using the web spaces on each side of the digit being anesthetized. First, the skin at the locations of needle insertion should be adequately cleansed. The hand should be positioned with the palmar surface facing downward. A small needle is inserted into the skin at the distal webspace on the dorsal surface of the finger along the edge of the phalanx. The dorsal nerve runs under the skin alongside a

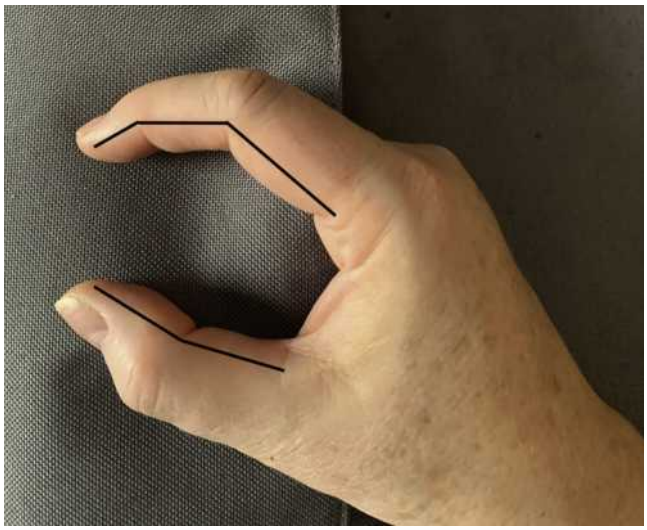

Fig. 42.16 The nerve, artery and vein bundle of the finger can be approximated on the skin by aligning the flexion creases of each joint. Avoiding this bundle when making an incision is desired. (Courtesy Clara Bihn, Butler University)

digital artery, so the operator should first aspirate to ensure there is no intravascular injection. A volume of 0.5 to 1 mL of local anesthetic is injected, and without withdrawing, the needle should be advanced into the volar side of the bony phalanx where an additional 0.5 to 1 mL of the anesthetic is injected. The same process should be repeated on the opposite side of the digit to ensure that all four nerves are anesthetized.

While it is possible to obtain appropriate anesthesia with local infiltration of anesthetic, there are several advantages of a digital block over local infiltration.[5] First, there are fewer injection sites, ideally resulting in less pain for the patient. Second, local infiltration creates edema along the wound margins leading to greater tissue distortion and greater difficulty in obtaining appropriate wound approximation, which can be avoided with a digital block. Third, less anesthetic is needed for most regional procedures.

Metacarpal and Transthecal Blocks

If more proximal anesthesia is desired, a metacarpal block may be performed. This block may be administered on either the dorsal or palmar side of the hand, though the dorsal approach is often preferred due to thicker skin on the volar surface as well as greater innervation, making penetration more difficult and less tolerable.

Fig. 42.17 Demonstration of two-point discrimination testing. (Jobe MT. Nerve injuries at the level of the hand and wrist. In: Azar F, Canale ST, Beaty J. *Campbell's Operative Orthopaedics*, ed 13. Philadelphia: Elsevier; 2016:3462-3477.)

For the palmar approach, the needle is inserted directly over the metacarpal head. When the needle is subcutaneous, it is directed to one side of the metacarpal. While advancing the needle approximately 1 cm, aspiration is performed to ensure the needle is not in a vessel, and approximately 3 mL of local anesthetic is injected. The needle is then partially withdrawn and redirected to the other side of the metacarpal and the procedure is repeated. With a transthecal digital block, the needle is similarly inserted into the palmar surface, though more proximally at the distal palmar crease. At a 45-degree angle, the needle is advanced directly into the flexor tendon sheath. If the sheath has been entered, there should be little to no resistance with injection of anesthetic. If there is significant resistance, the needle has likely entered the tendon and it should be gradually withdrawn.

The dorsal approach is similar to the traditional digital block. The needle is inserted along one side of the dorsal surface of the metacarpal approximately 1 cm proximal to the MCP joint. The needle is advanced until the palmar aponeurosis or the volar edge of the metacarpal where approximately 2 mL of anesthetic is injected. While withdrawing the needle, an additional 1 mL of anesthetic is injected along the tract. The procedure is then repeated on the dorsal surface of the opposite side of the same metacarpal.

Wrist Blocks

As discussed previously, the radial, median, and ulnar nerves supply sensation to the hand. Each nerve can be blocked individually to anesthetize its respective dermatome. Traditionally, these nerves have been blocked using anatomic landmarks at the wrist, though newer methods involve ultrasound-guided blocks at the forearm. These nerve blocks have the advantage of requiring less anesthetic volume and decreased need for opiate analgesia.[6] The goal is to inject around the nerve but not directly into the nerve. If the nerve is inadvertently injected the patient may feel an uncomfortable "shock-like" sensation.

Radial Nerve Block. The radial artery at the volar surface of the wrist is palpated. Immediately lateral (radial) to this region, after aspirating, approximately 2 to 5 mL of local anesthetic is injected.

Median Nerve Block. The tendon of the flexor carpi radialis at the volar surface of the wrist is palpated. The needle is inserted over the median nerve which is 1 cm ulnar from the flexor carpi radialis or between this tendon and the palmaris longus. The needle is advanced into the flexor retinaculum, where a "pop" may be felt, and the patient may complain of paresthesias. To avoid intraneural injection, the needle should be withdrawn a few millimeters where 3 to 5 mL of anesthetic agent is then injected. Due to baseline constriction at the flexor retinaculum, this procedure is a relative contraindication in patients with carpal tunnel syndrome.

Ulnar Nerve Block. The needle should be inserted between the ulnar artery and the flexor carpi ulnaris tendon and advanced approximately 1 cm. If the patient complains of paresthesia, the needle should be withdrawn a few millimeters with aspiration performed to ensure the needle is not in a blood vessel. Approximately 5 mL of anesthetic is then injected.

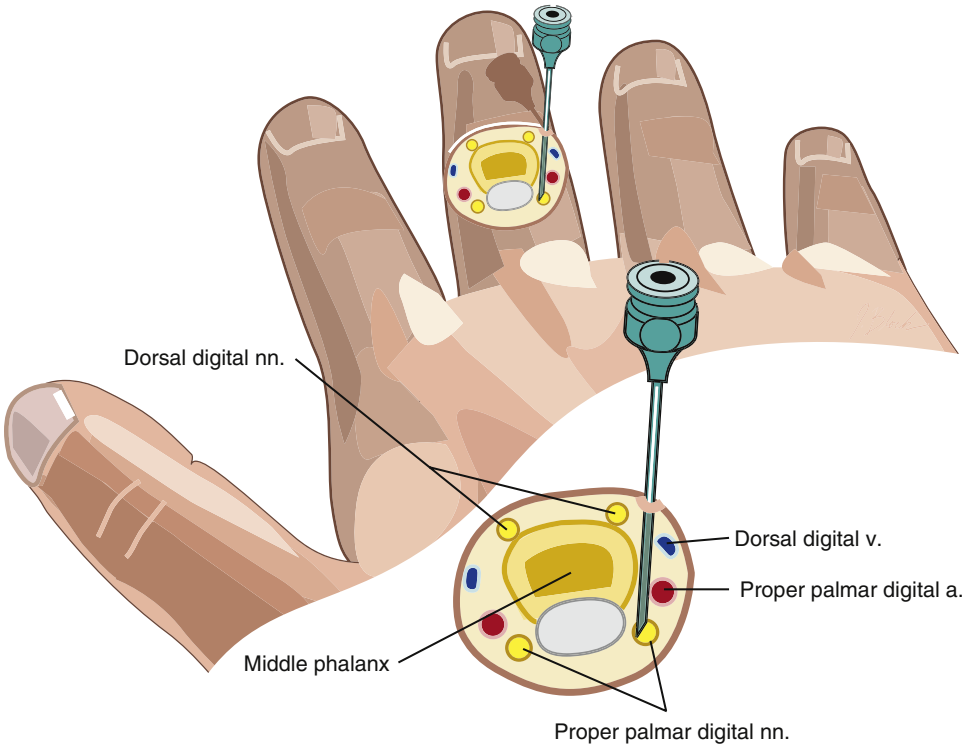

Fig. 42.18 Demonstration of digital and metacarpal nerve block with needle inserted at appropriate landmarks. (Waldman, SD. *Atlas of Interventional Pain Management*, ed 4. Philadelphia: Elsevier; 2015:275-278.)

Splinting

Splinting of hand injuries must take into account both the bony structures and the tendons that need to be protected. If a hand requires splinting for more than a day, the splint should maximize the length of the extensor tendons and the hand should be placed in a functional position. Specific positioning is needed for splints on patients with tendon or ligamentous injuries or certain fractures. The neutral position for general fractures of the hand or fingers is a volar splint with the wrist at 20 to 30 degrees extension, MCP at 70 to 90 degrees flexion, and the PIP and DIP kept in extension. This is also known as *intrinsic plus position* (Fig. 42.19). Appropriate positioning with splinting is critical because incorrect splinting is one the most common reasons for chronic hand stiffness after an injury.

Ring Removal

Early ring removal from an edematous finger is important because the ring acts as a tourniquet, causing further restriction of venous return and eventually arterial compromise if removal is delayed. Initial edema may occur secondary to a number of conditions such as infections, allergic reactions, fractures, arthritis, weight gain, or burns.

If the initial examination does not show signs of neurovascular compromise or severe constriction, the examiner may attempt removing the ring manually by lubricating the finger and then applying distal traction on the ring making twisting movements. The finger should be iced or elevated prior to this procedure to reduce swelling. If this is unsuccessful, there are other methods of ring removal.

In the absence of neurovascular compromise, deep ring erosion, or open wound, one may attempt less invasive methods such as the ring-wrap method, rubber-band method, or surgical glove method for ring removal. For the surgical glove method, the finger of a rubber or latex glove is cut off and placed over the patient's affected finger. The proximal end of the glove should be pulled underneath the ring (Fig. 42.20). Lubricant may be used to assist with this step. The proximal end of the glove should then be pulled back over the ring. Distal traction and twisting should be performed to advance the ring distally and assist in ring removal.

A similar technique has been described in the literature utilizing two rubber bands. These two rubber bands are advanced under the ring using a hemostat and are then used to pull distal traction on the ring for removal.[7]

In instances of deep ring erosion, an open wound, or obvious neurovascular compromise, prompt ring removal is essential. In these cases, we recommend use of a ring-cutting device if available (Fig. 42.21).[8] Most ring cutters have a circular blade and a hook or elevator. The hook should be slid under the ring. This serves as a barrier to the blade deep to the ring. The handle should be gripped, bringing the saw to the ring, where the grinding process through the ring can be performed. The ring may get hot during this process, and the patient may sustain a burn, so taking breaks approximately every 30 seconds is recommended. When the ring is cut, hemostats can aid in separating the two cut ends to remove the ring. Following ring removal, the patient should be monitored and examined for any signs of laceration or neurovascular compromise.

SPECIFIC HAND INJURIES

Phalanx and Metacarpal Fractures

Clinical Features

The hand is the most common location for fractures in the body. Specifically, phalanx and metacarpal fractures account for 10% of all fractures and the distal phalanx is the most common location.[9] These fractures are most common in young men and nearly a quarter occur during a sporting event. The type of fracture is classified based on

Fig. 42.19 Various types of splints for various hand injuries. Most hand injuries should be splinted in neutral (functional) position with the wrist slightly extended at 30 degrees, the MCP joints flexed to 90 degrees, and the PIP and DIP joints held in extension. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

Fig. 42.20 (A) The glove is pulled under the ring using hemostats. (B and C) The glove is moved over the ring, thereby removing it from the finger. (Haynes JH, Haynes AT, Hines TR. Ring removal from an edematous finger. In: Pfenninger JL, Fowler GC. *Pfenninger and Fowler's Procedures for Primary Care*, ed 3. Saunders; 2010:1320-1322)

location and stability. Common mechanisms of injury are with direct, crushing, penetrating, or blunt trauma.

Differential Diagnoses

The differential diagnoses for phalanx and metacarpal fractures are extensive and include tendon, joint-space, and ligamentous injuries (Table 42.2).

Diagnostic Testing

A standard x-ray series of the hand, including a PA, lateral, and oblique film, is sufficient imaging to detect most phalanx and metacarpal fractures. Ultrasound is another acute imaging modality, though it is inferior to x-ray imaging as previously described.

Fig. 42.21 Mechanical ring cutter. (Khodaee M, Tirabassi J. The hand-powered ring cutter: a useful tool in your wilderness medical bag. *Wilderness Environ Med*. 2015;26(3):441-442.)

Management

Transverse fractures are generally stable while oblique, intra-articular, comminuted fractures, and fractures associated with dislocations tend to be unstable. Most fractures can be managed with appropriate splinting (see Fig. 42.19), but there are certain situations which do require emergent surgical consultation, including open fractures, partial or complete amputations, displaced intra-articular fractures, and fractures that do not maintain reduction. Additionally, spiral, rotated, and oblique fractures tend to be unstable and require outpatient follow-up with a hand specialist for possible surgical fixation. Patients who have fractures that are amenable to closed reduction can generally tolerate the procedure with adequate anesthesia via hematoma block (metacarpal fractures) or digital block (phalanx fractures).

Although splinting varies based on individual clinical scenarios, there are certain principles for immobilization for fractures of the hand. For most phalangeal fractures, a long finger splint is sufficient, though in cases of instability and significant tendon and ligamentous injury, proximal immobilization at the wrist may be necessary. Further stabilization of phalanx fractures can be accomplished by dynamic splinting or "buddy-taping" the splinted injured finger to the adjacent uninjured finger. For metacarpal fractures and phalanx fractures with accompanying instability, a radial gutter splint may be used for fractures of the index and middle fingers. Similarly, an ulnar gutter splint may be used for fractures of the ring and little fingers. Fingers adjacent to the injured finger should be included in the splint. A thumb spica or radial gutter splint should be used for thumb fractures. We recommend a low threshold for splinting in skeletally immature pediatric patients if there is a high suspicion for fracture despite negative x-rays. Loss of motion, malunion, and nonunion are common complications for untreated fractures.

TABLE 42.2 Differential Diagnoses for Hand Injuries

Location of Injury	Differential Diagnosis
Distal phalanx/DIP joint	Tuft, shaft, or avulsion fracture Seymour fracture Crush injury Nail bed injury Subungual hematoma Mallet finger (dorsal) or jersey finger (volar) DIP dislocation or subluxation Collateral ligament injury Extensor digitorum communis injury FDP tendon injury
Middle phalanx/PIP joint	Head, neck, shaft, or base fracture Dorsal, volar, or lateral PIP dislocation or subluxation Volar plate or collateral ligament injury Central slip (extensor) injury FDP or FDS tendon injury
Proximal phalanx/MCP joint	Head, neck, shaft, or base fracture Dorsal, volar, or lateral MCP dislocation or subluxation Volar plate or collateral ligament injury Trigger finger Clenched fist ("fight bite") injury Extensor complex injury FDP or FDS tendon injury
Metacarpal/CMC joint	Head, neck, shaft, or base fracture Dorsal or volar CMC dislocation Ulnar nerve injury Extensor complex injury FDP or FDS tendon injury
Thumb distal phalanx/IP joint	Tuft, shaft, or avulsion fracture Crush injury Nail bed injury/subungual hematoma Mallet thumb IP joint dislocation or subluxation Volar plate or collateral ligament injury Extensor pollicis longus tendon injury
Thumb proximal phalanx/MCP joint	Head, neck, shaft, or avulsion fracture Ulnar collateral ligament injury (skier's or gamekeeper's thumb) Radial collateral ligament injury
Thumb metacarpal/CMC joint	Head, neck, or shaft fracture Base (Bennet or Rolando) fracture CMC joint dislocation or subluxation Oblique CMC ligament injury Abductor pollicis longus tendon injury

Phalanx Fractures

Distal Phalanx Fractures

Clinical Features

Distal phalanx fractures result from a direct blow to the dorsal surface of the finger or axial force to the extended fingertip. They are further classified into tuft, shaft, base, and intra-articular fractures (Fig. 42.22).

Tuft fractures generally occur secondary to a crush injury. These fractures are usually stable due to presence of the nail plate and pulp. They often involve injury to the distal phalanx with laceration to the nail bed or pulp and can be accompanied by subungual hematoma (see later).

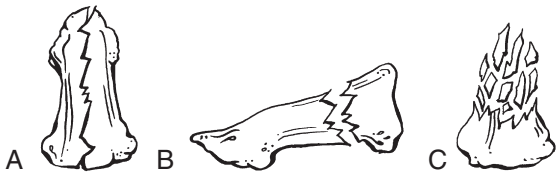

Fig. 42.22 Types of distal phalanx fractures. (A) Longitudinal, (B) transverse, and (C) comminuted. (Petering, RC. Finger fractures. In: Eiff MP, Hatch R, Higgins MK. *Fracture Management for Primary Care*. Ed 3 updated. Philadelphia: Elsevier Saunders; 2018:36-62.)

Fractures of the shaft are divided into transverse and longitudinal. Transverse fractures are generally stable and longitudinal fractures are unstable.

Fractures occurring at the base of the distal phalanx are usually unstable and intra-articular. These appear as avulsion fractures on x-ray and often are sports-related injuries. A common mechanism is an axial loading force on an extended distal phalanx resulting in forceful flexion or hyperextension at the DIP joint. Avulsion fractures at the base are further divided into dorsal injuries (e.g., mallet finger) and volar injuries (e.g., jersey finger). *Mallet finger* will present with inability to *extend* the distal phalanx at the DIP joint. Radiographs often show an avulsion fracture at the dorsal base of the DIP, though there may be an isolated distal extensor tendon rupture. In contrast, a *jersey finger* will present with inability to *flex* the distal phalanx at the DIP joint. X-rays may show an avulsion fracture at the volar base of the DIP, though there may be isolated rupture of the flexor digitorum profundus tendon.

The *Seymour fracture*, which is a transverse fracture of the distal phalanx involving the physis, occurs in the pediatric population.[10] This includes Salter-Harris type I and II fractures and typically involves a crush injury mechanism. It frequently occurs when a child gets a finger stuck in a door or folding chair. On exam, there will be exquisite tenderness at the distal phalanx and evidence of an associated nail bed injury, such as avulsion of the nail at the germinal matrix. This is considered an open fracture.

Differential Diagnoses

When considering a fracture of the distal phalanx, one should be mindful of other potential injuries or associated injuries to the distal phalanx. These include distal amputations, nail bed injuries, subungual hematomas, FDP tendon injuries, extensor mechanism injuries, collateral ligament injuries, and DIP dislocations or subluxations.

Diagnostic Testing

Standard x-ray imaging of the affected finger should be obtained if there is pain, swelling, tenderness, or loss of functional integrity following injury to the distal phalanx. Any separation, displacement, or angulation should be identified.

Management

Because most tuft fractures are stable and non-displaced, they are typically treated conservatively with analgesia and splinting. Splinting involves 2 to 4 weeks of protection with a finger cage splint or a molded aluminum splint that encloses the distal phalanx, though allowing for movement at the DIP. Hand specialist consultation is required for displaced fractures that are irreducible as well as for open fractures.

While antibiotics have traditionally been recommended for tuft fractures associated with nail bed or soft-tissue injuries, a recent meta-analysis involving 4 RCTs assessing rates of superficial infection and osteomyelitis in open distal phalanx fractures found no difference in rates of superficial infection and osteomyelitis in patients receiving antibiotics versus those who did not.[11] While there is strong evidence to support the use of antibiotics for open fractures elsewhere in the body, distal phalanx fractures are different in that most are secondary to deep lacerations or a crush injury where there is less periosteal stripping. The study suggests that the focus of treatment for open fractures should be on prompt irrigation and early débridement, rather than prophylactic antibiotics.

Transverse fractures at the shaft of the distal phalanx are usually non-displaced and require only protective splinting for 2 weeks. Reduction of displaced fractures should be attempted in the emergency department, though if closed manipulation is unsuccessful or if the fracture remains unstable, the distal phalanx should be splinted, and the patient referred to a hand specialist for pinning.

Longitudinal fractures should be splinted from the middle to distal phalanx, leaving the PIP joint mobile. Immobilization should be for 3 to 4 weeks followed by passive range-of-motion exercises until the finger is pain-free.

Almost all mallet finger injuries should be treated conservatively initially with splinting. The DIP joint is immobilized with splinting in neutral position or slight hyperextension continuously for 6 weeks. Compliance is critical. If the joint is flexed at any point during the 6-week splinting period, the course must be restarted. Stack splints or aluminum foam splints may be used (Fig. 42.23). Patients should be referred to a hand specialist as patients with a fracture involving one third or greater of the articular surface and those who fail conservative treatment are considered for surgical management by the hand specialist.

Avulsion fractures at the volar base of the distal phalanx may be treated conservatively with a dorsal or volar splint if there is some DIP joint flexion present. This is accomplished by immobilizing only the DIP joint in slight flexion (5–10 degrees) for at least 6 weeks. If there is no retained ability to flex the DIP joint, assume rupture of the FDP tendon (jersey finger) and refer the patient for surgical management. In the meantime, the finger should be immobilized in a splint that incorporates the wrist with the finger maintained in flexion.

Pediatric patients with Seymour fractures (Salter-Harris fracture of the finger in which the nail comes out from the nail fold) should ideally have repair performed in the emergency department. Irrigation, reduction, nail bed repair, and laceration repair may be performed by the emergency physician. If the fracture can be reduced and closed well, the patient can follow up in 7 to 10 days. If there is difficulty or instability to the injury after treatment in the ED, then the patient should be seen by a hand specialist within 24 hours. As these are open fractures, antibiotics (i.e., cephalexin 50 mg/kg/day divided q6 hours for 7–10 days) should be initiated. For repair of Seymour fracture injuries, it is important to save the fingernail, if possible, by carefully trimming a small amount of the proximal nail plate that is exposed and inserting it back underneath the eponychial fold with a mattress suture. With this, an acceptable reduction of the Salter-Harris fracture is obtained. One should avoid overdissection of nail bed from the nail plate as this may cause further damage. Repair of the nail bed with 6-0 or 7-0 chromic absorbable suture is done when the nail bed injury is visible. Careful reduction, nail bed repair, and fixation of the distal phalanx in slight hyperextension have been shown to improve outcomes and reduce the incidence of nail growth disturbance, growth plate damage, and long-term loss of flexor tendon function (Fig. 42.24 and 42.25).

Middle Phalanx Fractures

Clinical Features

Middle phalanx fractures are classified based on location, deformity, and stability. They may involve the head, neck, shaft, or base.

Fig. 42.23 Thumb stack splint immobilizing the IP joint as seen in (A) AP and (B) lateral views. (Courtesy of Mary Jo Wagner, MD, FACEP; Central Michigan University COM.)

Fig. 42.24 Seymour fracture presentation. (A) Open fracture of the distal phalanx of the ring finger together with nail avulsion. (B) X-ray demonstrating open juxta-epiphyseal fracture of the distal phalanx. (Metcalfe D, Aquilina AL, Hedley HM. Prophylactic antibiotics in open distal phalanx fractures: systematic review and meta-analysis. *J Hand Surg (European vol)*. 2016;41(4):423-430.)

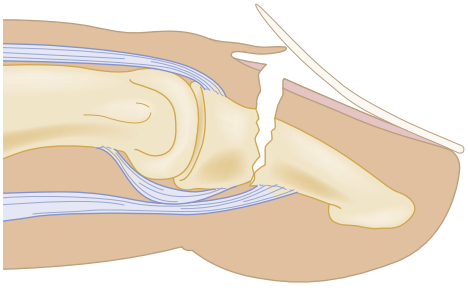

Fig. 42.25 Seymour fracture illustration demonstrating a lateral view with open avulsion fracture at the distal phalanx base and nail bed avulsion. (Modified from: Metcalfe D, Aquilina AL, Hedley HM. Prophylactic antibiotics in open distal phalanx fractures: systematic review and meta-analysis. *J Hand Surg (European vol)*. 2016;41(4):423-430.)

Deformity and displacement are dependent on the location of the fracture and result from the dynamic forces of the flexor and extensor tendons involved. The flexor digitorum superficialis divides and inserts along the volar surface while the extensor tendon (central slip) inserts at the proximal base (Fig. 42.26). As a result, fractures of the distal middle phalanx usually result in volar angulation, while proximal fractures near the base tend to result in dorsal angulation[9] (Fig. 42.27).

Fractures at the base include intra-articular types which appear on x-ray as avulsion fractures and are classified based on their location: *condylar, volar,* and *dorsal*. There is also the possibility of complete disruption of the articular surface (*pilon fracture*) in which multiple tendons are involved with instability in all directions.

Differential Diagnoses

One should consider volar plate, collateral ligament, central slip, FDP tendon, and FDS tendon injuries when assessing for a possible fracture. Associated IP joint dislocations or subluxations should also be considered.

Diagnostic Testing

Standard x-ray imaging of the digit is sufficient to identify most clinically significant fractures.

Management

Stable non-displaced transverse fractures can be treated with dynamic splinting (Fig. 42.28) and by buddy taping to an adjacent uninjured digit. Dynamic splinting offers the advantage of providing some degree of stability while preventing joint stiffness. Immobilization should be for 2 to 3 weeks followed by range-of-motion exercises.

Transverse shaft fractures that are angulated, shortened, or have rotational deformity require surgical referral. Displaced transverse fractures typically have volar angulation and require closed reduction which can be performed with longitudinal traction followed by flexion of the distal fragment to align with the proximal fragment. Oblique, spiral, and comminuted fractures, in addition to unstable transverse

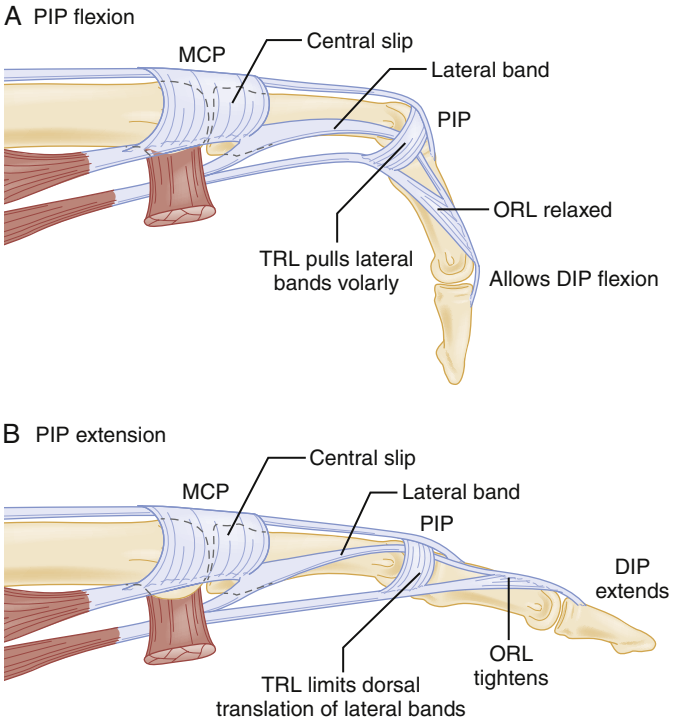

Fig. 42.26 (A) With PIP flexion, the transverse retinacular ligament (TRL) pulls the lateral bands into the volar position, while the oblique retinacular ligament (ORL) relaxes and helps coordinate DIP flexion. (B) With the PIP in extension, the TRL prevents PIP hyperextension by limiting the dorsal displacement of the lateral bands while the ORL tightens (permitting coordinated DIP extension). (From: Elzinga K, Chung KC. managing swan neck and boutonniere deformities. *Clin Plast Surg.* 2019;46(3):329-337.)

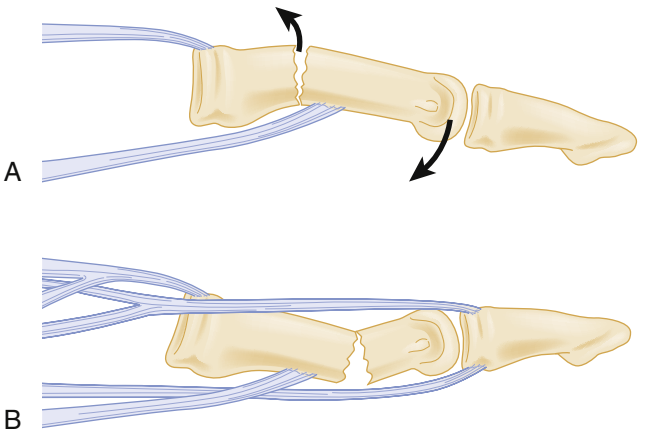

Fig. 42.27 Illustration of deforming forces acting on middle phalanx fractures (A) Transverse fractures proximal to the FDS insertion angulate dorsally. (B) Fractures distal to the FDS insertion angulate in the volar direction. (From: Capo JT, Hastings H II. Metacarpal and phalangeal fractures in athletes. *Clin Sports Med.* 1998;17(3):508. Fig. 15.)

fractures, should be immobilized to the level of the wrist with an ulnar or radial gutter splint to eliminate deforming tendon forces.

Fractures of the base that include 50% or greater of the articular surface or fractures requiring greater than 30 degrees of flexion to maintain reduction are almost always unstable and require surgical management.[12] Non-displaced stable fractures involving 20% or less of the articular surface may be managed by extension splinting.

Fig. 42.28 Dynamic splint demonstrated in a patient. (Hays PL, Rozental TD. Rehabilitative strategies following hand fractures. *Hand Clin.* 2013;29(4):585-600. Fig. 7.)

Proximal Phalanx Fractures

Clinical Features

Fractures at the proximal phalanx may result from a direct blow, forcible hyperextension, or rotational forces and are classified based on location: *head*, *neck*, *shaft*, or *base*. Fractures of the head that are condylar or involve displacement are considered unstable. Similar to middle phalanx fractures, fractures at the shaft are prone to opposing tendon forces. Displaced fractures tend to have a visible apex volar deformity and involve the proximal fragment in flexion (interossei) and the distal fragment in extension (central slip)[9] (Fig. 42.29).

Differential Diagnoses

In addition to fractures, other injuries around the proximal phalanx should be considered including injuries to the volar plate, collateral ligaments, extensor mechanism, FDP tendon, and FDS tendon. For proximal injuries, the MCP joint should be assessed for evidence of clenched fist ("fight bite") injuries, trigger finger, and dislocations or subluxations of the MCP joint.

Diagnostic Testing

Standard x-ray imaging is sufficient to identify most proximal phalanx fractures.

Management

Non-displaced transverse fractures, and other stable fractures of the proximal phalanx, may be managed nonoperatively by splinting.[13] Splinting should be performed with a dorsal aluminum padded splint extending from the metacarpal to the middle phalanx with the MCP joint at 70 to 90 degrees of flexion and the PIP joint at 30 degrees of flexion. Displaced fractures should be reduced and splinted. Similar to stable non-displaced fractures, a dorsal splint should be placed with the MCP and PIP in slight flexion. Further stabilization at the wrist with a radial or ulnar gutter splint should be added. Oblique, spiral, angulated, and unstable intra-articular fractures should be splinted similarly, though they also require outpatient follow-up with a hand specialist for surgical repair to be performed within one week.

Unicondylar or bicondylar fractures of the head of the proximal phalanx are considered unstable even if nondisplaced. These types of fractures often require surgical management as displacement often occurs with splinting alone. The patient should have urgent outpatient follow-up with a hand specialist so that surgical fixation could occur within one week.

Fig. 42.29 (A) AP and (B) lateral x-rays of proximal phalanx fracture of the fifth finger, resulting in the typical angulation from apex volar deforming forces. (C) Illustration of the deforming forces acting on proximal phalanx fractures with the central slip pulling the distal fracture fragment into extension. (Cotterell IH, Richard MJ. Metacarpal and phalangeal fractures in athletes. *Clin Sports Med.* 2015;34:69-98.)

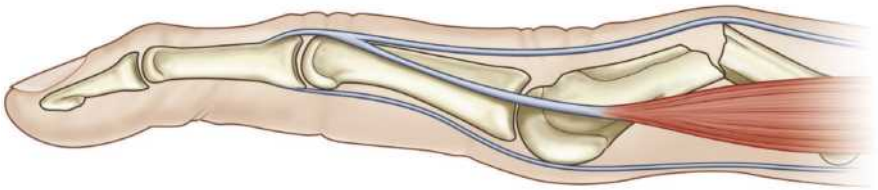

Fig. 42.30 Typical metacarpal fracture apex dorsal angulation occurring secondary to the location of the interosseous muscles. (Khouri JS, Hammert, WC. Hand fractures and joint injuries. *Plast Surg.* 2018;6:146-169.)

Metacarpal Fractures

Clinical Features

Patients with metacarpal fractures generally present after a direct blow to the dorsum of the hand or an axial loading force over the metacarpal head. The hand should be thoroughly examined for tendon integrity, deformity, and any evidence of open fracture or fight bite. Like phalanx fractures, metacarpal fractures are classified based on location: head, neck, shaft, and base.

Fractures of the metacarpal head are rare and usually occur secondary to a direct or crushing force. They often are intra-articular and accompanied by an extensor tendon injury.

The neck is the most common location for metacarpal fractures because the bone is weakest at this location. These fractures commonly occur secondary to punching a firm object, hence the term *boxer's fracture* given to fractures at the neck of the fifth metacarpal. Displacement is usually apex dorsal angulation owing to forces from the extrinsic flexor tendons which flex the distal fragment (Fig. 42.30). The carpometacarpal (CMC) joints inherently have greater stability and less range of motion at digits 2 and 3 relative to digits 4 and 5. Greater range of motion at the ulnar aspect of the hand, especially in flexion, enables a powerful grip. It also accounts for a greater degree of tolerable displacement in the ulnar metacarpals because the deformity can be more easily compensated (Table 42.3).

TABLE 42.3 Metacarpal Fracture Allowable Angulation

Digit	Acceptable Shaft Angulation (Degrees)	Acceptable Neck Angulation (Degrees)
II and III	10	10-15
IV	20	35
V	20–30	45[a]

[a]Various sources have quoted acceptable angulation of up to 70 degrees for the fifth digit

Metacarpal shaft fractures occur secondary to direct impact or an axial loading force. Like metacarpal neck fractures, they also present with apex dorsal angulation though they are comparatively less tolerant to angulation because more proximal fractures present with greater deformity given the same degree of angulation. While angulation is easily assessed from x-ray imaging, rotation is assessed more easily from physical exam. Malrotation will be noted with overlap of the digits when they are held in flexion (cascade sign) and are often associated with oblique or spiral fractures. As little at 10 degrees of malrotation in the fifth metacarpal may cause visible deformity. If there are adjacent metacarpal fractures, there is high risk for shortening and instability

due to loss of intermetacarpal ligament stabilization. Shortening is not well tolerated and may result in *pseudoclawing*, an extensor lag secondary to compensatory hyperextension at the MCP leading to inadequate extension at the PIP. Greater than 5 mm of shortening in any metacarpal is not acceptable because this results in an extensor lag that is no longer compensated by the MCP joint's natural hyperextension capability.

Fractures of the metacarpal base occur secondary to an axial loading force with the wrist in flexion. These fractures are often intra-articular and associated with CMC joint dislocations, which can be missed on standard x-ray imaging.

Intra-articular fractures at the base of the fifth metacarpal are also known as *reverse Bennet* fractures. The radial aspect of the fifth metacarpal base is stabilized by the intermetacarpal ligament while tension from the extensor carpi ulnaris causes ulnar and proximal displacement of the remainder of the base. The hypothenar muscles displace the shaft radially.

Differential Diagnosis

In addition to fractures, other injuries around the metacarpal should be considered including CMC joint dislocation, clenched fist injury, extensor mechanism injury, and FDP or FDS tendon injury. Compartment syndrome should also be considered if there is a crush injury mechanism, excessive swelling of the hand, pain out of proportion, or neurovascular compromise.

Diagnostic Imaging

Because CMC dislocations with metacarpal base fractures are often missed, in addition to standard hand x-rays, a 30-degree pronated lateral view for the index and middle fingers should be obtained for higher diagnostic sensitivity. Similarly, a supinated lateral view for the ring and little fingers should be performed. For metacarpal neck and shaft fractures, special attention should be paid to the degree of angulation to determine if reduction is needed (see Table 42.3).

Management

Because of the intra-articular predilection for metacarpal head fractures, patients should be referred to a hand specialist because they will likely require open reduction and internal fixation (ORIF). Special attention should be paid to the soft tissue surrounding the metacarpal head, as puncture wounds, lacerations, and particularly fight bite wounds require emergency consultation for surgical débridement and irrigation. Patients with closed fractures without signs of open soft tissue injury may be splinted in neutral position and referred for outpatient hand specialist follow-up within one week. The traditional method for splinting metacarpal fractures is in neutral position with the wrist at 20 to 30 degrees extension, MCP at 70 to 90 degrees flexion, and the PIP and DIP kept in extension.

Non-displaced or minimally angulated fractures of the metacarpal neck (below threshold for reduction) can be managed conservatively with immobilization for 3 to 4 weeks (see Table 42.2). These injuries that do not exceed the threshold are unlikely to cause functional impairment, so do not require anatomical reduction in the ED. The traditional recommendation is to immobilize the metacarpal in neutral position with a radial (digits 2 and 3) or ulnar gutter splint (digits 4 and 5). However, recent studies suggest that less immobilization may not be harmful and may actually yield benefits. A recent prospective study in patients with boxer's fractures found similar long-term clinical and radiologic results in patients treated with functional metacarpal splinting (FMS) compared to ulnar gutter splinting, though there was actually earlier return of grip strength at 2 months in the FMS group.[14] Similarly, a recent meta-analysis found that immobilization with a splint or cast was not superior to soft wrap in most cases.[15] Yet, given the importance of stability following an acute fracture, we recommend standard immobilization at least as a temporary measure if the patient is able to follow up with a hand specialist within one week.

Acute metacarpal neck fractures that exceed the threshold of acceptable angulation require reduction. This can be attempted in the emergency department via the Jahss manipulation technique for closed reduction. Using this method, the MCP joint and PIP joints are flexed to 90 degrees, upper (dorsal) pressure is applied through the proximal phalanx, and downward pressure is applied over the proximal metacarpal shaft (Fig. 42.31).

Metacarpal shaft fractures are managed similarly to metacarpal neck fractures, though with less acceptable angulation. The Jahss technique may be used for closed reduction. Patients with greater than 5

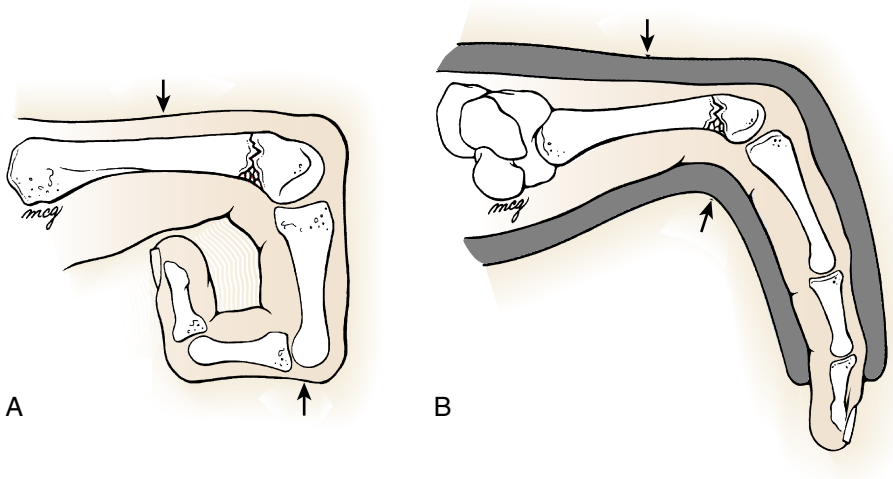

Fig. 42.31 Reduction of metacarpal fracture using the Jahss maneuver. (A) Arrows indicate direction of pressure for fracture reduction. (B) Fingers are held in intrinsic-plus (safe) position, after reduction, in ulnar gutter splint with molding pressure indicated by arrows. (Day CS. Fractures of the metacarpals and phalanges. In: Wolfe SW, Hitchkiss RN, Pederson WC, et al., eds. *Green's Operative Hand Surgery*. Philadelphia: Elsevier; 2017:231-277.)

mm of shortening, clinically significant rotation, and unstable fracture types should have prompt referral to a hand specialist for possible ORIF.

Intra-articular fractures at the base generally require surgical fixation to prevent posttraumatic arthritis.

Thumb Fractures

Clinical Features

Due to the highly mobile nature of the thumb, there is a lower frequency of fractures compared to the other phalanges. Similar to other distal phalanges, mallet injuries of the thumb may occur though they are rare and occur secondary to avulsion of the extensor pollicis longus tendon at its distal insertion point. Mallet injuries of the thumb, unlike mallet injuries of the fingers, are less likely to result in subluxation.[16] With a *skier's* or *gamekeeper's thumb*, there may be an associated avulsion fracture at the base of the proximal phalanx.

Most fractures of the thumb metacarpal occur at the base. There are strong ligamentous forces limiting abduction of the thumb (anterior oblique and first inter-metacarpal ligaments). An axial loading force on the partially flexed metacarpal creates an avulsion type fracture. The ligamentous forces are so strong that a fracture at the metacarpal base is actually far more common than a CMC joint dislocation. Two unique fractures at the metacarpal base are the Bennett fracture and the Rolando fracture.

The *Bennett fracture* is an oblique intra-articular fracture accompanied by a dislocation at the metacarpal base (Fig. 42.32A). The anterior oblique ligament holds the volar-ulnar base fragment in place while the remaining articular surface and shaft are displaced proximally and adducted by the abductor pollicis longus and adductor pollicis respectively.

The *Rolando fracture* is a comminuted complete intra-articular fracture at the metacarpal base that is T-shaped or Y-shaped on x-ray (see Fig. 42.32B).

Differential Diagnoses

When considering fractures of the thumb, other injuries including mallet injury, volar plate injury, collateral ligament injury, IP or CMC joint dislocation or subluxation, extensor pollicis longus tendon injury, or UCL or RCL injury should be considered.

Diagnostic Testing

Special x-ray views are necessary when evaluating potential thumb fractures or dislocations because the thumb is situated outside of the hand plane. One such view is the Robert view where the hand is hyperpronated with the dorsum of the thumb on the radiograph plate, creating a true AP view.

Management

There are no major differences in treatment for thumb phalangeal fractures compared to digits 2 through 5, though proximal fractures should be immobilized with a thumb spica splint for 4 weeks. Due to instability and associated deforming forces, both Bennett and Rolando fractures require urgent referral to a hand specialist for further management.

Joint Injuries

Clinical Features

The interphalangeal and metacarpophalangeal joints of the hand are stabilized by multiple tendons and ligaments. In particular, the collateral ligaments protect against radial and ulnar deviation of the IP joints. The volar plates are fibro-ligamentous structures that protect the joint capsule against hyperextension.

Mechanism predicts the injury. Forced hyperextension of the respective joint may result in volar plate tears and dorsal dislocations. Lateral forces may result in collateral ligament injury and lateral dislocation. Axial loading forces are responsible for intra-articular fractures. Injuries to ligaments generally accompany dislocations and range from small tears (grade I) to complete tears (grade III).

Inspection may show deformity and swelling. Active range of motion is the best test for joint functioning and stability. Sufficient local analgesia (i.e., digital block) is necessary for accuracy of this exam. Passive range of motion and ligament stressing are useful in identifying the location and severity of injuries, though this should be done gently to prevent further ligamentous injury.

Differential Diagnoses

The differential diagnoses for joint injuries are extensive and include associated fractures, dislocations, subluxations, tendon injuries, and ligamentous injuries (see Table 42.2).

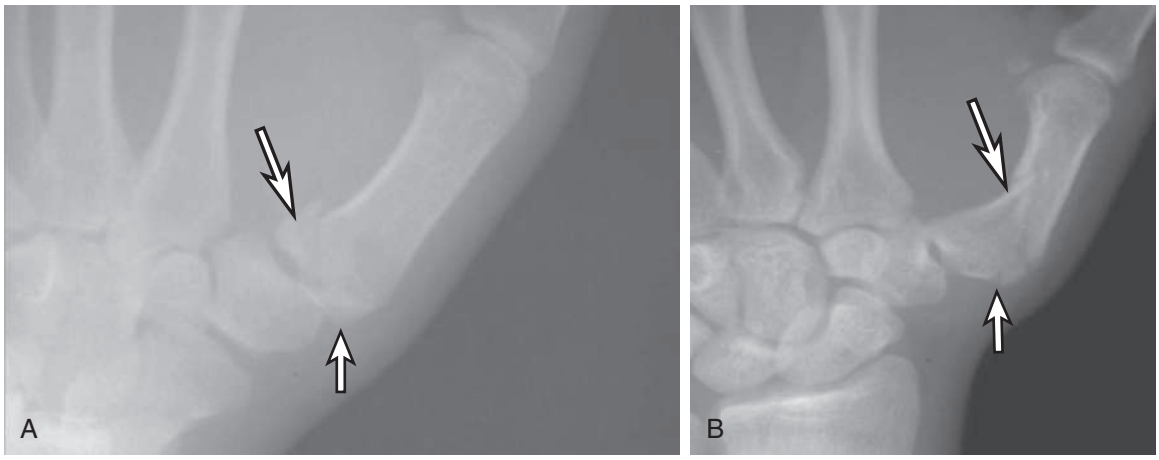

Fig. 42.32 Thumb metacarpal intra-articular fractures. (A) AP radiograph demonstrating a Bennett fracture. The long arrow points to the fracture site and the short arrow points to the fracture fragment that has minimal radial subluxation. Note the minimal subluxation. (B) AP view of a comminuted Rolando fracture. (Scanelli J, Deal N, Chhabra B, Sanders T. Hand fractures. In: Miller MD, Sanders TG, eds. *Presentation, Imaging and Treatment of Common Musculoskeletal Conditions*. Philadelphia: Elsevier Saunders; 2012:258-267. Fig 58-7.)

Diagnostic Testing

Standard x-ray imaging should include true lateral films of the affected digit to accurately identify dislocations and subtle subluxations. The classic "V sign" results from dorsal widening of the joint when there is minimal subluxation (Fig. 42.33).

Fig. 42.33 Typical "V sign" seen on lateral view where there is a fracture at the volar base of the middle phalanx and dorsal subluxation of the PIP joint. (Chauhan A, Sikora-Klak J, Abrams R. Dynamic homemade digital external fixators for proximal interphalangeal joint injuries. *J Hand Surg.* 2018;43(9):875. Fig 5.)

Management

Most dislocations are amenable to closed reduction in the emergency department. Reduction should be performed immediately after identifying the injury because delays are associated with lower success rates and higher rates of neurovascular compromise. Following adequate analgesia, gentle longitudinal traction should be applied to the affected joint followed by hyperextension (if dislocation is dorsal) or hyperflexion (with volar dislocations) along with pressure at the base of the dislocated phalanx in the proper direction for realignment (Fig. 42.34). Active range of motion should be tested following reduction and a post-reduction film should be obtained.

Indications for emergent surgical management include neurovascular compromise after closed reduction, inability to reduce (often due to obstruction from soft tissue, volar plate, or osteochondral fragments), and contaminated open dislocations requiring extensive irrigation. Additionally, dislocations that remain unstable after reduction and those accompanied by displaced or sizeable intra-articular fractures require surgical intervention. Surgical referral for open reduction is also indicated in chronic dislocations, or those present for greater than 3 weeks.

Splinting principles are designed to prevent residual joint and flexion stiffness, which are common complications of immobilization. Uninvolved joints should have only minimal immobilization, if any. The MCP joint should be immobilized at 60 to 70 degrees flexion, whereas the IP joints should be flexed approximately 30 degrees. One

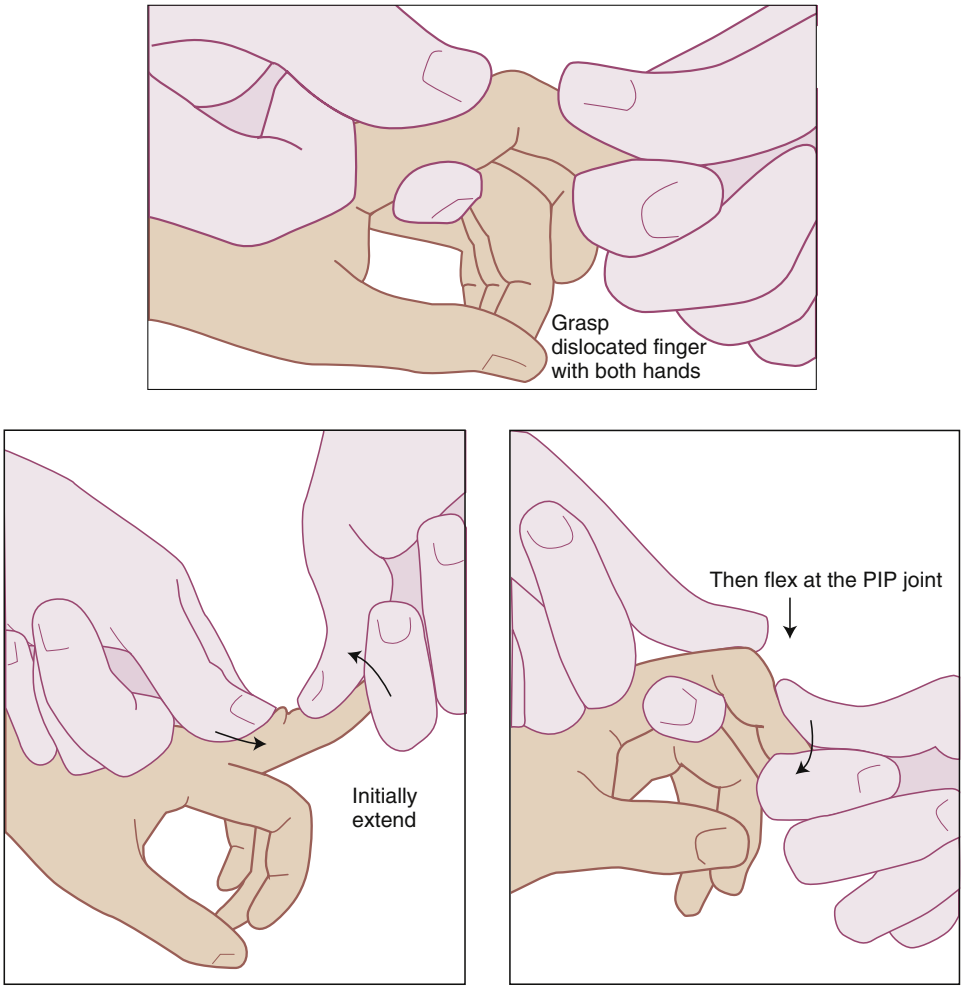

Fig. 42.34 Reduction technique for finger dislocation (PIP joint). (Buttaravoli P, Leffler, Stephen M. *Minor Emergencies*, ed 3. Philadelphia: Elsevier Saunders; 2012:419-422. Fig 109-1.)

exception to this principle is volar dislocations of the PIP which must initially be splinted in extension to avoid a boutonnière deformity. Simple sprains may be treated with buddy taping or dynamic splinting. Complete ligament tears require prolonged immobilization and surgical repair.

Interphalangeal Joint Injuries

Clinical Features

The distal interphalangeal joint is highly stable, and dislocations are rare. When dislocations do occur, they are almost always dorsal. Radiographs should be analyzed for dislocations complicated with mallet avulsion fractures. Uncomplicated dislocations of the DIP are generally stable after closed reduction, since the flexor and extensor tendons are attached to the distal phalanx.

The PIP joint is the most frequently injured joint in the hand. The collateral ligaments and accessory ligaments merge into the volar plate which is further anchored by the collateral ligaments proximally (see Fig. 42.9). This creates a three-dimensional hinge. Multiple supporting structures must be disrupted to cause joint instability. The PIP joint may be dislocated in any of three directions—dorsal, volar, or lateral.

Dorsal dislocations of the PIP joint are most common and frequently are associated with ball-handling sports. The mechanism is secondary to axial load and forced hyperextension resulting in rupture of the volar plate and tearing of collateral ligaments. This creates an easily recognizable bayonet-like dorsal displacement deformity seen on inspection (Fig. 42.35). Dorsal dislocations accompanied by fractures involving greater than one-third of the articular surface are considered unstable, because they are associated with greater detachment of the collateral ligament insertion at the middle phalanx.

Volar plate tears may also occur secondary to hyperextension and may be present without evidence of dislocation at the PIP joint. A volar horizontal skin laceration over the joint is often visible along with a hyperextension deformity. Pain and locking may be evident on active flexion of the PIP joint.

Volar dislocations of the PIP joint are rare and are frequently missed. Dislocations occur with disruption of the central slip. The head of the proximal phalanx ruptures through the retinacular fibers between the lateral band and central tendon (Fig. 42.36).

Lateral dislocations of the PIP joint occur from a lateral force with the PIP joint in extension, resulting in rupture of a collateral ligament. The patient may present with radial or ulnar deviation at the PIP joint, though these dislocations frequently reduce spontaneously. Collateral ligament integrity should be tested by providing lateral stress on the

Fig. 42.35 Dorsal dislocation of the PIP joint on radiograph. (Courtesy of Timothy Kaufman, MD; Central Michigan University COM)

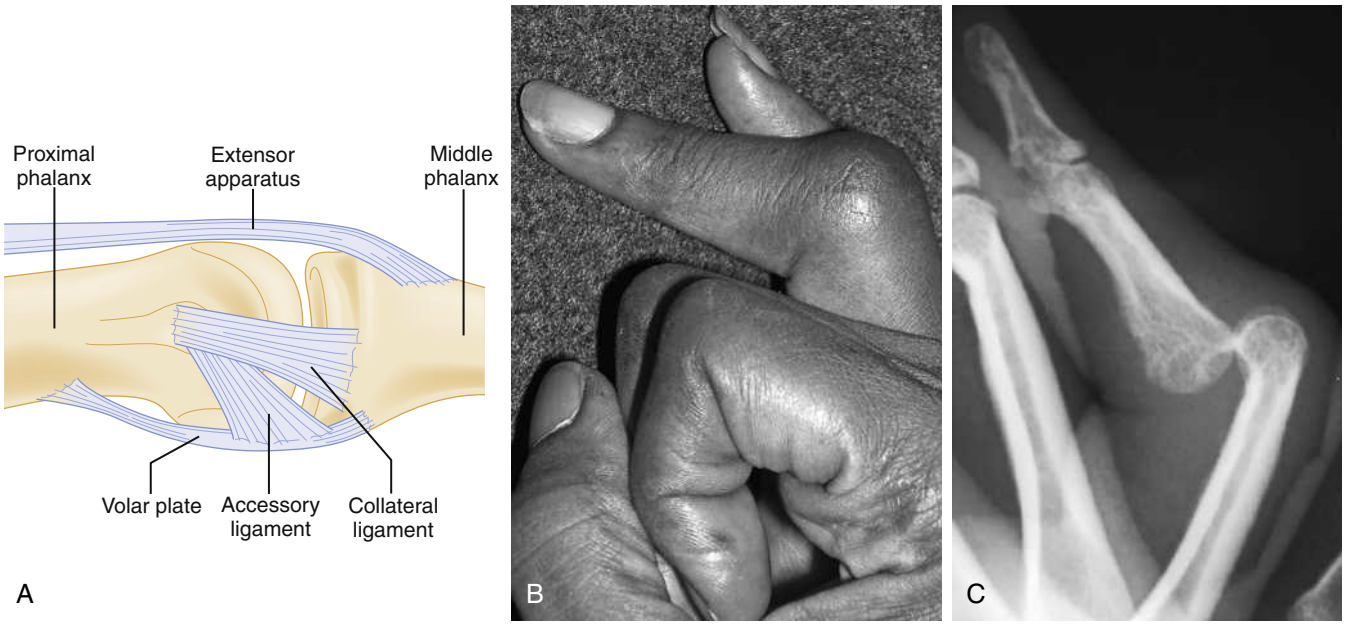

Fig. 42.36 (A) Key stabilizing forces surrounding the PIP joint. (B and C) Examination and radiograph of patient with volar PIP dislocation. (Bindra RR, Foster BJ. Management of proximal interphalangeal joint dislocations in athletes. *Hand Clinics*. 2009;25(3):423-435. Fig. 1 and 5.)

radial and ulnar sides of the joint. Ability to flex and extend the finger at the PIP joint is usually preserved.

Differential Diagnoses

When suspecting an interphalangeal joint injury, one must also consider associated fractures including open, closed, and avulsion fractures. Tearing of the volar plate, central slip, and collateral ligaments commonly accompanies dislocations and subluxations.

Diagnostic Testing

A standard 3-view x-ray of the affected digit is sufficient to identify subluxations and dislocations of the IP joints.

Management

Uncomplicated DIP joint dislocations that are functionally stable after closed reduction, as tested with active range of motion, should be immobilized for 2 to 3 weeks. Immobilization of reduced dislocations can be accomplished with an aluminum padded splint extending from the dorsal surface of the middle phalanx to the distal phalanx with the DIP slightly flexed to 30 degrees.

Closed reduction should be attempted for uncomplicated dorsal dislocations of the PIP joint. Functionally stable PIP dislocations and those not accompanied by intra-articular fractures can be managed with splinting for 2 weeks. Dorsal dislocations are splinted with the PIP in slight flexion (30 degrees). Fracture-dislocations of the PIP should have hand specialist referral following closed reduction, ideally within 3 days of presentation.

Patients with suspected isolated volar plate tears at the PIP joint should similarly be splinted in 30 degrees of flexion for at least 3 weeks.[17]

Reduction of volar dislocations can be challenging given obstruction from the lateral band. These dislocations often require open reduction by a hand specialist. We recommend discussing the case with a hand specialist prior to attempting closed reduction because many advocate for open reduction with central slip repair in all volar dislocations. If closed reduction is performed in the emergency department, the central slip integrity must be examined afterward. Inability to extend the PIP against resistance indicates significant central slip injury and the joint must be splinted appropriately in full extension (4 to 6 weeks) to avoid formation of a boutonnière deformity over time.

Lateral dislocations of the PIP that are deemed stable after reduction should be splinted with the PIP immobilized at 30 degrees of flexion for 2 to 3 weeks, though some advocate for simple buddy or dynamic taping. Joints that are unstable or associated with an avulsion fracture, require immobilization with prompt surgical referral, ideally within 3 days of presentation.

Metacarpophalangeal Joint Injuries

Clinical Features

The metacarpophalangeal joint should be taut in flexion, though it naturally has some laxity in extension allowing some lateral movement. Strong collateral ligaments, the transverse metacarpal ligament (volar plate), and intrinsic musculature provide significant dynamic stability to lateral forces. Thus, injuries to the lateral structures are rare. Injury to the collateral ligament should be suspected if there is pain or laxity at the MCP joint in extension when radial or ulnar stressing is applied.

In contrast, the shape of the MCP joint and lack of the collateral ligaments result in less stability for resisting hyperextension, responsible for dorsal dislocations of the MCP joint and hyperextension injuries.

With dorsal dislocations of the MCP joint, there is generally visible deformity with dorsal displacement of the proximal phalanx, hyperextension of the MCP joint, and slight flexion of the interphalangeal joints. There are two types of dorsal dislocations: simple and complex.

Simple dislocations of the MCP joint are technically subluxations because the articular surfaces remain in partial contact. Yet, examination may show significant deformity with the proximal phalanx locked in greater than 60 degrees of hyperextension.

Complex dislocations of the MCP joint occur when the metacarpal head ruptures through the volar plate, which becomes entrapped within the joint space. Examination may show less hyperextension compared to simple dislocations. Classically, there may be dimpling of the skin at the proximal palmar crease.

Differential Diagnoses

When assessing injuries at the MCP joint, also consider dislocations, subluxations, dorsal lacerations indicating fight bite injuries, associated metacarpal head and neck fractures, tears to the volar plate and collateral ligaments, trigger finger, and FDP or FDS tendon injuries.

Diagnostic Testing

Standard 3-view hand x-rays are sufficient in identifying most dislocations and subluxations. However, findings may be subtle for significant injuries. For example, complex dislocations of the MCP joint may show only mild widening of the joint space, sometimes with presence of a sesamoid. Physical examination should be relied upon to assess for ligamentous injury; MRI is rarely used for these types of injuries in the emergency setting.

Management

Treatment for collateral ligament injury at the MCP is splinting the joint in neutral position for 3 weeks. Unstable injuries and those with intra-articular fractures require surgical referral.

Simple dislocations of the MCP joint may be treated by closed reduction. With the wrist and MCP joint held in flexion, dorsal pressure over the proximal phalanx should be applied in a volar and distal direction. Special care should be taken to avoid longitudinal traction on the joint as this may entrap the volar plate into the joint, creating a complex dislocation. Following reduction, the MCP joint should be immobilized at 60 to 70 degrees flexion for 1 week followed by buddy or dynamic taping. Complex dislocations, due to entrapment of the volar plate, are irreducible by closed methods and require emergent surgical consultation for open reduction.

Carpometacarpal Joint Injuries

Clinical Features

The carpometacarpal joint is highly stable and requires significant force for injury. Dislocations are rare, though are frequently missed. Posterior dislocations (85%) are more common than volar dislocation.[18] The fifth CMC joint is most frequently involved, often occurring secondary to closed fist injury. Dislocations of the fifth CMC (metacarpohamate) joint may result in ulnar nerve injury resulting in claw-hand deformity in severe cases**.** Thorough ulnar nerve testing is required for fifth CMC joint dislocations. Examination often reveals no gross deformity, though there is usually significant dorsal swelling at the base of the metacarpal.

Differential Diagnoses

One should consider associated fractures of the carpal bones and metacarpal base, tendon, and ligamentous injuries when assessing injuries at the CMC joint.

Diagnostic Testing

All three radiographs of the hand—PA, lateral, and oblique—should be obtained if this injury is a concern. Special attention should be made to the lateral and oblique radiographs to identify CMC joint dislocations as well as any associated metacarpal fractures which frequently coexist. Due to the dorsal positioning of the dislocation, a cursory review of the PA film might lead to missing the diagnosis. The lateral film has significant bony overlap of the heads of the metatarsals so may also conceal a fracture or dislocation.

Management

Reduction of CMC joint dislocations should be performed in the emergency department, though hand specialist referral within 24 hours, where possible, is recommended because reduction is difficult to maintain. Immobilization alone is often inadequate, and surgical intervention is often necessary.

Thumb Dislocations and Ligamentous Injuries

Clinical Features

Interphalangeal joint dislocations of the thumb, similar to DIP joints of the other phalanges, are usually dorsal and occur secondary to hyperextension injury. The MCP joint of the thumb is the most mobile joint in the hand and is oriented obliquely, making it a common site of injury from radial forces. Dorsal dislocation may occur from volar plate disruption, while lateral dislocation may occur from a collateral ligament tear. The mechanism and morphology of the deformity is similar to that of other phalanges. Injuries to the collateral ligaments of the thumb are common, particularly ulnar collateral ligament injuries (ten times more common than radial).[19]

Ulnar collateral ligament injuries usually occur secondary to sudden radial deviation of the thumb while it is abducted. Classically, this occurs in skiers falling on an abducted thumb while holding onto a pole (skier's thumb). Less commonly, injuries to the UCL may occur chronically from repetitive valgus stress at the MCP joint. Radial collateral ligament injuries occur from sudden ulnar deviation of the thumb toward the fingers and palm.

With acute injuries of the collateral ligaments, there is usually pain and swelling at the MCP joint of the thumb. In UCL injuries, pain on the ulnar side of the thumb with radial stress indicates an injury. The classical round palpable mass is rarely noted along the ulnar side of the metacarpal neck with a complete tear of the UCL (Stener lesion). Stability of the MCP joint should be tested in full extension and 30 degrees flexion, assessing for UCL and RCL integrity. The examiner should stabilize the metacarpal with one hand and passively stress the proximal phalanx in the radial and ulnar direction with the other hand. If there is significant laxity at the MCP with radial deviation, assume there is a tear to the UCL. Likewise, if there is laxity with ulnar deviation, assume there is a tear to the RCL. RCL tears are much less common than UCL tears of the thumb. The thumb CMC joint is stabilized anteriorly and posteriorly by respective oblique ligaments. Isolated dislocations are rare, though associated fractures (e.g., Bennet fractures) are common.

Differential Diagnoses

Associated intra-articular fractures, volar plate, collateral ligament, extensor pollicis longus tendon, and abductor pollicis longus injuries should be considered.

Diagnostic Testing

X-rays should be performed in patients with suspected UCL or RCL injuries, looking for associated subluxation or avulsion fracture. A stress view is particularly useful. Greater than 30 degrees of lateral laxity compared to the opposite thumb at the MCP joint indicates complete disruption of the associated collateral ligament. As with other hand injuries, nonemergent MRI has been found to be reliable in identifying these types of tendinous and ligamentous injuries.[20]

Management

For IP joint dislocations, closed reduction should be performed followed by active range-of-motion testing. Most are stable after reduction, though integrity of the joint and flexor pollicis longus tendon should be examined. The IP joint should be immobilized in 30 degrees of flexion for 3 weeks. Irreducible dislocations and open dislocations require surgical management.

The same technique for closed reduction of other MCP joints should be used for the thumb, avoiding longitudinal traction and likewise avoiding entrapment of the volar plate. Stability, particularly of the collateral ligaments, should be assessed following reduction. Stable dislocations should be immobilized with the MCP joint in slight flexion for 4 to 6 weeks.

For collateral ligament injuries, most stable grade I and II injuries (less than 30 degrees of laxity) may be managed conservatively with immobilization of the MCP joint via thumb spica splinting for 4 weeks. Complete tears (grade III) should likewise be immobilized in a thumb spica splint, but also require prompt referral for surgical management.

If there is pain and tenderness at the CMC joint of the thumb, ligamentous injury or carpal injury should be assumed and thumb spica splinting should be performed. Dislocations should be reduced, though they are often unstable and require follow-up with a hand specialist.

Tendon Injuries

Lacerations, puncture wounds, forced extension or flexion, and crush injuries may result in a tendon injury ranging from strain to complete disruption. After a thorough neurovascular exam and identifying the point of maximal tenderness, a digital block should be considered prior to assessment of tendon integrity. Each digit should be examined individually to avoid a masking effect from adjacent tendons. Motor function should be assessed by having the patient flex and extend the fingers against resistance. Pain with preserved strength on active range of motion may indicate a partial tear, while weakness may indicate complete tendon disruption. X-rays should be obtained to assess for avulsion fractures which commonly occur with tendon disruptions.

Extensor Tendon Injuries

Clinical Features

The extensor mechanism includes muscles that originate proximal to the wrist whose tendons insert on the extensor surface of the fingers (extrinsic extensors). The extensor digitorum communis (EDC, digits II–V) connects with the lateral bands to form the central slip. The central slip inserts at the base of the middle phalanx and functions to extend the phalanx at the PIP joint. The lateral bands themselves arise from the intrinsic muscles (lumbricals and interossei) (see Fig. 42.9).

The extensor mechanism is divided into 9 zones. The classification is relevant to specific injuries and management of those injuries. The even numbered zones are located over bones while the odd numbered zones are located over joints. Zone VIII and IX are located proximal to the wrist (Fig. 42.37). The thumb has its own classification: TI for the interphalangeal joint, TII for the proximal phalanx, TIII for the MCP joint, TIV for the metacarpal, and TV for the carpus.

Thorough inspection should focus on evidence of lacerations, open wounds, and swelling. The extensor tendons should be palpated for tenderness, laxity, or step-off. This is best accomplished with the palm

down on a table. The most common extensor tendon injury is mallet finger in zone I.

Zone I Extensor Injuries. This zone includes the distal phalanx and DIP joint. Terminal tendon disruption from sudden flexion of the extended DIP joint results in the common mallet injury (Fig. 42.38). This injury is common in ball-handling sports from a jammed finger.

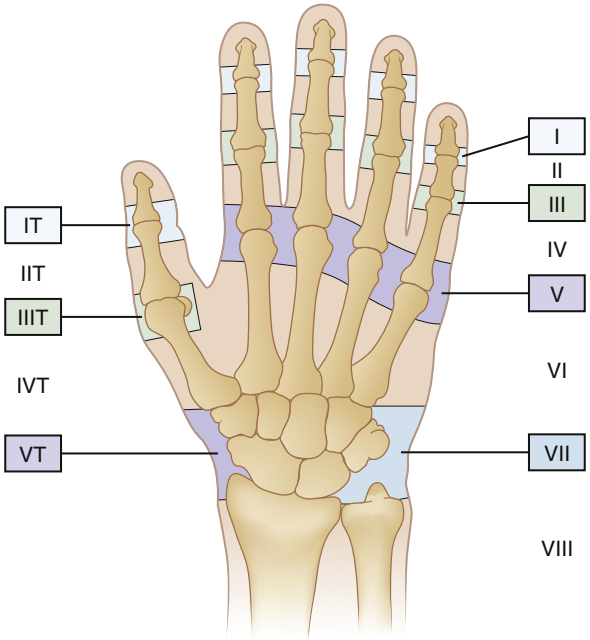

Fig. 42.37 Extensor tendon injury zones of the hand. Zones VIII and IX are located proximal to the wrist. (Rosenthal EA, Elhassan BT. The extensor tendons: evaluation and surgical management. In: Skirven TM, Osterman AL, Fedorczyk JM, Amadio PC. *Rehabilitation of the Hand and Upper Extremity*, ed 6. Philadelphia: Elsevier Mosby; 2011:487-520. Fig. 38-10.)

There is often pain and tenderness over the DIP joint, and extensor lag is associated with complete disruptions. X-rays should be evaluated for associated avulsion fractures, common with this injury.

Zone II Extensor Injuries. Injuries occur over the middle phalanx and are usually due to a laceration. Rarely, a mallet deformity will form from a laceration of the tendon's central and lateral bands.

Zone III Extensor Injuries. Injuries in this zone involve the PIP joint and the central slip. Boutonnière injury (flexion at the PIP joint with hyperextension at the DIP and MCP joints) occurs with central slip disruption (Fig. 42.39). Multiple mechanisms are responsible for these injuries including forced PIP flexion, deep laceration, blunt injury to the dorsum of the PIP joint, or volar PIP joint dislocation.

If there is disruption of the central slip and triangular ligament, there will be inability to extend the finger at the PIP joint. However, if the triangular ligament remains intact, there may be normal motion initially. Because deformities may not form until after the acute phase of injury, there should be a high index of suspicion and a low threshold for splinting.

Integrity of the central slip is best assessed with the *Elson test*. For this test, the PIP is held in maximum passive flexion. The examiner holds resistance against extension at the middle phalanx. If the central slip is intact, when attempted, the patient will not be able to extend the distal phalanx at the DIP due to distal slack at the lateral bands. Conversely, if there is a complete disruption of the central slip, there is increased tone at the DIP joint and there is extension or hyperextension at the PIP joint, indicating a positive test (Fig. 42.40).

The modified Elson test offers direct comparison of the injured to uninjured digit. The patient is asked to hold fingers against each other at the dorsal surface of the middle phalanx with the PIP joint at 90 degrees. The patient then attempts to extend each finger. If there is significant difference in the ability to extend the DIP in one digit compared to the digit in the other hand, assume a central slip injury (see Fig. 42.40).

The examiner should be aware of the *pseudo-boutonnière deformity* where PIP flexion contracture is present though there is no increased

Fig. 42.38 Mallet finger deformity seen clinically with extensor lag and radiographically with an associated avulsion fracture. (Zhang W, Zhang X, Zhao G, Gao S, Yu Z. Pressing fixation of mallet finger fractures with the end of a K-wire. *Injury*. 2016;47(2):377-382. Fig. 3 and 7.)

extensor tone at the DIP (negative Elson test). Thus, the extensor mechanism is actually intact for patients with this deformity.

Zone IV Extensor Injuries. This zone includes injuries over the proximal phalanx. Like in zone II, injuries usually occur from lacerations. The tendon is wide and flat at this location, so most lacerations are partial.

Zone V Extensor Injuries. Injuries at this zone involve the sagittal band at the MCP joint. The most common injury is to the radial sagittal band of the middle finger. The common mechanism is forced flexion or direct blunt force. Swelling and tenderness over the dorsal MCP joint will generally be appreciated on exam. The patient can usually keep the joint in extension, though with active extension from the finger in flexion, there is a snapping relocation of the extensor mechanism. Human bite wounds should be considered with any laceration in this area (i.e., fight bite).

Injuries in zone V are classified based on whether there is no tendon instability (type I), tendon subluxation or snapping (type II), or complete tendon disruption (type III). One specific type of injury is boxer's knuckle. As the name implies, this injury usually occurs from punching an object, resulting in rupture of the sagittal band at the MCP joint.

Zone VI Extensor Injuries. Injuries at this zone occur over the metacarpals, most frequently secondary to lacerations. Complete lacerations are often missed as full extension may remain intact due to juncturae tendinum transmitting extension forces from adjacent tendons.

Zone VII Extensor Injuries. Lacerations over the carpals and extensor retinaculum account for most injuries at this zone, though injuries may also occur with a closed fracture. Wounds should be explored for tendon injury while the patient flexes and extends the fingers.

Differential Diagnoses

Patients with suspected extensor tendon injury often have associated avulsion fractures at the insertion points of the extensor mechanism (e.g., mallet finger). Patients with zone V extensor tendon injuries have a snapping relocation of the extensor mechanism with active extension, which is often mistaken for a trigger finger. With pain and swelling near joint spaces, there may be underlying ligamentous injury, fracture, dislocation, or subluxation. As there is difficulty extending the digit, one should also consider flexor tenosynovitis or Dupuytren contracture. To help with the differential diagnosis, note that Dupuytren contracture is a chronic condition and does not present as an acute injury.

Diagnostic Testing

Due to the strength of the tendon attachments to the bones of the hand, x-ray imaging should be done for symptomatic patients. In the ED, more advanced imaging is not generally used, though the

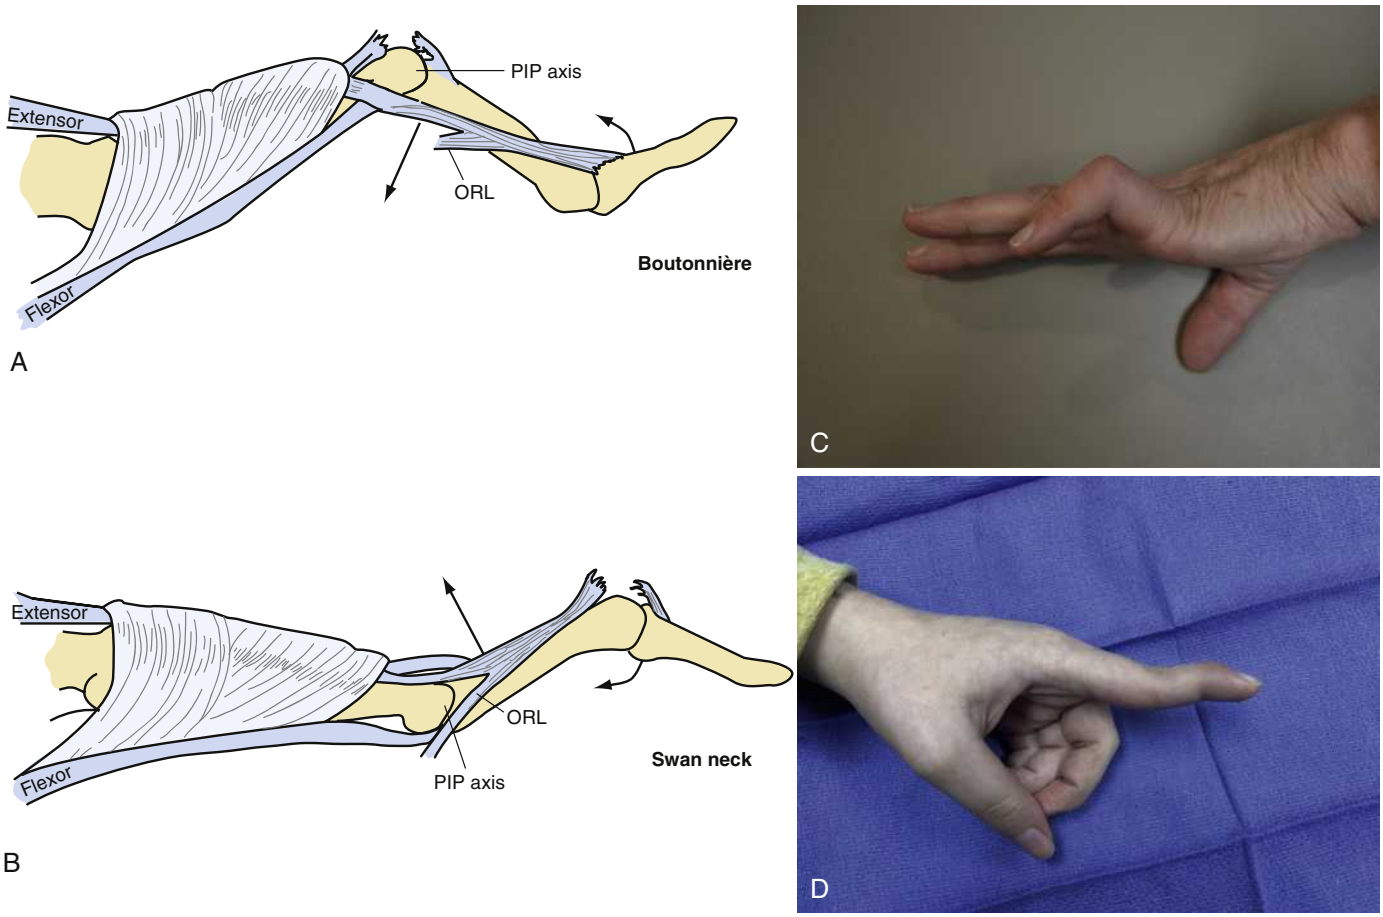

Fig. 42.39 (A) A Boutonnière injury (zone III injury) allows the ORL to subluxate volar to the axis of rotation at the PIP joint. (B) Mallet finger (zone I injury) that has resulted in a swan-neck deformity due to dorsal subluxation of the oblique retinacular ligament (ORL) (lateral bands). (C) Boutonnière deformity seen on physical examination. (D) Swan-neck deformity seen on physical examination. (A and B: Bortel DT. Extensor tendon repair. In: Pfenninger JL, Fowler GC. *Pfenninger and Fowler's Procedures for Primary Care*, ed 3. Saunders; 2020:1154-1159. Fig. 172.1; C: Courtesy of Anthony Zacharek, MD; D: Courtesy of Mary Jo Wagner, MD, FACEP and Thomas Ferreri, MD.)

utility of ultrasound for making the diagnosis of tendon injury is being investigated.[21-23]

Management

Closed extensor injuries are treated acutely with immobilization. Grossly contaminated open lacerations, including crush injuries and large open wounds, should have emergent consultation with a hand specialist for operative management. Irrigation, tetanus immunization, and IV prophylactic antibiotics covering skin flora (e.g., first-generation cephalosporin such as cefazolin 1 g IV q8 hours or for patients with penicillin allergy, vancomycin 1 gm IV with subsequent dosing calculated by pharmacy) should be initiated in the emergency department. Simple, noncontaminated extensor tendon lacerations may be repaired by the EM physician if properly trained with this procedure (see details later). Patients with open lacerations should have thorough irrigation and splinting. They should be discharged with prophylactic oral antibiotics covering skin flora (e.g., a first-generation cephalosporin such as cephalexin 500 mg q8 hours for 7 to 10 days or for penicillin allergic patients, doxycycline 100 mg po BID for 7 to 10 days).

Zone I Extensor Injuries Management. Most mallet finger injuries are successfully treated with immobilization, though injuries accompanied by fracture dislocations may require surgical fixation. For splinting, only the DIP joint should be immobilized, and it should be held in full extension for 6 to 8 weeks followed by nighttime only splinting. A premolded Stack splint is often placed due to its ease of use while performing normal activities. If this is not available, use of an AlumaFoam splint on the dorsal side of the finger is also appropriate. Some patients (15%) have residual extensor lag following splinting, which is considered an acceptable result.[24] We recommend hand specialist follow-up within one week of injury.

Patients with improperly treated mallet injuries may develop a swan-neck deformity where there is hyperflexion at the DIP joint with hyperextension at the PIP joint (see Fig. 42.39). Duck bill deformity may develop at the thumb.

Zone II Extensor Injuries Management. Incomplete lacerations can be managed with simple closure and splinting of the DIP in extension for 2 weeks. Complete lacerations require urgent surgical follow-up for repair and the splint will need to be maintained for 6 weeks. Similar to zone I injuries, if untreated, the patient may develop a swan-neck deformity.

Zone III Extensor Injuries Management. Central slip disruptions (boutonnière injuries) are treated by splinting the PIP joint in extension for 4 to 6 weeks followed by night splinting. DIP flexion exercises should also be performed multiple times each day to help correctly align the lateral bands.

Chronic boutonnière injuries should similarly be treated conservatively with splinting, though these patients often require surgical PIP joint release and should be referred to a hand specialist. Depending on the degree of flexor tendon contracture, complete extension may be unrealistic with initial splinting. Serial splinting, until complete extension is obtained, may be necessary.

Zone IV Extensor Injuries Management

If there is no loss of extension, conservative treatment with splinting is usually sufficient. Splinting, like for zone III injuries, should be performed with the PIP in extension and the DIP free to move. Tendon repair is indicated in patients with loss of active extension.

Zone V Extensor Injuries Management. Stable sagittal band injuries (type I) can be treated with buddy or dynamic taping for 3 to 4 weeks. Acute injuries with subluxation (type II) may be treated with an MCP

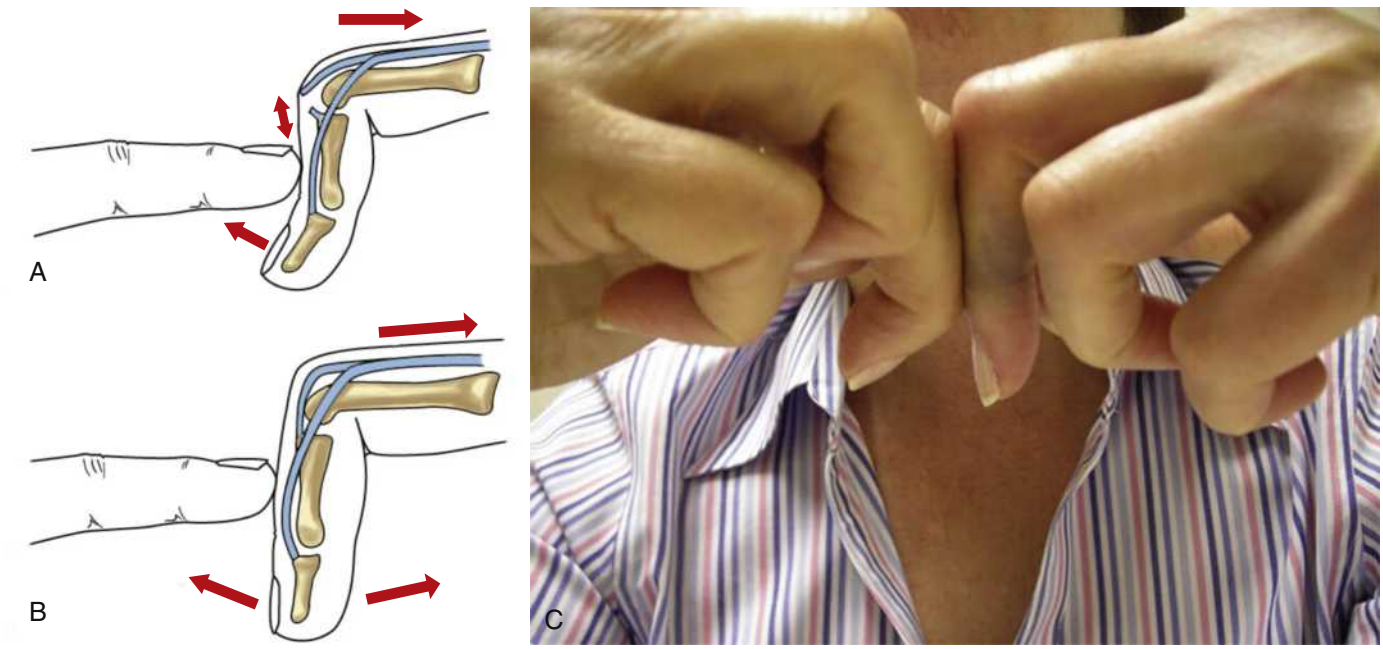

Fig. 42.40 The Elson test (A and B) and modified Elson test (C) are used for evaluation of central slip extensor injury. (A) With a disrupted central slip, the distal phalanx is held in extension as attempted active extension of the PIP joint against resistance allows proximal movement of the origin of the lateral bands. (B) With an intact central slip, attempted active extension of the PIP joint against resistance affects the middle phalanx but prevents extension of the distal phalanx. (C) Abnormal DIP extension of the injured left middle finger as demonstrated by modified Elson test. (A and B: From: Gause T. Boutonniere deformity. In: Miller MD, Hart JA, MacKnight JM. *Essential Orthopaedics*, ed 2. Philadelphia: Elsevier; 2020:327-329. Fig 84.3; C: Posner MA, Green SM. Diagnosis and treatment of finger deformities following injuries to the extensor tendon mechanism. *Hand Clinics*. 2013;29(2):269-281. Fig 13.)

flexion blocking splint (MCP joint in extension with the PIP and DIP joints free) for 8 weeks. Complete disruptions of the sagittal band (type III) should also be stabilized with an MCP flexion blocking splint, though patients with these injuries require referral to a hand specialist for surgical repair. Similarly, patients who have failed splinting and those with chronic injuries (>3 weeks) require hand specialist follow-up for surgical management.

Zone VI Extensor Injuries Management. Clean, complete tendon lacerations may be repaired by an EM physician, though we recommend discussion with a hand specialist first, if possible. Urgent follow-up with a hand specialist is indicated, ideally within one week. Initial splinting should immobilize the wrist at 30 degrees of extension, MCP joint in extension, and the PIP and DIP joints free to move.

Zone VII Extensor Injuries Management. If there is no need for immediate surgical intervention (such as gross contamination), wounds should be thoroughly irrigated followed by skin closure. The hand and wrist should be immobilized with a volar splint, keeping the wrist at 30 degrees of extension and the MCP joints at 15 to 20 degrees of flexion. Hand specialist follow-up is indicated, ideally within one week.

Disposition

In any case where there is concern for an extensor tendon injury, either open or closed, referral to a hand specialist is recommended from the ED. Due to risk of chronic functional impairment, patients with complete tendon lacerations should have urgent follow-up with a hand specialist so that surgery may occur within 2 to 3 weeks. Any delay that might come about by an initial referral to a primary care appointment should be avoided if possible, and patients should be instructed about this timeline. Loss of motion is the most common chronic complication of tendon injuries. This may be accompanied by extensor lag or joint contracture.

Flexor Tendon Injuries

Clinical Features

The majority of flexor tendon injuries are open injuries secondary to a deep laceration.

Closed flexor tendon injuries are less common in general and are less common than extensor tendon injuries. They tend to occur in athletes from having forced hyperextension of a digit that is in active flexion. The two most common flexor tendon injuries of the hand involve the flexor digitorum profundus (FDP) and the flexor digitorum superficialis (FDS) (Fig. 42.41). Most closed flexor tendon injuries occur at the fourth finger, involving the FDP. The FDS is generally spared. Patients will complain of a "pop" or "tear" with pain over the flexor surface, as well as loss of active flexion or weakness of the tendon. Bowstringing tends to occur only when multiple pulleys have been injured. This usually involves the two strongest pulleys A2 and A4 (see Fig. 42.12). A flexor tendon injury should be considered when an injured finger does not assume its naturally flexed position on cascade testing.

Specific tendon function testing should be performed (see Table 42.1). Recall that the FDP tendon inserts at the base of the distal phalanx and the FDS tendons insert at the base of the middle phalanx. The FDP tendon should be examined by holding the patient's MCP and PIP joints in extension and having him or her attempt to flex the DIP joint. The examiner should be sure not to impede the motion of the other digits when doing this or a false-positive test can occur. Inability to flex indicates a tendon laceration. Weakness or pain when flexing indicates that there is likely incomplete disruption or strain. To accurately assess FDS integrity, the FDP must be restrained. This is accomplished by holding all uninjured digits in full extension. Inability to flex at the PIP using this technique indicates FDS disruption. If there is partial or complete disruption of the FDS, the involved finger will rest with less flexion than normal and will be unable to flex at the PIP joint. With similar injury to the FDP, the PIP joint will be held in extension and the patient will be unable to flex at DIP joint or be able to pinch or grip with this finger.

Tendon avulsions are very rare in isolation for FDS injuries, though are far more common with the FDP tendons. There are three main types of FDP avulsion injuries. Type I involves a completely avulsed tendon migrating proximally through the flexor sheath into the palm. There is risk for compromised vascular supply to the tendon and surgery is recommended as soon as possible (no later than 7 to 10 days). Type II injuries involve a complete avulsion with proximal retraction to the level of the PIP joint. Similar to type I injuries, the patient may have

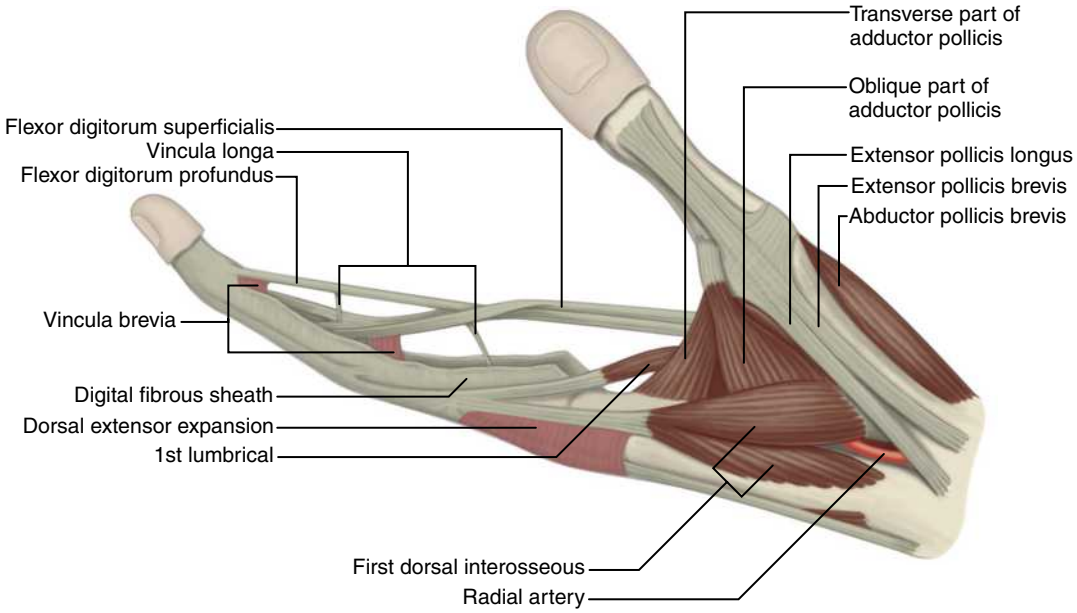

Fig. 42.41 Lateral view of the hand showing the flexor tendons of the finger. (From Standring S: *Gray's Anatomy: The Anatomical Basis of Clinical Practice*, ed 39. Edinburgh: Churchill Livingstone; 2005.)

compromised vascular supply and patient should have expedited surgical repair. For type III injuries, the avulsed tendon retracts only to the level of the A4 pulley. There is less concern for vascular compromise, though surgery is still recommended within 7 to 10 days.

The flexor tendons are divided into 5 anatomic zones (Fig, 42.42). Zone I extends from the insertion of the FDP at the distal phalanx to just distal to the insertion point of the FDS at the middle phalanx. FDP tendon avulsion from its insertion at the base of the distal phalanx is the most common (jersey finger) injury. With this specific injury, the patient is unable to flex the DIP. It classically occurs in football players who may grab onto an opponent's jersey to tackle or slow the runner and there is forced hyperextension with the digit in active flexion.

Zone II extends from the distal palmar crease to the proximal portion of the middle phalanx and includes both FDP and FDS tendons. Because the injured tendons and associated structures are within the tight space of the flexor sheath in this zone, repair is technically more demanding and results in a greater frequency of complications relative to other zones. As a result, it has been historically referred to as "no man's land." Advances in technique over the years have made primary repair of flexor tendons a standard option for treatment.

Zone III extends from immediately distal to the carpal tunnel to the proximal flexor sheath of the digits. Generally, injuries to this zone have good outcomes.

Zone IV includes the carpal tunnel. Damage to the median nerve is common, stressing the importance of a thorough neurovascular exam. Because of protection from the flexor retinaculum, other injuries in this zone are relatively rare.

Zone V is proximal to the carpal tunnel. Injuries in this zone usually occur from a deep laceration and involve multiple tendons.

Differential Diagnoses

Associated avulsion fractures are common with flexor tendon injuries (e.g., jersey finger). Other underlying fractures, ligamentous injuries, dislocations, and subluxations should also be considered.

Diagnostic Studies

X-rays may be obtained to rule out associated avulsion fractures. Ultrasound has also become increasingly popular as a dynamic bedside study.[21-23]

Management

Patients with flexor tendon injuries, both open and closed, should see a hand specialist given risk for chronic disability. Urgency depends on the injury, and any acute rupture or laceration is urgent. Emergency consultation is indicated in patients with associated open fractures or dislocations, grossly contaminated wounds, bites, arterial injury, or if the wound overlying the tendon cannot be closed in the ED. Follow-up within 3 days is indicated for most other patients with acute flexor tendon lacerations, because delay may result in retraction of the tendon ends, creating a more difficult repair and risk for worse outcome.

The tendon should also be immobilized with a blocking splint to prevent further retraction of the flexor tendons. Splinting should be performed with the wrist in neutral to slightly flexed position, the MCP joints flexed to 70 to 90 degrees, and the IP joints minimally flexed at 10 to 15 degrees. A thumb spica splint should be used for patients who have flexor tendon lacerations involving the thumb with the wrist, MCP, and IP joints in similar flexion.

Patients with any open wounds should be started on oral antibiotics covering skin flora for 5 to 7 days. Cephalexin 500 mg PO TID for 7 to 10 days or doxycycline 100 mg PO BID for 7 to 10 days (for penicillin-allergic patients) are appropriate regimens.

Disposition

Primary repair, or end-to-end repair, is defined as occurring within 24 hours of injury.[25] Referral for *delayed repair*, defined as occurring within 3 weeks of injury, may be considered if an experienced specialist is not available on the day of the injury and the wound has not been grossly contaminated. Direct communication with the hand specialist should occur to help ensure there is timely follow-up, since the success

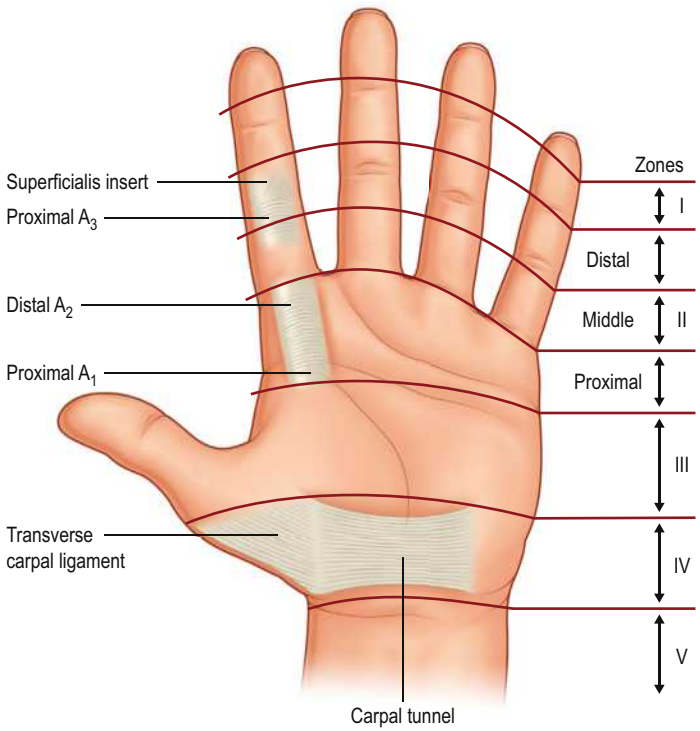

Fig. 42.42 Flexor tendon zones. (From: Chang J, Legrand A, Valero-Cuevas F. Anatomy and biomechanics of the hand. In: *Plastic Surgery: Vol 6: Hand and Upper Extremity*, ed 4. London: Elsevier; 2017:1-48. Fig. 1.39.)

and ease of the repair is improved with less delay than 3 weeks. If the patient will be undergoing delayed primary closure, the overlying wound should be thoroughly irrigated and closed with loose sutures and the hand splinted in the functional position.

Adhesions, infection, and tendon contracture are common complications. One rare complication following repair is recurrent rupture. This usually occurs within 5 weeks of repair. Patients will present to the ED complaining of feeling a "pop" or new acute pain with a sudden loss of function if the patient is in a dynamic splint. The diagnosis can often be made by noting an abnormal flexion cascade sign. The EM physician should avoid having the patient attempt any flexion activities that have not already been approved by the hand specialist or physical therapist and should not remove the splint. Referral back to the hand specialist within 3 days is appropriate.

Trigger Finger

Clinical Features

Trigger finger, often referred to as stenosing tenosynovitis, occurs from overuse. The common mechanism is repetitive forceful flexion. This leads to inflammation and narrowing at the A1 pulley, thereby inhibiting normal smooth tendon movement. The patient will usually complain of catching and pain with flexion and extension of the fingers (Fig. 42.43). Trigger finger is most common in patients with underlying inflammatory joint disease, diabetes mellitus (DM), and hypothyroidism. A snapping sensation is appreciated with examination of active and passive range of motion. In chronic cases, a nodule may be felt on the flexor surface of the MCP joint.

Differential Diagnoses

When considering trigger finger, one should consider underlying inflammatory joint disease, subluxation of the extensor tendon, or Dupuytren contracture. In the presence of preceding trauma, one should also consider underlying fracture, tendon injury, or ligamentous injury.

Diagnostic Testing

The diagnosis of trigger finger is made exclusively from history and exam, but if there is more to the clinical picture and there is concern for an underlying pathology such as DM, hypothyroidism, or inflammatory joint disease, then laboratory studies including blood glucose, HgbA1c, TSH, free T4, ESR, and CRP may be obtained in the ED. Hand radiographs are generally not needed, but if there is a history of acute trauma or concern for an avulsion injury, x-rays may be performed to rule out an underlying fracture.

Fig. 42.43 Trigger finger in a patient with the ring finger stuck in flexion. (Courtesy of Anthony Zacharek, MD)

Management

Initial treatment of trigger finger involves conservative measures including NSAIDs and splinting. Immobilization with an MCP blocking splint at slight flexion (10 to 15 degrees) for 6 to 10 weeks has been shown to improve symptoms.[26] Corticosteroid injections have also been shown to be effective in reducing symptoms though there is higher risk for recurrence (50% at 1 year). Injections may be performed by the EM physician, though we also recommend that injections be reserved for patients who have failed conservative measures. Following acute treatment, the patient should modify activity to limit overuse and recurrence.

Hand specialist referral for surgical management (A1 pulley release) is indicated in patients who fail conservative treatment. A Cochrane review of two RCTs comparing treatment with open surgery versus steroid injection (control) found that 92% of patients had resolution of symptoms without recurrence compared to 61% of patients in the control group. There is a lower risk of recurrence in patients with open surgery, though there are greater complaints of pain during the first week following treatment.[27]

Corticosteroid injections may be used in patients with trigger finger who have failed conservative measures such as splinting, icing, and NSAIDs. Corticosteroid injections have been shown to improve long-term pain in patients with trigger finger. In one study, greater than 68% of patients reported complete resolution in pain and snapping one month after the injection. In this same study, greater than 57% reported resolution of PIP flexion contracture.[28] There are two methods for corticosteroid injections in these patients: intra-sheath injection and extra-sheath injection. Ultrasound guidance is helpful in identifying landmarks. A linear-array transducer should be placed in the long-axis orientation along the volar side of the affected finger at the MCP joint.[29] The flexor digitorum superficialis and flexor digitorum profundus tendons as well as the A1 pulley should be identified (Fig. 42.44). For the intra-sheath technique, at approximately 45 degrees and using a distal to proximal long-axis approach, the needle should be advanced until the tip of the needle is between the FDS and FDP tendons. Approximately 0.5 mL of steroid such as triamcinolone acetonide 10 mg/mL suspension, mixed with a local anesthetic, is injected. The extra-sheath technique is similar, though the tip of the needle should rest at the distal end of the A1 pulley, superficial to the FDS and FDP, which is the site of injection. If there is resistance with injection or if the needle moves with flexion and extension of the digit, the needle is likely deep in the tendon and it should be withdrawn slightly. If, with flexion and extension of the digit, there is a sensation of the tendon rubbing against the needle point but no significant movement of the needle, it is likely in correct position in the tendon sheath.

Finger and Nail Bed Injuries

Nail Bed Injuries

Clinical Features. The nail bed is frequently injured in a manner that ranges from minimal to severe. Injury occurs after direct trauma to the fingertip with the nail compressed against the thin layer of skin (nail bed) and the bony tuft immediately underneath. A subungual hematoma or bleeding under the nail plate is described by the percentage of the nail bed that is covered by the blood with an unbroken fingernail and intact nail root. Pain results from the pressure caused by the blood within the closed space of the nail plate, nail bed, and nail fold. Identification of the extent and depth of any laceration of

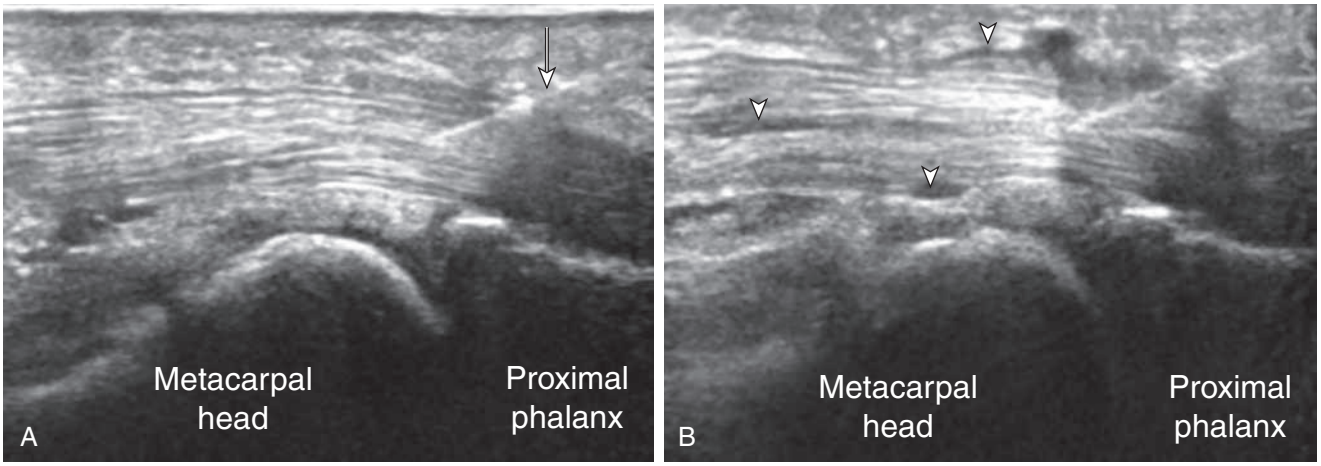

Fig. 42.44 Intra-sheath steroid injection technique using ultrasound guidance. (A) The needle tip is placed between the FDS and FDP tendons (*arrow*). (B) Expansion of material into the space between the FDS and FDP tendons or the margin of the flexor tendons (*arrowheads*). (Reprinted by permission of Elsevier, from Shinomiya R, Sunagawa T, Nakashima Y, Yoshizuka M, Adachi N. Impact of corticosteroid injection site on the treatment success rate of trigger finger: a prospective study comparing ultrasound-guided true intra-sheath and true extra-sheath injections. *Ultrasound Med Biol.* 2016;42(9):2203-2208.)

the nail bed or along the lateral or proximal nail folds will determine management options.

Differential Diagnoses. When evaluating a patient with a suspected nail bed injury, the EM clinician should also consider an underlying tuft fracture, open fracture, subungual hematoma, mallet injury, or FDP tendon injury.

Diagnostic Testing. Imaging is needed to determine if there is fracture of the finger tuft. PA, lateral, and oblique radiographs will identify a fracture and determine if surgical repair will be needed. Comminuted fractures are generally stable due to the fibrous septae of the pulp that are tightly adherent to the tuft. Transverse fractures of the distal phalanx and intra-articular fractures will need surgical referral, ideally within one week. If the only injury is a subungual hematoma, an x-ray is not needed if the mechanism or clinical findings do not indicate a fracture that would leave an unstable fingertip.

Management. For a subungual hematoma covering greater than 50% of the nail bed, the typical practice is to trephinate, or create an opening in the nail to release the blood. A hole to provide drainage of the hematoma can be created with a sterile 18-gauge needle or electrocautery. Several studies have shown that if the nail remains generally intact, trephination without nail bed repair achieves equal healing and cosmesis compared to the more invasive and painful removal of the nail and repairing the nail bed. If the fracture is only a parcellar (nondisplaced) fracture of the fingertip, no treatment with antibiotics is needed (Fig. 42.45).

If a finger tuft is unstable due to a fracture, surgical repair is needed to stabilize the bony support and use of the finger. Repair of the tissue injuries can be done during the surgical procedure, though some EM clinicians will primarily repair the laceration, as the bony damage can be stabilized at a later time. The decision whether or not to primarily repair the laceration in this situation is dependent on the local standard of care.

If there is disruption of the nail bed or root, then repair of these structures should be done (Fig. 42.46). Anesthesia using digital block in older children and adults is appropriate, though younger children may need procedural sedation to accomplish the repair. Use 6-0 absorbable suture to directly repair the laceration, or tension sutures to approximate the nail bed when the tissue is too disrupted. The goal is to cover the bony surface as well as possible. Some practitioners have used tissue adhesive to repair the nail bed, which may be appropriate instead of suturing if approximation is more easily achievable. Some practitioners use the tissue adhesive to repair the nail plate if it is cracked, so it can be used to cover the nail bed. Subsequent dressing with a nonadhesive covering is needed.[30]

Specific recommendations regarding the replacement of the nail plate after nail bed repair are rapidly changing. Historically, the practice has been to replace the nail plate after repairing nail bed lacerations, including putting the nail plate into the nail fold to prevent blocking the ability of a new nail to grow from the germinal matrix. However, no systematic trials have been done to determine if this is necessary or might decrease the infection rate (2% to 5%). In a recent large British study, one-third of specialists did not replace the nail plate and of those who did replace the nail plate, one-third did not secure the nail and 20% used tissue adhesive.[31] A more recent pilot study showed fewer infectious complications and less pain without replacement of the nail. A large prospective randomized trial is in progress to delineate a more definitive recommendation.[32,33] With the current debate in the literature, we recommend repositioning the nail after repair of the nail bed. The nail serves as the best source of a biologic splint for the injuries of the soft tissues and bone. If the nail is reinserted under the eponychial fold, the soft tissue can often be stabilized to it.

Most studies of antibiotic use in nail bed injuries with disruption of the nail plate included only patients that were referred to hand specialists, providing a selected population; no ED-based studies demonstrating appropriate treatment were found. In the survey of current practice for consultants caring for pediatric hand injuries in Britain, half of nail bed injuries were generally associated with fractures of the distal phalanx. Almost two-thirds used antibiotics even if there was no underlying fracture associated with a nail bed injury.[31] As previously noted, distal phalanx fractures have less periosteal stripping, so they do not have the infection rate of other open fractures in the body. A 2016 meta-analysis suggests that the focus of treatment should be on prompt irrigation and early débridement without the need for prophylactic antibiotics. Specifically speaking to fingertip entrapment (an injury generally from a finger being crushed in a door or window), the most recent Cochrane review indicates there are no well-designed studies to guide our practice for any specific repair or the need for antibiotics. Internationally, the practice variability ranges from giving

Fig. 42.45 Subungual hematoma in a 6-year-old boy with middle and ring fingertip crush injury. (Nellans, KW, Chung KC. Pediatric hand fractures. *Hand Clini.* 2013;29(4):569-578.)

a first dose of IV first-generation cephalosporin followed by 10 days of oral cephalosporin, to no antibiotics except for clearly contaminated wounds. Without clear evidence, following the recommendations of the local hand specialist that will ultimately care for the patient is most appropriate.

Disposition. The injuries resulting in subungual hematomas with non-displaced fractures can be followed up by primary care physicians as most do not need further treatment. Hand specialists should be consulted if primary care follow-up is not an option, and for injuries that are complex, including those with missing tissue, unstable fractures such as transverse fractures of the distal tuft or fractures that involve a joint.

Amputations

Fingertip Amputations

Clinical Features. Amputations of the fingertips are common, most often occurring in children. These injuries can result in macerated tissue, but any available amputated part should be initially preserved. With amputations of the fingertip, there are several different classification systems, based on the involved vascular structures or tissue structures. For EM physicians, the injuries have been classified by zones as shown in Figure 42.47. Zone I is distal to the bony distal phalanx, zone II is the area between the distal phalanx and the lunula, and zone III is proximal to the lunula. Practically, a functional description is more helpful to the hand specialist. The injuries in zone I and II allow for retention of the full function of the digit, even if there is some shortening of the digit. An injury more proximal than the lunula line generally indicates damage or loss of the flexor digitorum profunda (FDP) with the resultant loss of flexion and stiffness at both the DIP and PIP joints. The presence or absence of exposed bone will also determine management. In young children (less than 3 to 4 years old) with distal tip amputations, the tissue can be reattached as a composite graft if it measures typically 1.0 cm in size or less. Consultation with a hand surgeon is recommended in these situations.

With more proximal amputations, an accurate description or image of the injury will assist in the determination of where and which management would be appropriate. The hand specialist can help the EM physician determine if reimplantation is the proper course of action. Indications for reimplantation include amputation of the thumb, multiple adjacent digits, pediatric patients, and clean, sharp amputations. Relative contraindications include severely crushed or contaminated wounds, patients with significant comorbid conditions, and multilevel amputations of the same digit.

Differential Diagnoses. When caring for a patient with a digit amputation, one should consider associated foreign bodies, proximal fractures, ligamentous injuries, tendon injuries, and neurovascular injuries.

Diagnostic Testing. Standard 3-view x-rays of the affected digit should be performed.

Management. Initial management includes assessment of the wound, control of bleeding, and thorough irrigation of the injury without further disruption of the tissue. A methodical exploration of the injury to provide a detailed description to the hand specialist will allow for determination of the appropriate management. One of the most important objectives is to identify if there is disruption of the proximal portion of extensor or flexor tendon attachment to the distal phalanx. The work-up is assisted by appropriate radiographs, identifying any chip fractures. Coordination and possible transfer to a center with hand specialists that perform microsurgery may be needed. If reimplantation of finger or fingertip is to be attempted, the

Fig. 42.46 Nail bed injury and repair. (A) Injury to eponychium prior to repair. (B) Separation of the nail plate from the sterile matrix with a fine scissor directly under the distal nail plate attachment. (C) The eponychium tissue is removed with scissor and the nail plate is removed with forceps traction. (D) Following nail bed repair. (Brown DJ, Jaffe JE, Henson JK. Advanced laceration management. *Emerg Med Clin N Am.* 2007;25(1):83-99. Fig. 1.)

amputated tissue should be placed in a normal saline-soaked gauze, in a clean plastic bag, and then this bag is placed in ice water to promote its viability over the next few hours.

In patients with small tuft avulsions (defined as less than 1 cm^3 loss of soft tissue with the nail intact and covered bone), healing by secondary intention is appropriate and does not seem to prolong pain or increase infection. The wound should be thoroughly irrigated and débrided of nonviable tissue, then loosely approximated if tissue allows. Patients generally report moderate discomfort for 7 to 10 days, with complete healing in 4 to 6 weeks, so appropriate counseling to set reasonable expectations should be provided to patients.[34] Even with a small tip of bony exposure, using a rongeur to trim the bone back and allowing it to heal with secondary intention has not been shown to change long-term outcome compared to other surgical options (Fig. 42.48). If coverage is needed for the tuft, then soft tissue from the pulp can be obtained with local tissue rearrangement or for a flap closure, such as a V-Y advancement flap (Fig. 42.49).

The majority of fingertip avulsion injuries of the distal tip in North America are managed nonoperatively, though in Asia and Europe, there is more focus on attempted reimplantation, with success rates of 70% to 90%.[35,36] This appears to be secondary to cultural concerns of missing digits, compared to a priority in the United States of rapid return to function. In the ED, optimizing the opportunity for a successful reimplantation in more significant injuries should be the goal as these patients have less pain and better functional outcome than those whose digit is amputated. The patients that should be referred immediately to a reimplantation specialist include those with loss of a thumb, multiple fingers, or the fingertip, and any child with loss of a digit.

If reimplantation is not an option, then a hand specialist may select several options for closing a larger wound. Free grafts, cross-flaps, advancement flaps, skin grafts, and healing by secondary intention are all possible treatment options for these injuries. If a patient who has previously undergone surgery for this injury such as a cross-finger flap presents to the ED, extreme care must be taken to avoid tension that may pull apart the graft site (Fig. 42.50). It may be of benefit to call the surgeon before removing the dressing.

The use of antibiotics has long been debated and, although prescribed for many patients with open tuft fractures with nail bed injuries, studies do not demonstrate that use of antibiotics reduces the risk of infection in a well-cleansed wound.[37] The consensus is that antibiotic prophylaxis (oral cephalexin 500 mg TID or oral doxycycline 100

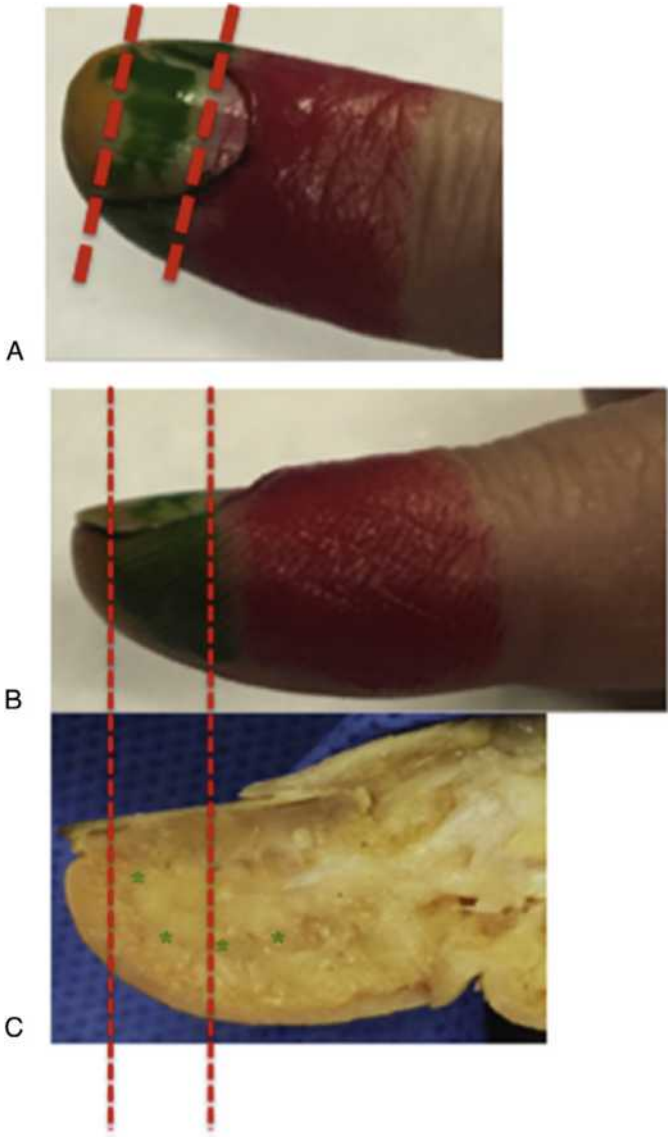

Fig. 42.47 Fingertip amputation zones: *Zone I* amputations include pulp and distal nail which generally heal by secondary intention. *Zone II,* Bone exposed—revision amputation soft tissue flap (e.g., V-Y advancement flap). *Zone III* involves the eponychium. Most require amputation of the distal phalanx at the DIP joint. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

mg BID (for penicillin-allergic patients for 7 days) should be given for grossly contaminated wounds but is not necessary in clean wounds in immunocompetent patients.

Disposition. Immediate consultation with the hand specialist is needed for all but those with zone I and other minimal injuries. In the United States, it is rare that an isolated fingertip amputation will get reimplanted. If the emergency physician is not comfortable with the closure described, then the hand specialist should see that patient at the time of the initial ED visit. After the patient's fingertip avulsion has been treated with coverage of the bone and tendon, the patient should have follow-up with the hand specialist in 7 to 10 days.

Transfer to a reimplantation center may be necessary during the initial ED visit. The success of reimplantation from specialized centers is reported to be 90% or better. Many clinicians are concerned about

Fig. 42.48 Volar finger-tip amputation. (Courtesy of Ronald Barry, MD, FACS)

delay to reimplantation after amputation. Recent studies have shown that the success rate of reimplantation remains above 90% whether done immediately or even with an overnight delay from injury to surgery.[38] The most common residual subjective symptom reported is cold intolerance to the tip of the finger. Other undesirable outcomes include infection, insensitivity, abnormal cosmetic appearance, and decreased range of motion.

Degloving Injuries

Degloving injuries and ring avulsion injuries (traumatic removal of a ring from a digit) result from trauma of a digit or the hand that pulls off the tissue, involving a varying degree of skin, muscle, tendons, flexor pulleys, and the associated neurovascular bundles (Fig. 42.51). The Urbaniak classification for ring avulsion injuries (Box 42.3) is helpful to determine treatment and prognosis. The more severe the injury, the less likely hand specialists are to attempt repair rather than amputation and the more likely for complications of flap coverage, revascularization, and reimplantation. Patients with class I injury should be seen by a hand specialist for assessment and wound closure. Class II or III injuries needs microsurgery with immediate referral to a hand specialist and facility capable of performing this repair. The most important indication of success is the ability to restore adequate revascularization.[39]

Mutilating Hand Injuries

Severe mutilating injuries of the hand can occur from explosions, gunshots, crushing industrial accident, motor vehicle collision, home equipment or environmental activities. These dramatic wounds are generally associated with other traumatic injuries that can be life-threatening, so appropriate evaluation for trauma patients should be prioritized without being distracted by the injured hand. Controlling the bleeding from a major hand wound can generally been done with direct pressure, or if not successful, by the use of a pneumatic or blood pressure cuff. Though challenging, a physical examination should be done to document the remaining function and sensation, if possible. Assessment of the vascular system might be difficult, but evidence of

Fig. 42.49 Example of a V-Y advancement flap and an oblique triangular neurovascular island flap used for reconstruction of a small size pulp defect in the index and long fingers, respectively. (A) Flap design. (B) After advancement of flap. Direction of flap advancement as indicated by the black arrow. (Ono S, Sebastin SJ. a pulse can be obtained through the use of a Doppler ultrasound or placement of a pulse oximeter. Immediate consultation with the hand specialist should be obtained after the patient is stabilized from other life-threatening injuries. In the ED, one dose of IV antibiotics (first-generation cephalosporin such as cefazolin 2 to 3 gm or vancomycin 10 to 15 mg/kg for adults) and appropriate tetanus prophylaxis are indicated prior to surgical stabilization. For the surgeon, the priorities are to have a stable thumb or a first digit post of at least the length of the IP joint, to have one or preferably two opposing digits, and to achieve coverage of tissue with sensation for the involved functioning extremity.

BOX 42.3 Urbaniak Classification for Ring Avulsion Injuries

- Class I: Circulation adequate
- Class II: Circulation inadequate
- Class III: Complete degloving injury or complete amputation

Skin and Soft Tissue Injuries

Clinical Features

Lacerations to the hand and fingers are approached with more care than those on the proximal extremities and torso due to the numerous structures covered by minimal tissue. Knowledge of hand anatomy will assist when performing careful exploration of each laceration to determine if any structures have been injured. A full examination of the function of surrounding tendons and muscles must be performed, and any abnormalities documented. Abnormal positioning of the hand or fingers may indicate a tendon injury or displaced fracture. Two-point sensation of each of the fingers should be tested distal to the laceration to identify possible nerve injury. Foreign bodies such as glass can easily be missed in the wounds, so identifying the risk and instructing patients accordingly is important. Finally, all rings or constricting material should be removed on the injured hand to avoid swelling with resulting vascular congestion.

Diagnostic Testing

X-rays of the hand or digit with the laceration may help if there is concern for a foreign body, or to determine if there is air in the joint from a laceration.

Management

Initial assessment of any laceration includes direct visualization and complete examination of the muscle, tendon, and neurovascular functions of the hand and fingers. Determination of tetanus vaccination status should be assessed, and immunization updated if appropriate.

Each laceration should be explored to assure there is no injury to the tendon, joint or neurovascular bundle. If there is a laceration near a joint, the wound should be explored to determine if there is intrusion into the joint space, which would require extensive washout to decrease the chance of infection. If the laceration is over any region with a tendon, it is advised that exploration should occur while carefully examining the tendon moving through the entire length of its range of motion. A commonly missed injury is a partial tendon injury undiscovered because the patient's function with formal testing may be normal. A partial tendon laceration could put the tendon at risk for further injury later.

Generally, bleeding from the digital arteries distal to the DIP joint can be controlled with local compression and closure of the skin. An artery could be tied off without complication due to the collateral circulation of each digit, but this is rarely needed. Care should be taken to avoid tying off the accompanying digital nerve if it is intact.

Most hand and finger skin lacerations can be closed with simple interrupted sutures, 4-0 or 5-0 nonabsorbable (nylon) sutures using the standard technique including everting the wound edges. Absorbable (Vicryl) 4-0 or 5-0 suture material is used for deep layers. Care must be taken to avoid other structures in the hand while closing simple wounds. For wounds in the palm or other gapping wounds, it is difficult to approximate the wound edges due to the tension of the skin, so horizontal mattress sutures may be more advantageous. Tissue adhesive can be used on wounds that have bleeding controlled in areas that lack tension and if no underlying structures would be exposed to the adhesive.

Laceration of the joint capsule should be discussed with the hand specialist in the ED because many are brought to the operating room for an extensive wash-out. After expert consultation, distal joints may be copiously irrigated and closed within the ED with close follow-up. A first dose of empirical antibiotics (cephalexin 500 mg BID for 7 days) can be discussed with the consultant. Similarly, lacerations of the flexor tendons should be discussed with and cared for by the hand specialist. If delayed primary repair is recommended by the consultant, the wound should be copiously irrigated, then the skin should be closed with 5-0 non-absorbable sutures. The hand should be splinted to minimize stretch on the flexor tendon. In a dorsal blocking splint, the splint is placed on the dorsal side of the extremity with the wrist flexed at a 30-degree angle, the MCP joints at 70 degrees of flexion, and the IP joints in extension, flexed at only 15 degrees. Follow-up with the hand specialist should be arranged within a few days to reduce contraction of the tendons more proximally.

Laceration of the Extensor Tendon. Evaluation of a laceration over the extensor tendon includes obtaining visualization of the underlying tendon throughout its entire range of motion. If a tendon is cut by less than 50%, functional testing, even against a force, might be normal. It has been shown that a laceration of less than 50% can heal with conservative treatment including overlying wound care and splinting. It is very important to trim any minimal tags to allow for the gliding mechanism of the extensor tendon. After discussion with the hand specialist, an emergency physician can repair a complete or near-complete extensor tendon laceration. A nonabsorbable suture material should be used, 4-0 in the finger and 3-0 in the hand to repair the tendon. In thin tendons, a figure-of-eight or mattress stitch can be used or modified Bunnell or Kessler stitch in larger tendons that have enough width to hold the tension of the suture (Fig. 42.52).

Disposition

All lacerations of the hand should be followed up by a provider to assess for possible infection. If there is any concern for an infection, appropriate antibiotics should be started, such as a first-generation cephalosporin (cephalexin 500 mg BID) or doxycycline (100 mg BID) for 7 days for patients with true penicillin anaphylaxis. Due to the close association between the tissue of the digits and the bony phalanxes, osteomyelitis is a risk for any patients with an infected wound in the tissue of the digits. All patients with a potential tendon or joint laceration need close follow-up with a hand specialist, ideally within 3 days.

Clenched Fist Injuries

Specific laceration injuries to the hand include the clenched fist injuries, tooth-knuckle injuries or fight bites in which a patient develops a laceration from the impact of hitting another human's mouth or teeth with a fist. This must be considered in any laceration on the dorsum of the hand and lead to a concern for intrusion into a joint, tendon sheath or even bone. The delay in treatment, deep wounds, and PIP joint injuries significantly increases the complication rate. In a meta-analysis of these wounds, greater than one-third of patients had tenosynovitis, joint infections or osteomyelitis.[40] Treatment should include coverage for *Staphylococcus*, *Streptococcus viridans*, and *Eikenella corrodens*. For patient with an infection who will be admitted, we recommend the use of broad-spectrum antibiotics such as ampicillin/sulbactam (3 g IV q6 hours) due to the aerobic and anaerobic, polymicrobial nature of these infections. For outpatient therapy, one can also use amoxicillin/clavulanate 875 BID or clindamycin 600 mg q8 hours for 7 days plus a fluroquinolone (i.e., levofloxacin 500 mg daily) in a patient with true penicillin anaphylaxis. In addition, exploration and surgical wash-out

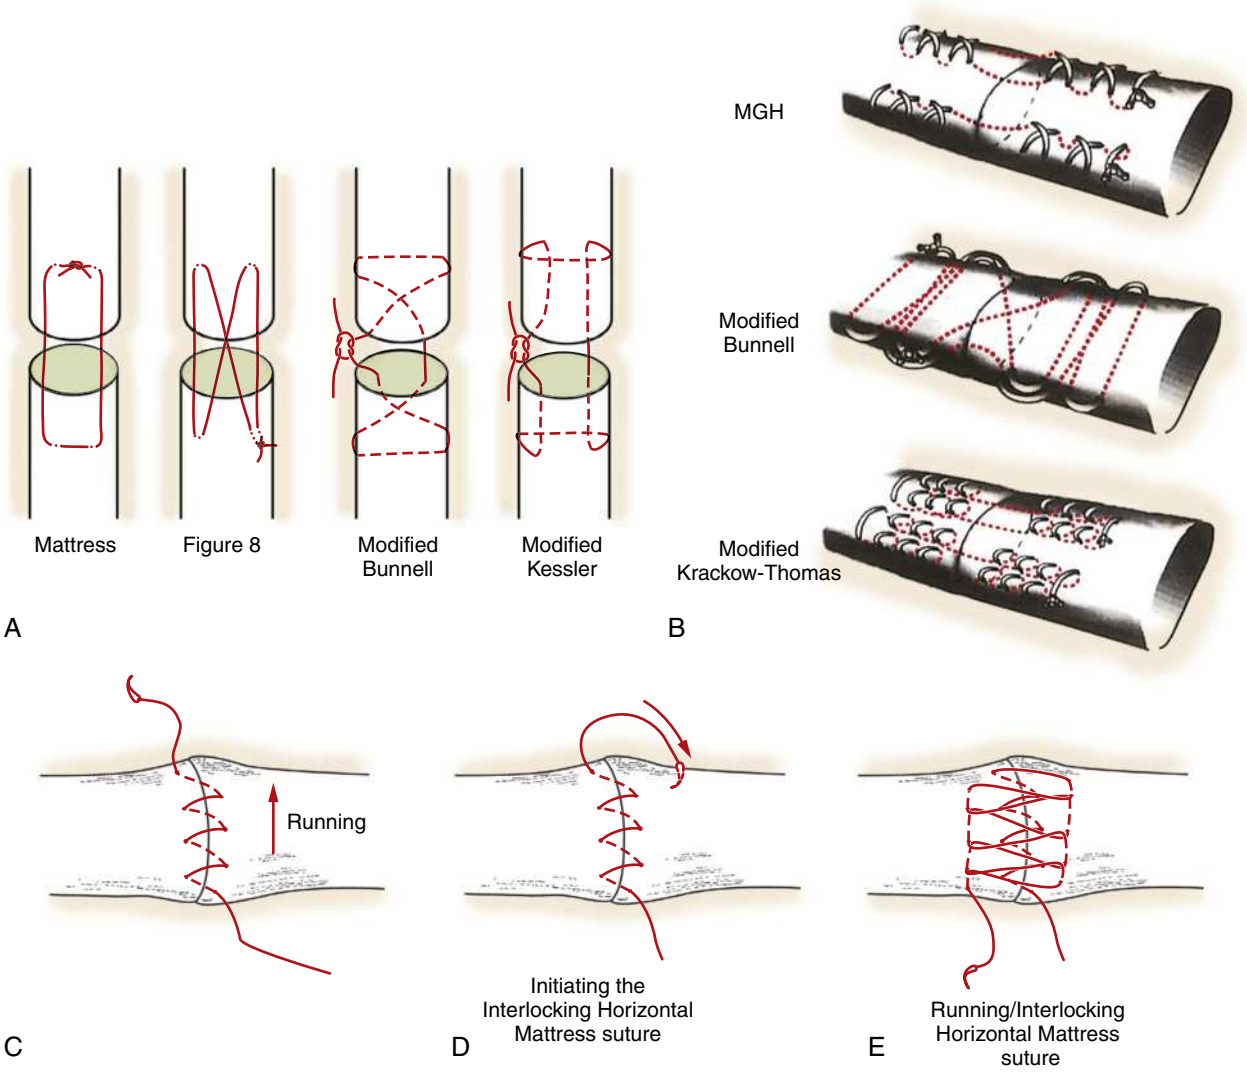

Fig. 42.52 (A–E) Demonstration of extensor tendon injury repair techniques. of the wound is indicated, due to the high incidence of joint or tendon sheath intrusion.[41]

INFECTIOUS DISORDERS OF THE HAND

General Hand Infections

Infections of the hand occur due to direct inoculation and open wounds. In one large study, almost 50% of infections in the hand had cultures positive for MRSA organisms, with increasing resistance to clindamycin and levofloxacin, especially in patients with intravenous drug abuse (IVDA) and patients with immunocompromised conditions such as diabetes mellitus.[42]

Paronychia

A paronychia is acute inflammatory changes or infectious changes in the skin in or under one of the nail folds that line the nail bed (Fig. 42.53). This is often due to trauma or a foreign body, such as a dry cuticle or open wounds from picking and pulling of skin in this region. Incision and drainage should be accomplished using general principles, including inspection for removal of any foreign body, opening of abscess to allow drainage, and avoiding damage to the nail bed or plate. The nail fold is elevated by blunt dissection or scalpel to release the purulent fluid while avoiding damage to the nail plate and nail matrix. On occasion, if the edge of the nail is the inciting irritant, a partial nail plate excision could be done to eliminate the cause and allow the nail to grow back in a corrected manner. With adequate incision, no treatment with postprocedural antibiotics is

Fig. 42.53 (A) Paronychia of patient's index finger. (B) Felon. (C) Onycholysis. The detached nail plate is white in color. (A: Courtesy of Angela Gregory, MD and Ian Keck, DO. Central Michigan University COM); B: Rerucha, Caitlyn et al. Acute hand infections. Am Fam Phys. 99(4):228- 236, 2019; Fig 4.; C: Tosti A. Diseases of hair and nails. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, ed 26. Philadelphia: Elsevier; 2019:2655-2664. Fig. 413-15.)

appropriate.[43] If there is no abscess to incise, the digit can be soaked with 1% acetic acid and warm water for 15 minutes 2 to 4 times daily to decrease the bacterial count of *Pseudomonas aeruginosa* and other infectious agents.[44] Topical mupirocin daily for 7 to 10 days may also be used in combination with a topical steroid at night to decrease inflammation.

Chronic paronychia can be caused by topical irritation or hypersensitivity reaction. Treatment can include topical steroid medications such as triamcinolone cream once to twice per day for three months. If the patient indicates that the paronychia has been present for months, it is likely to be a fungal infection. Systemic medications for suspected fungal irritants are not useful because the irritation is topical and not due to an actual tissue infection. The patient should be informed to stop soaking it, keep it dry, and apply a topical antifungal (terbinafine 1% cream twice daily). A hand specialist could be consulted for marsupialization or other surgical treatments if necessary.

Onychomycosis

Onychomycosis is a mycotic infection within the nail rather than the nail folds and should be treated with antifungal medications for an extended period of time. The classic finding is thickening of the nail itself (hyperkeratosis) from invasion of the fungi. Though antifungal medication such as oral fluconazole 150 mg to 450 mg weekly could be started by the emergency clinician, the long-term nature of the therapy and possible systemic complications makes it more appropriate for a primary care provider to develop the treatment plan.

Felon

Felon is an infection of the pulp space of the fingertip, caused by penetrating trauma such as a diabetic lancet, though often no specific known source is identified (see Fig. 42.53). The fibrous septae of the fingertip create small compartments which restrict swelling, leading to increased pressure, nerve and vascular compression, and then necrosis of the tissue. This explains the severe pain associated with this infection and the increased risk of osteomyelitis and tenosynovitis. Oral antibiotics (cephalexin 500 mg TID for 7 days) and warm soaks can be used when this fingertip infection is at the stage of cellulitis, but when there is an abscess, incision and drainage is necessary. The incision should be along either the lateral side of the tuft, along the flexion crease, just below the nail edge dorsal to the neurovascular bundle and distal to

the DIP joint and pulley system, or midline on the dorsum of the tuft. Incisions to avoid include one around the edge to the tip of the finger and a double longitudinal incision pattern on the same side, because both will destabilize the fingertip.

Herpetic Whitlow

Clinical Features. Herpetic whitlow is a cutaneous herpes simplex virus (HSV) infection seen on the fingers from contact with oral lesions via self-inoculation (thumb sucking) or seen in health care workers such as respiratory therapists from oral care of intubated patients.

Differential Diagnoses. Herpetic whitlow is sometimes confused with a paronychia or felon. Special attention should be given to the presence of vesicular lesions which are not typically seen with a paronychia or felon.

Diagnostic Testing. Diagnosis is made through viral culture or PCR assay of the unroofed lesions.

Management. No antiviral therapy is indicated in immunocompetent patients because the disease is generally self-limited, though oral acyclovir (800 mg BID) or valacyclovir (500 mg BID) for 7 days may be used to decrease the infectivity of those whose infection may cause a risk to others, such as health care workers. If the patient has systemic infectious signs, IV acyclovir may be needed for treatment.[45]

Purulent Flexor Tenosynovitis

Clinical Features. The most common symptom of purulent flexor tenosynovitis is fusiform swelling of the digit, with direct tenderness over the flexor sheath as the most specific finding (Fig. 42.54). The findings described by Dr. Allen B. Kanavel a century ago remain the cardinal symptoms of patients with flexor tenosynovitis (Box 42.4). Diffuse swelling is often labeled the most common sign, however it is very nonspecific. Though both are independent predictors of infectious tenosynovitis, we find that pain with passive extension is a more specific sign compared to tenderness along the tendon sheath as the latter is found in most patients with cellulitis.[45] The EM physician should remain vigilant for patients with tenosynovitis because the initial presentation may be subtle and Kanavel findings are sensitive, but not very specific, for this infectious process. It has been found that direct inoculation is the primary infectious process. Less than 15% of all patients in one review had comorbid conditions, indicating this condition is generally found in immunocompetent hosts.[46]

Differential Diagnoses. One should also consider trigger finger (stenosing tenosynovitis), Dupuytren contracture, tendon injury, inflammatory arthritis, simple cellulitis, or underlying paronychia or felon when evaluating a patient with suspected infectious tenosynovitis.

Diagnostic Testing. Plain films do not appear to distinguish between tenosynovitis and other general hand infections, though they are used to assess for subcutaneous air in the tissue.[47] New studies are demonstrating the use of ultrasound for diagnosis of inflammatory and infectious tenosynovitis; though the specificity is low, the negative predictive value makes this modality useful.[48] The addition of an ESR may help guide the diagnosis as well, though other inflammatory markers were not found to be statistically sensitive.[45]

Management. Skin contaminants of gram-positive bacteria are typical in these infections, making early use of antibiotics appropriate. Initial treatment with vancomycin 10 to 15 mg/kg IV (with subsequent dosing per pharmacy adjusted for renal insufficiency) is appropriate in the emergency department, without waiting for surgical cultures, because early antibiotics use appears to decrease the serious complications associated with this disease. Definitive treatment remains surgical wash-out, so admission for operative management by a hand specialist is necessary. A systematic review showed that IV antibiotics and catheter wash-out, rather than open surgical drainage of the tendon sheath, improved outcomes. The most common outcome noted variable range of motion, which was clearly linked to how early the diagnosis was made in the course of the disease.[46]

Fig. 42.54 Flexor tenosynovitis of the third digit. (Courtesy of Catherine Champagne, DO and Dan Coffey, DO; Central Michigan University COM.)

BOX 42.4 Kanavel Signs

1. Exquisite tenderness over the course of the sheath, limited to the sheath
2. Flexion of the finger
3. Exquisite pain on extending the finger, most marked at the proximal end
4. The whole of the involved finger is uniformly swollen (fusiform swelling)

Deep Space Infections

Clinical Features. Deep space infections of the volar side of the hand are found under the flexor tendons but above the interosseous muscles in the thenar, hypothenar, and mid-palmar spaces. The deep dorsal subaponeurotic space is between the aponeurosis of the extensor tendons and their attachment distally while the interdigital spaces are between the distal metacarpal heads of each digit. Each may present with distinctive complaints due to the involved tendons and muscles that course through and around the spaces. Given the variability of the components of the compartments, there are no classic descriptions of each. Initially, the patient will complain of aching pain and decreased movement of the digits without systemic symptoms.

Differential Diagnoses. Consider compartment syndrome in patients with exceptional swelling, disproportional pain, and neurovascular compromise.

Diagnostic Testing. Ultrasound and MRI are more sensitive than CT scan and often are needed to make the diagnosis early in the course of the disease.[49] For patients who are ill with systemic symptoms with signs such as fever, blood cultures should be obtained prior to antibiotic administration.

Management. The classic infectious organisms include *Staphylococcus aureus* and *Streptococcus* spp. Because there has been an increase in gram-negative and atypical organisms, the use of early broad-spectrum

Fig. 42.55 High-pressure injection injury. (A and B) Index finger following injection of paint thinner. There is a small wound from the paint thinner and associated pallor throughout finger and swelling seen on the lateral view. (C) Following decompression and débridement of right index finger. Return of blood flow is demonstrated. The wound was left open without formal closure. (D and E) Follow-up postoperative pictures showing healed wound and functional range of motion. (Cannon TA. High-pressure injection injuries of the hand. *Ortho Clin N Am*. 2016;47(3):617-624. Fig. 2.)

antibiotics such as vancomycin (10 to 15 mg IV followed by pharmacy dosing) and piperacillin-tazobactam (3.375 g IV q6 hours) can decrease extension of the infection or complications. Early consultation with a hand specialist in the ED is imperative to assist with the decision on whether the patient requires surgical intervention.

Skin and Soft Tissue Disorders

Onycholysis

Onycholysis is the separation of the nail from the nail plate at the distal end and slowly separating more proximally (see Fig. 42.53). The etiology can be as simple as trauma or fungal infection, but consideration should be given to systemic diseases such as thyroid disease, psoriasis, and certain chemotherapeutic agents.[50]

High-Pressure Injury

High-pressure injection injuries occur when a finger is accidentally placed over the nozzle of a paint, oil, water or other high-pressure injector, often when it is being cleaned. Because the injection comes from a small pin, the entrance wound to this injection is unassuming and often the damage underestimated. The caustic chemical injected and the tissue destruction from the high pressure will cause increasing swelling, leading to ischemia. This creates a compartment syndrome, often within the flexor tendon sheath, which will require surgical decompression and wash-out (Fig. 42.55). High-pressure injections of air, water, and some medications do not seem to cause the same severe damage. Management recommendations for the patient in the ED include administering the first dose of IV antibiotics (first- or third-generation cephalosporin such as cefazolin 1 to 2 g IV or ceftriaxone 1 to 2 g IV) and pain control. Any injection injury should have emergent consultation in the ED by the hand specialist, who will determine if exploration of the wound is needed. Surgical débridement, if needed, has been found to decrease the rate of amputation if done within 6 hours.[51]

Ganglion Cysts

In the ED, patients present with cysts due to increased pain, often blamed on acute trauma. Typical ganglion cysts are mobile firm cysts filled with mucin that develop adjacent to joints and tendons, most commonly on the dorsal or volar surface of the wrist. Retinacular ganglion cysts are found on the volar finger at the proximal phalanx or MCP joint and are generally much smaller and less mobile, associated with the first two flexor tendon pulleys. Multiple theories have been formed to explain the development of ganglion cysts, but they do not seem to be related to direct trauma. The dorsal DIP joint ganglion cyst, known as a mucoid cyst, is often associated with osteoarthritis. Mucoid cyst walls are thinner and more likely to erode or rupture, which can lead to infection. These do not appear to connect directly to the joint, so the typical antibiotic treatment for skin infection is adequate.

Aspiration of the cyst may improve the patient's pain symptoms, but there is more than a 50% recurrence rate. Even with the use of ultrasound for guidance in the aspiration of the cyst, there is a high recurrence rate.[52] Surgical removal or excision has a much lower recurrence rate (average 6% noted in a meta-analysis).[53] Given the high recurrence rate and option for surgical removal, we recommend that most ganglion cysts not be aspirated in the emergency department. Injection of corticosteroids into the DIP joint space reduced ganglion cysts without complication but had a 50% recurrence rate[54] and other studies have shown that direct aspiration with injection of steroids had a slightly lower recurrence rate. Historically, these cysts were "popped" through direct compression from a "slap of the family bible." Based on an interesting study using internet videos with survey follow-up, direct blunt force successfully disrupted ganglion cysts and less than 50% had a recurrence at 2-year follow-up.[55]

Fig. 42.56 Dupuytren contracture as demonstrated with typical nodule-like and cordlike changes in the ulnar digits resulting in the characteristic flexion contractures. (Kelly B Isaacs JE. Dupuytren contracture. In: Miller MD, Hart JA, MacKnight JM. *Essential Orthopaedics*, ed 2. Philadelphia: Elsevier; 2020:341-344. Fig 88.2. Courtesy of Bobby Chhabra, MD.)

Dupuytren Contracture

Dupuytren contracture is the result of fibrosis of the palmar fascia which causes the tightening of an area of fascia, creating a cord that limits the motion of a specific finger or area of the palm. In the ED, diagnosis can be made based on the clinical findings as shown in the Figure 42.56. Treatment is limited to appropriate referral to a hand specialist who may use percutaneous needle aponeurotomy, collagenase injections, or open surgery to treat this contracture.[56]

CHAPTER 42: QUESTIONS AND ANSWERS

1. Which of the following demonstrates the motor function of the median nerve?
   - **a.** Extending the hand at the wrist
   - **b.** Making an "OK" sign with the thumb and first finger
   - **c.** Pulling the thumb across the palm to touch the little finger
   - **d.** Spreading out the fingers of the hand

Answer: B. Making an "OK" sign with the thumb and first finger. The median nerve controls the flexors of the thumb and index finger that allow the hand to make the "OK" sign. The ulnar nerve innervates the adductor pollicis that pulls the thumb across the palm so it can touch the little finger and innervates the interosseous muscles to allow the hand to spread out or abduct the fingers. The radial nerve innervates the extensor carpi radialis longus and the other wrist extensors.

2. A 25-year old woman comes to the emergency department complaining of hitting the tip of her finger on a basketball. She has difficulty extending the tip of her ring finger. What is the most appropriate splinting technique for this injury?
   - **a.** Aluminium volar splint with finger in position of function
   - **b.** Dorsal blocking splint with DIP at 15 degrees of flexion
   - **c.** Stack splint with extension of distal phalanx
   - **d.** Ulnar gutter splint to include ring finger to the tip

Answer: C. Stack splint with extension of distal phalanx. The description of the injury is consistent with a mallet finger injury, where the distal extensor tendon has pulled off the proximal end of the distal phalanx. The premolded Stack splint keeps the distal phalanx in extension and can remain in place for 6 weeks for healing. The position of comfort for the finger in an aluminium volar splint is with the PIP and DIP at approximately 10 to 15 degrees of flexion, not complete extension as needed to allow the tendinous insertion to reattach. A straight aluminium splint could be used on the dorsal surface of the finger to keep the DIP joint straight. A dorsal blocking splint is used for flexor tendon lacerations or ruptures, preventing any extension in the digit and hand to decrease the contraction of the flexor tendon, which will increase the extensor tendon strain. The ulnar gutter splint provides much more extensive immobilization than is necessary for this injury.

3. After cutting her hand while washing a drinking glass, a patient complains of a laceration to her finger. In which location of the palmar hand surface is this laceration most likely to cause a lack of flexion to the index finger PIP joint?
   - **a.** Base of the thenar eminence
   - **b.** Distal end of the middle phalanx
   - **c.** Proximal end of the proximal phalanx
   - **d.** Volar crease of the MCP joint

Answer: D. Volar crease of the MCP joint. The flexor digitorum superficialis (FDS) functions to flex the finger at the PIP joint. It attaches at the proximal end of the middle phalanx as well as the distal end of the proximal phalanx. A laceration along the volar crease of the MCP joint will cut the FDS tendon when the fingers are in extension and reduce the flexion of the PIP joint. The flexor digitorum profundus (FDS) inserts at the proximal end of the distal phalanx. Cutting the finger from the mid aspect of the middle phalanx distally results in an injury to the FDP and an inability to flex at the DIP joint. There are no tendons running within the thenar webspace.

4. Which of the following is the most disease-distinguishing finding of a patient with pyogenic flexor tenosynovitis?
   - **a.** Involved finger is held in flexion
   - **b.** Pain on extension of the finger
   - **c.** Tenderness over the tendon sheath
   - **d.** Uniform swelling of the involved finger

Answer: B. Pain on extension of the finger. All of these findings are components of Kanavel's findings for infectious tenosynovitis. Even though uniform involved swelling has been listed as the most common sign in some studies, this is misleading as swelling is the most common sign in many hand problems and is very nonspecific. What most commonly separates purulent flexor tenosynovitis from other finger infections is pain with passive extension. Many patients with even just cellulitis have pain with palpation over the area of infection on the finger, so this does not distinguish it well. Only half of the patients diagnosed with pyogenic flexor tenosynovitis have all of Kanavel's findings.

5. A patient presents after a fist fight with a puncture wound to his hand. Which description of the presentation has the best prognosis?
   - **a.** Fingertip penetration
   - **b.** Delay in treatment
   - **c.** Depth of the wound
   - **d.** Involvement of joint

Answer: A. Fingertip penetration. The three factors that have been found to worsen the prognosis for a "fight bite" injury are delay in identification and treatment of the wound, an increase depth of the wound as it is more likely to include the tendon, and intrusion into the joint of the tooth. A puncture wound of the fingertip is much less likely to create a significant infection due to the close septae that decrease the likelihood of spreading bacteria in an open wound.

43

Wrist and Forearm Injuries

Vanessa S. Franco and Hyung T. Kim

KEY CONCEPTS

- On plain radiographs of the wrist, three distinct arcs, known as *Gilula's lines*, and equal spacing between carpus bones (1–2 mm), known as *parallelism*, assist in the radiographic diagnosis of carpal injuries.
- In the setting of trauma, there is a high incidence of occult fractures and soft tissue injuries of the wrist. Because of the associated risk of malunion, nonunion, posttraumatic arthritis, and avascular necrosis (AVN), splint immobilization is recommended if pain persists despite normal appearing radiographs.
- Routine wrist radiographs which include anteroposterior (AP), lateral, and oblique projections, may fail to detect scaphoid fractures.
- Thumb spica immobilization is recommended for suspected scaphoid and other carpal fractures. Expedited orthopedic follow-up for repeat assessment, radiographs, or advanced imaging (e.g., MRI, CT, or bone scan) is indicated.
- Triquetral dorsal chip fractures are best seen on the standard lateral view of the wrist as a small avulsion fracture fragment, although a more oblique pronated lateral view may be necessary to visualize these types of fractures.
- Hamate and pisiform fractures are best visualized with a carpal tunnel or reverse supinated oblique radiograph.
- Lunate dislocations result in a characteristic triangular appearance of the lunate on the posteroanterior (PA) view (commonly referred to as the "piece of pie" sign) owing to rotation of the lunate in a volar direction. This rotation also is visible on the lateral view of the wrist, where the lunate appears like a cup tipped forward, spilling its contents into the palm (referred to as the "spilled teacup" sign).
- A Colles fracture is a transverse fracture of the distal radial metaphysis, which is dorsally displaced and angulated. The Smith fracture is a transverse fracture of the metaphysis of the distal radius, with associated volar displacement and angulation.
- Ulna fractures associated with radial head dislocation are commonly known as Monteggia fractures. Galeazzi fractures refer to fractures of the middle to distal third of the radius associated with injury to and dislocation of the distal radial ulnar joint (DRUJ).

WRIST

FOUNDATIONS

Anatomy, Physiology, and Pathophysiology

The wrist joint is broadly defined as the anatomic area from the distal radius and ulna bones of the forearm to the carpometacarpal junctions of the hand. It is anatomically and biomechanically complex, allowing for diverse functional capabilities. The wrist is composed of many complex articulations, including the radiocarpal, midcarpal, and distal radial ulnar joints (DRUJs), allowing for flexion, extension, abduction (radial deviation), adduction (ulnar deviation), and circumduction movements. Pronation and supination of the hand are primarily movements of the forearm occurring at the proximal radial ulnar joint and DRUJ.

The wrist includes the distal radius, ulna, and eight carpal bones, which are arranged in two transverse rows and are commonly referred to as the carpus (Fig. 43.1). Each carpal row contains four bones. The more mobile, proximal row, listed radial to ulnar, consists of the scaphoid, lunate, triquetrum, and pisiform bones and the distal row consists of the trapezium, trapezoid, capitate, and hamate bones.

The radius has three articular surfaces at the wrist—radiocarpal joint, DRUJ, and an interface with the triangular fibrocartilage complex (TFCC), also known as the articular disk. The distal radius articulates directly with the carpus via the scaphoid and lunate bones, which forms the common wrist joint. The ulna is separated from direct articulation with the proximal carpal row by the TFCC. The articular disk binds the distal ends of the radius, ulna, lunate, and triquetrum together. The DRUJ is a synovial pivot where the distal radius articulates and rotates around the relatively fixed ulna, and this joint is primarily stabilized by the TFCC.

Aside from the pisiform, a sesamoid bone embedded within the flexor carpi ulnaris (FCU) tendon, the carpal bones are lined by synovium that creates a continuous capsule throughout the intercarpal joints, distally to the metacarpal articulations. The only muscular insertions that occur throughout the carpus are the origin of the abductor digiti minimi from the pisiform, and the point at which the FCU tendon inserts onto the hook of the hamate. As a result, nearly all carpal bone movements are passive, based on muscular insertions on the distal radius, ulna, and metacarpal bases.

The stabilizing ligaments of the wrist are divided into two major groups, the intrinsic and extrinsic ligaments. The intrinsic ligaments interconnect the individual carpal bones, and the extrinsic ligaments link the carpal bones to the distal radius, ulna, and metacarpals. The intrinsics are named for the adjacent bones to which they connect; the most important for maintaining carpal stability are the scapholunate and lunotriquetral ligaments. The extrinsics are divided into volar and dorsal groups. The volar extrinsic ligaments are thicker and stronger than the dorsal extrinsic ligaments and are the most important in providing stability to the wrist. Between two volar ligaments over the proximal capitate, there is an area relatively devoid of ligamentous support, called the *space of Poirier*. This space enlarges when the wrist is dorsiflexed, and an injury to the joint capsule in this region can result in significant carpal instability (Fig. 43.2).

Most structures that cross the wrist joint are contained within individual compartments formed by the deep fascia of the wrist. On the dorsal surface of the wrist, the extensor tendons are divided by the extensor retinaculum into six compartments, each having a separate

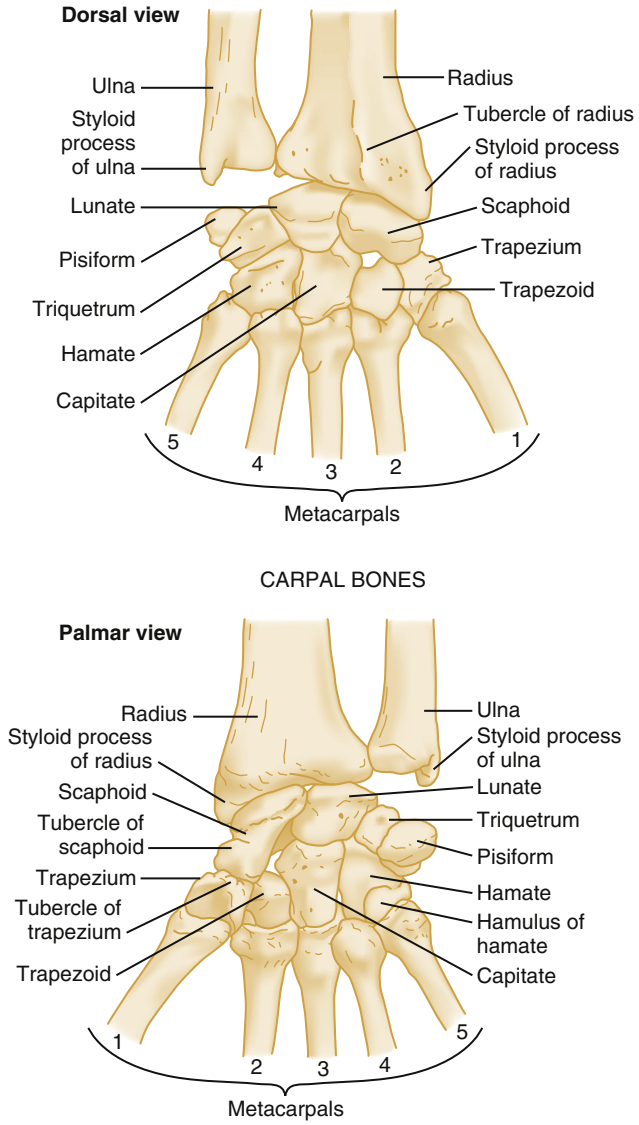

Fig. 43.1 Bones of the Wrist. The wrist joint includes the distal articular surfaces of the radius and ulna and the proximal and distal carpal rows. (Adapted from Netter FH. *Atlas of human anatomy*. 3rd ed. Teterboro, NJ: Icon; 2003.)

synovial sheath that extends proximally and distally to the retinaculum. On the volar surface of the wrist, the flexors of the digits and median nerve are contained within the carpal tunnel, which is formed by the flexor retinaculum superficially and its attachments to the carpal bones. Radially, the flexor retinaculum attaches to the scaphoid tubercle and ridge of the trapezium. On the ulnar side, it attaches to the pisiform and hook of the hamate. Both the trapezoid and capitate bones form the floor of the carpal tunnel. Radially and superficially to the carpal tunnel, the flexor carpi radialis tendon crosses the wrist joint in its own compartment.

The vascular supply to the wrist is provided by the radial and ulnar arteries, which join in a series of dorsal and palmar arches to supply the bones of the carpus. The intrinsic blood supply to most carpal bones enters the distal portion, leaving the proximal area, placing them at risk for devascularization and avascular necrosis (AVN) when fractured. This is particularly true for the scaphoid, capitate, and lunate bones, which receive their blood supply commonly from a single distal vessel (Fig. 43.3).

The wrist and hand are innervated by the radial, median, and ulnar nerves. The radial nerve and dorsal sensory branch of the ulnar nerve cross the dorsum of the wrist near the radial and ulnar styloids, respectively. The median nerve crosses within the carpal tunnel on the volar aspect of the wrist, just radial and deep to the palmaris longus tendon. The ulnar nerve is contained within *Guyon canal*, between the pisiform and hook of the hamate (see Fig. 43.3). In the setting of trauma, motor and sensory function of the radial, median, and ulnar nerves can be clinically assessed at the wrist and distally, based on their anatomical innervations (Table 43.1).

CLINICAL FEATURES

The clinical examination of the patient with a wrist injury begins with a history focusing on the mechanism of injury and location of pain. The physical examination begins with inspection of the wrist, with the opposite uninjured wrist used as the normal reference. The range of motion, and the presence of swelling, discoloration, or obvious deformity should be noted.

Several bony prominences serve as useful landmarks; their locations are best described in relation to the lateral and medial reference points in the wrist, the radial and ulnar styloids, respectively. Just distal to the radial styloid is the *anatomic snuffbox*, bordered radially by the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons, and ulnarly by the extensor pollicis longus (EPL) tendon. The body of the scaphoid is palpable within the snuffbox and is more prominent with ulnar deviation of the wrist. *Lister tubercle* can be palpated on the dorsum of the wrist, just ulnar to the radial styloid. The scapholunate joint lies just distal to the tubercle and is a common site of ligamentous injury in the wrist. With the wrist in a neutral position, the capitate is palpable in a small depression found midway between the base of the middle metacarpal and Lister tubercle. Bringing the wrist into flexion can bring the lunate forward into a palpable position at this same site. Lister tubercle divides the second and third dorsal extensor compartments of the wrist and is also used as a primary landmark for radiocarpal arthrocentesis. On the dorsal aspect of the wrist in the ulnar direction from Lister tubercle is the DRUJ. The triquetrum is palpable distal to the ulnar styloid in the proximal carpal row and is made more prominent with radial deviation of the wrist.

On the volar aspect of the wrist, the scaphoid tubercle is palpable just distal and palmar to the radial styloid. It is felt as a rounded prominence at the base of the thenar muscles and is more prominent when the wrist is extended. On the ulnar border of the wrist, the pisiform is palpable at the base of the hypothenar muscles, just distal to the wrist crease. In addition, approximately 1 cm distal and radial to this point, the prominence formed by the hook of the hamate can be palpated. Radial and ulnar pulses are easily palpable on the volar surface of the wrist, and the presence of adequate circulation should be assessed with all wrist injuries.

DIFFERENTIAL DIAGNOSES

Differential diagnoses for wrist pain depend on the mechanism of injury and the location of pain. A patient presenting with acute traumatic ulnar-sided wrist pain should raise suspicion for fracture of the distal ulna and the adjacent carpal bones (including the hamate, triquetrum, lunate, and pisiform). Pisiform or hamate fractures may cause ulnar artery or nerve damage, so ulnar artery pulse and ulnar nerve function should be tested. Extensor carpi ulnaris (ECU) tendinopathy is another cause of ulnar-sided wrist pain, and may be associated with substantial pain, erythema, and tenderness with range of motion. Tenderness over the TFCC and pain with axial loading of the TFCC suggests TFCC injury. DRUJ instability should also be considered in patients with ulnar-sided wrist pain as well as the

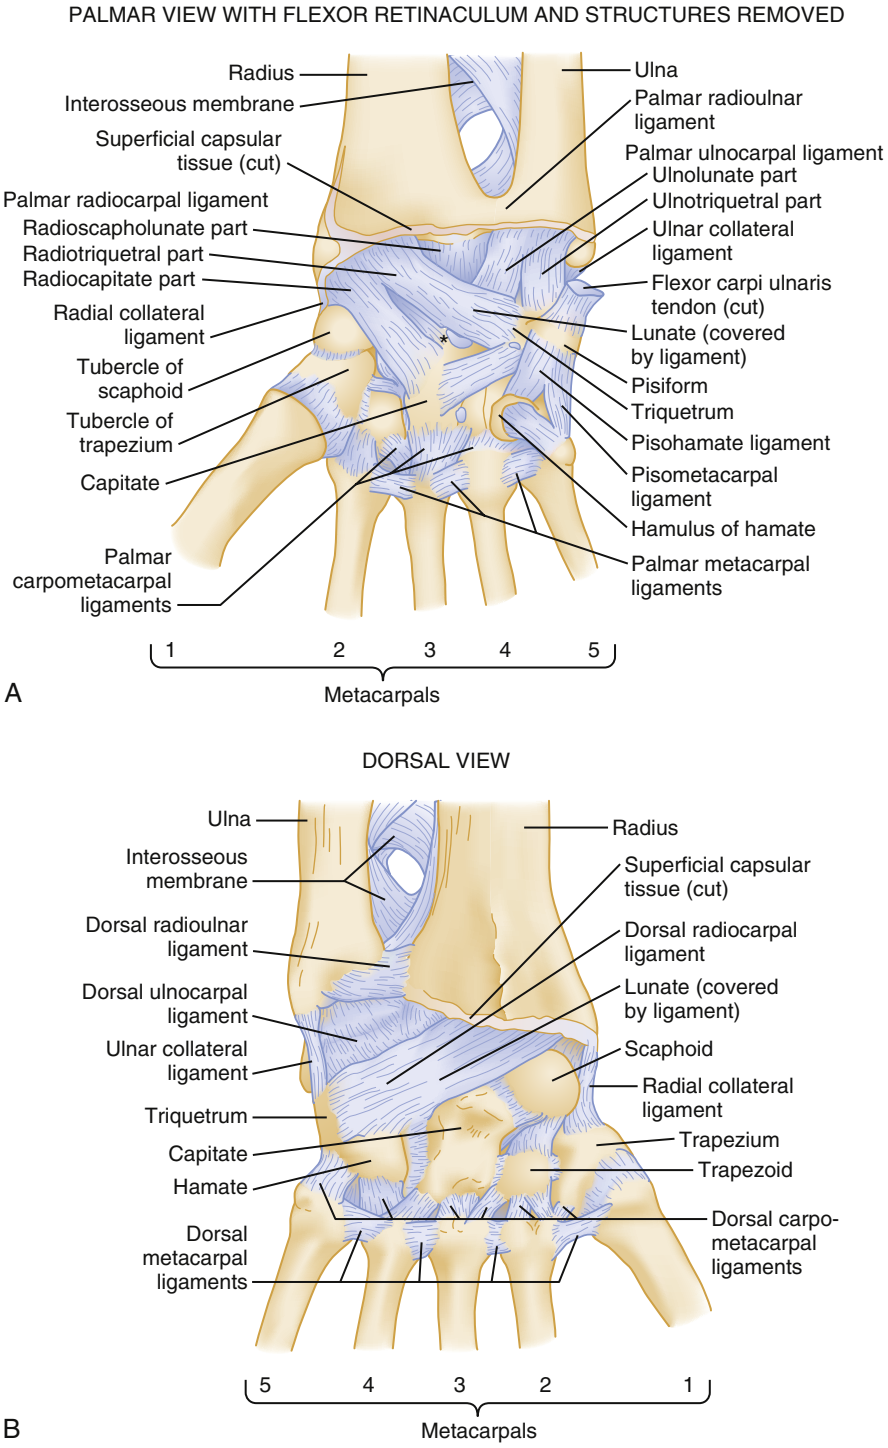

Fig. 43.2 Ligaments of the Wrist. (A) The volar extrinsic ligaments are most important in providing stability to the wrist. These include the radial collateral, radiocapitate, radioscaphoid, radiotriquetral, ulnotriquetral, capitotriquetral, and ulnar collateral ligaments. The space of Poirier (*) is a gap in the volar ligaments and the site of potential weakness. (B) The intrinsic (intercarpal) ligaments connect the individual carpal bones. The most important of these are the scapholunate and lunotriquetral ligaments. (Adapted from Netter FH. *Atlas of human anatomy*. 3rd ed. Teterboro, NJ: Icon; 2003.)

hypothenar hammer syndrome (caused by a single or repetitive blunt impact on the hypothenar eminence with injury to the hook of the hamate resulting in thrombosis of the superficial palmar arch of the ulnar artery).

Acute, traumatic radial-sided wrist pain is concerning for a scaphoid fracture, as suggested by tenderness over the scaphoid or anatomic snuffbox. Fractures of the distal radius and other adjacent carpal bones should also be considered (such as the trapezium and trapezoid). Patients with *de Quervain tenosynovitis* exhibit radial-sided wrist pain associated with overuse. Examination classically reveals tenderness over the radial styloid and a positive *Finkelstein test* (described later in the chapter). Tenderness to palpation more

TABLE 43.1 Median, Radial, and Ulnar Nerve Innervations and Clinical Examination

Parameter	Median	Radial	Ulnar
Innervation	Pronator teres	Brachioradialis	Flexor carpi ulnaris
	Flexor carpi radialis	Extensor carpi radialis longus	Flexor digitorum profundus
	Palmaris longus	Extensor carpi radialis brevis supinator	Opponens digiti minimi
	Flexor digitorum superficialis	Extensor digitorum	Abductor digiti minimi flexor
	Flexor digitorum profundus	Extensor digiti minimi	Lumbricals 3 and 4
	Flexor pollicis longus	Extensor carpi ulnaris	Dorsal interossei
	Prone for quadrates	Abductor pollicis longus	Palmar interossei
	Opponens pollicis	Extensor pollicis longus	Adductor pollicis
	Adductor pollicis	Extensor pollicis brevis	Palmaris brevis
	Superficial head FPB	Extensor indicis	Superficial head FPB
Motor	Thumb opposition	Wrist extension	Finger abduction
	Pincer function (thumb, index finger)	Finger extension	Finger abduction
	Pronation	Supination	
	"A-OK" sign	"Thumbs-up" sign	
Sensory	*Sensation*	*Sensation*	*Sensation*
	Index finger, volar tip	First dorsal web space	Little finger, volar tip
	Volar	Dorsal	Volar dorsal

proximal to the radial styloid suggests intersection syndrome. Pain or instability with axial loading, manipulation, and palpation of the carpometacarpal (CMC) joint indicates CMC joint pathology such as arthritis or subluxation.

Many wrist injuries may cause pain in the dorsal or volar wrist. Fracture or dislocation of any of the carpal bones, the distal radius, or the distal ulna may cause dorsal-sided or volar-sided wrist pain. Perilunate or lunate dislocations may also present with dorsal- or volar-sided wrist pain and instability. Ganglion cysts often cause dorsal or volar wrist pain and may not always be visible or palpable on examination.

Traumatic isolated dorsal-sided wrist pain should raise concern for scapholunate dissociation, as this injury is often missed. The *Watson shift test* combined with dedicated clenched fist radiographs are useful in assessing for this injury. Triquetral fractures, dislocations, or even fractures to the base of the third metacarpal may also cause dorsal-sided wrist pain following trauma. *Kienbock disease*, or AVN of the lunate, is suggested by tenderness and swelling over the lunate. In the setting of overuse, intersection syndrome and wrist extensor tendinitis should be considered in patients with dorsal-sided wrist pain, while *carpal tunnel syndrome* and wrist flexor tendinitis would typically cause volar-sided wrist pain.

Gross deformity, swelling, and pain of the entire wrist should raise concern for radiocarpal dislocation. Arthritis and wrist sprains should be considered in differential diagnoses for patients presenting with

wrist pain in any location, but these conditions are largely a diagnosis of exclusion.

DIAGNOSTIC TESTING

Plain radiographs remain the cornerstone of emergent diagnosis of trauma to the wrist. Routine radiographic views include the posteroanterior (PA), lateral, and oblique projections each obtained with the wrist in neutral position.

On a correctly positioned PA view of the wrist, the ulnar styloid rises from the lateral aspect of the distal ulna; the ECU tendon groove should be visualized at, or radial to, its base. The radial styloid process extends beyond the end of the articular surface of the ulna by a normal distance of 9 to 12 mm. This normal difference in length is called the radial length measurement (Fig. 43.4). There may be some degree of ulnar variance that affects the radial length measurement on a PA radiograph. The distal articular surface of the ulna may terminate proximal or distal to the radiolunate articulation as a result of wrist rotation, flexion, extension, anatomic variation, or injury. Neutral ulnar variance (as seen in Fig. 43.4) is described when the distal ulnar and radiolunate articular surfaces terminate at the same point. A positive ulnar variance (ulnar articulation is more distal) or negative ulnar variance (ulnar articulation is more proximal) is independent of styloid size and may be associated with wrist pathology (e.g., ulnar impaction syndrome and Kienbock disease, respectively). The ulnar slant of the articular surface of the radius, referred to as radial inclination, is visible on the PA view and normally measures 15 to 25 degrees (see Fig. 43.4). Both of these measurements are important in assessing the degree of radial shortening seen in association with some fractures of the distal radius. The normal appearance of the carpus on the PA view shows an approximately equal distance (usually 1 to 2 mm) between each of the carpal bones, and opposing articular surfaces are parallel to one another (an arrangement known as *parallelism*). On radiographs, three smooth curves normally can be drawn along the carpal articular surfaces, known as carpal or *Gilula arcs* (Fig. 43.5). Disruption of these curves or widening of the carpal spaces is an indication of carpal ligament disruption, instability, or fracture.

The normal volar tilt of the distal radial articular surface is visible on the lateral view of the wrist and typically measures 10 to 25 degrees (Fig. 43.6). Adequacy of a lateral view of the wrist is assessed based on the relationship among the scaphoid, pisiform, and capitate (S-P-C) projections. The palmar cortex of the pisiform should project midway between the palmar margins of the distal pole of the scaphoid and capitate head, forming the S-P-C lateral (Fig. 43.7). The normal alignment of the distal radius with the lunate and capitate also is seen on the lateral view, which will show two concentric cups—the cup of the distal radius containing the lunate and the cup of the distal lunate containing the capitate. Ideally, the long axis of the radius, lunate, capitate, and third metacarpal should appear as a straight line on the lateral view, although the so-called normal alignment usually is within 10 degrees of this line (Fig. 43.8). The carpal alignment on the lateral view is defined further by the scapholunate angle, which should measure 30 to 60 degrees, and capitolunate angle, which is 0 to 30 degrees (Fig. 43.9). Abnormalities in these angles are seen in patients with carpal ligament injuries and instability.

The soft tissues of the wrist also offer valuable clues to the presence of underlying bony injuries. On most normal lateral radiographs of the wrist, the pronator quadratus line is visible as a linear, lucent, fat collection in the volar soft tissues just anterior to the distal radius (Fig. 43.10). Fractures of the distal radius or ulna result in a pronator quadratus sign representing volar displacement, anterior bowing, or complete obliteration of this line. This sign has a higher specificity than sensitivity for occult fracture, so its absence does not exclude a fracture.[1,2] A positive pronator quadratus sign has also been observed in soft tissue injuries and infectious and inflammatory conditions.

Many wrist injuries are occult and may not be identified or clearly characterized by routine wrist radiographs. Additional radiographic imaging of the wrist may assist the emergency clinician with diagnosis based on the mechanism of injury and physical examination

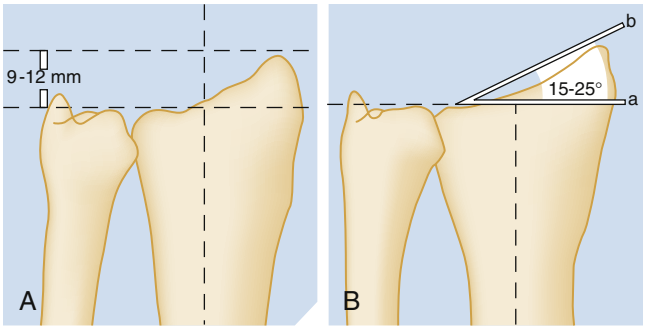

Fig. 43.4 Normal Radiographic Appearance of the Wrist on a Posteroanterior View. The ulnar styloid arises from the lateral aspect of the distal ulna, and the tendon groove for the extensor carpi ulnaris should be visualized at, or radial to, its base. (A) Radial length measurement with neutral ulnar variance. The radial styloid extends 9 to 12 mm beyond the articular surface of the distal ulna. The ulna may terminate distal, at, or proximal to, the radiolunate articulation affecting radial length measurement with a positive, neutral, or negative variance, respectively. (B) The ulnar slant of the distal radius (angle ab) normally measures 15 to 25 degrees. (From Greenspan A. *Orthopedic radiology: a practical approach.* 2nd ed. New York: Gower Medical; 1992.)

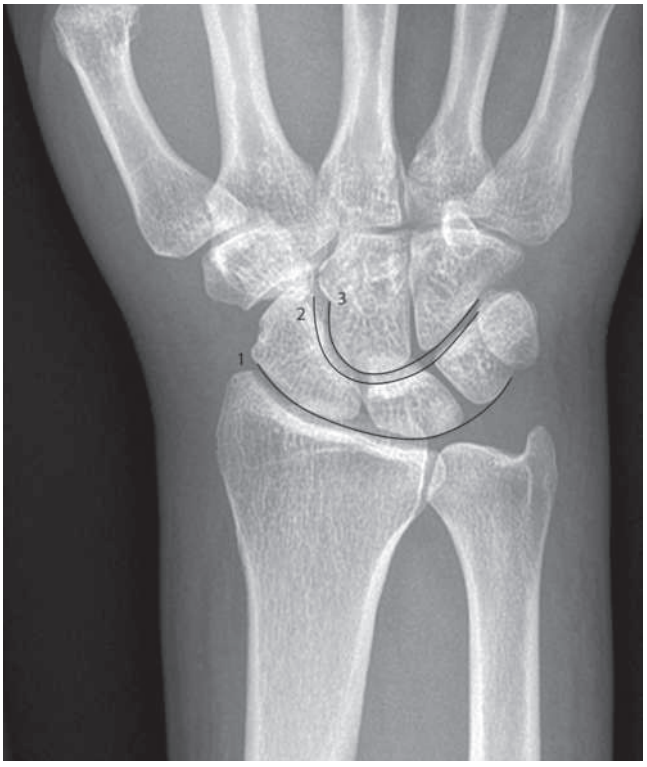

Fig. 43.5 Carpal *(Gilula's)* Arcs. On a posteroanterior radiograph of the wrist, three arcuate lines (1 to 3) can be drawn along the articular surfaces. Although small indentations at joint lines may occur, a step-off or broken arc suggests fracture, ligamentous instability, or disruption of the wrist.

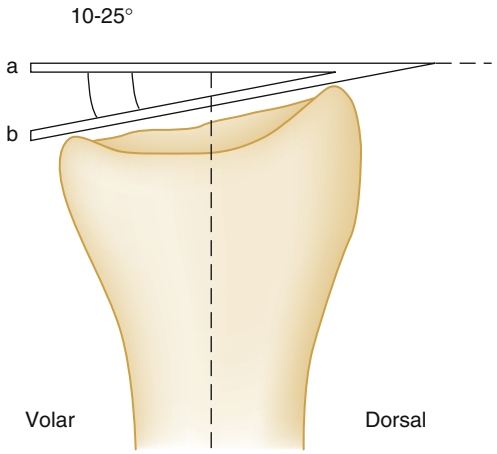

Fig. 43.6 Normal Radiographic Appearance of the Wrist on a Lateral View. The distal radius has a normal volar tilt (angle ab) of 10 to 25 degrees. (From Greenspan A. *Orthopedic radiology: a practical approach*. 2nd ed. New York: Gower Medical; 1992.)

Fig. 43.7 Normal S-P-C (Scaphoid-Pisiform-Capitate) Lateral View of the Wrist. The palmar cortex of the pisiform *(P)* is shown bisecting the line between the palmar aspect of the scaphoid *(S)* and capitate *(C)* bones.

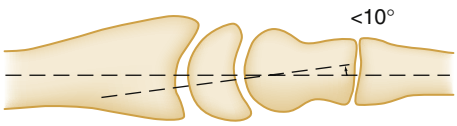

Fig. 43.8 Normal Relationship of Carpal Bones on a Lateral Radiographic View. The concavity of the radius and lunate and convexity of capitate form three C-shaped areas *(stippled)* along a straight line that runs through the central axis of these bones.

findings, including specific areas of tenderness. In addition to the standard PA, lateral, and oblique wrist radiographs, emergent patient-specific imaging helps delineate otherwise occult fractures or abnormal motion of the carpus resulting from ligamentous injuries. When a scaphoid fracture is suspected, a pronated ulnar deviated view of the wrist allows for better visualization of the bone along its long axis. The carpal tunnel view is performed with the wrist hyperextended and provides an axial volar image of bony margins. A hook of the hamate fracture is often radiographically occult and is better assessed with a dedicated carpal tunnel view. The carpal tunnel and reverse (supinated) oblique views help identify fractures involving the hook of the hamate and pisiform secondary to hypothenar wrist trauma. The clenched fist views drive the capitate proximally, causing diastasis within the scapholunate joint if ligamentous instability is present (Table 43.2).

MANAGEMENT AND DISPOSITION

There is a high incidence of radiographically occult wrist fractures. Thus, when radiographs are normal but significant localized pain persists, immobilization and a repeat examination should be arranged within 1 week. A thumb spica should be applied in the setting of suspected scaphoid fractures with orthopedic reassessment in 1 week. Occult fractures or soft tissue injuries may be diagnosed emergently, urgently, or on a routine basis with advanced computed tomography (CT) or magnetic resonance imaging (MRI) imaging protocols.[3,4] Although advanced imaging occasionally identifies an otherwise occult injury, emergent CT or MRI wrist imaging is rarely indicated in the emergency department (ED) in lieu of splinting and arranging for orthopedic follow-up, unless expedited outpatient orthopedic follow-up is not possible.

Carpal Injuries

Scaphoid Fractures

Foundations. Scaphoid fractures often occur after a fall on the outstretched hand, causing hyperextension of the wrist. These injuries are rare in skeletally immature patients because the carpus is composed entirely of cartilage at birth and remains predominantly cartilaginous until the adolescent years. Although the physis of the radius is more susceptible to injury, scaphoid fractures (with and without radial fracture) have been observed in pediatric patients. In older adults, a distal radius metaphysis fracture is more likely to occur. Scaphoid fractures are classified by their anatomic location and may be divided into three groups—fractures of the tuberosity and distal pole, waist, and proximal pole. Of these three patterns, fractures through the waist of the scaphoid are the most common (Fig. 43.11).

Clinical features. Patients typically report radial-sided wrist pain distal to the radial styloid with decreased range of motion of the wrist and thumb. The physical examination reveals tenderness with palpation of the scaphoid, often within the anatomic snuffbox. For scaphoid tenderness to be elicited, a combination of maneuvers can be performed, including ulnar deviation, palpation of the scaphoid tubercle volarly, a *Watson scaphoid shift test*, axial compression of the first metacarpal, resisted supination of the wrist, and a positive *clamp sign* (subjective radial pain caused by a thumb-index finger pinch on both sides of the wrist). Except for the absence of snuffbox tenderness, physical examination findings lack accuracy to effectively diagnose or exclude scaphoid fractures, and no validated clinical decision rules exist.

Diagnostic testing. Radiographic imaging remains the cornerstone for the evaluation of acute wrist trauma, but radiographic diagnosis of scaphoid fractures is challenging. An additional ulnar-deviated PA

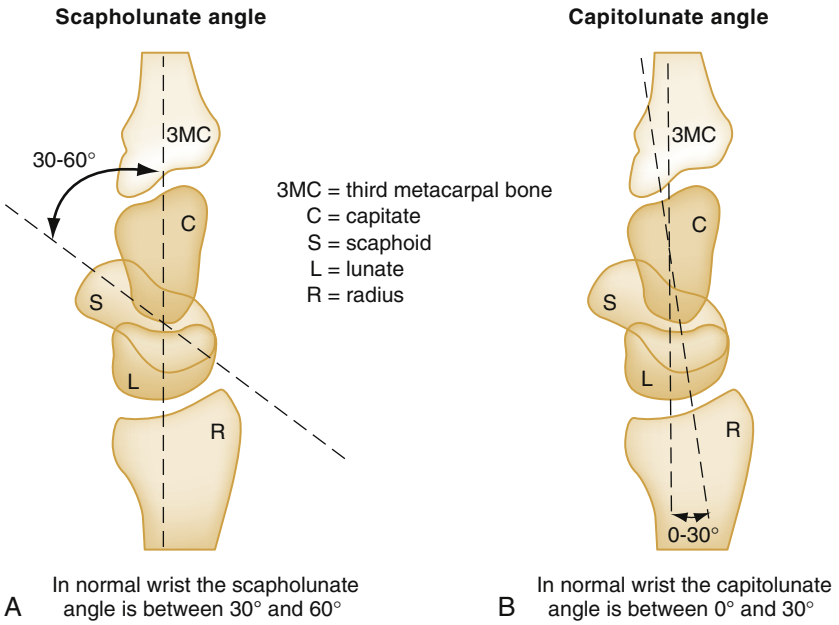

Fig. 43.9 (A) The normal scapholunate angle is formed by the intersection of the longitudinal axes of the scaphoid and lunate and normally measures 30 to 60 degrees. (B) The normal capitolunate angle is formed by the intersection of the capitate and lunate central long axes and normally measures 0 to 30 degrees. (From Greenspan A: Orthopedic radiology: a practical approach, ed 2, New York, 1992, Gower Medical.)

Fig. 43.10 The Pronator Quadratus Fat Pad. (A and B) A narrow fat stripe *(arrow)* located on the volar surface of the radius is seen on the lateral view of the wrist. Although not highly sensitive, volar displacements, anterior bowing, or complete obliteration of this line caused by hematoma in the setting of trauma is suggestive of wrist injury or fracture.

view of the wrist may assist with fracture visualization. A visible bony lucency or cortical disruption may be absent, and a more subtle change, such as bowing, obliteration, or displacement of the scaphoid fat pad may be the only visible clue that a wrist injury is present. However,

TABLE 43.2 Additional Radiographic Wrist Views

Radiographic View	Benefit
Clenched fist (AP or PA)	Exposes scapholunate ligament injury; pushes capitate into proximal carpal row
Scaphoid (PA with ulnar deviation)	Elongates scaphoid; exposes wrist fractures
Carpal tunnel and reverse supinated oblique	Identifies fractures involving hamate and pisiform; identifies bony encroachment onto carpal tunnel

AP, Anteroposterior; *PA,* posteroanterior.

these signs are not reliably present, and plain radiographs obtained soon after injury may fail to detect a distinct fracture.

While bone scintigraphy has the highest sensitivity for scaphoid fractures, this modality suffers from a lower specificity, resulting in a large number of false positives.[4] There is some evidence suggesting ultrasound may be more accurate in diagnosing scaphoid fractures than X-ray,[5] but other studies show mixed results.[6,7] Thus, ultrasonography may be a useful adjunct for the diagnosis of scaphoid fractures for those clinicians with sonographic proficiency, but this method still requires external validation. CT and MRI imaging permit the diagnosis of most radiographically occult scaphoid fractures. Despite its high cost and variable availability, MRI has greater sensitivity for diagnosing scaphoid fractures and soft tissue injuries than CT.[3] Despite extensive studies and multiple adjunct imaging modality options, emergent advanced CT or MRI protocols to rule out scaphoid fractures remain investigational and we do not recommend their routine use in the ED.

Management and disposition. To avoid complications associated with delayed diagnosis, such as occult fracture displacement and AVN, patients with suspected scaphoid fracture should have thumb spica immobilization placed in the ED with orthopedic follow-up within

Fig. 43.11 Scaphoid Wrist Fracture. A posteroanterior view of the wrist in ulnar deviation (scaphoid view) illustrates a nondisplaced fracture of the scaphoid waist *(arrow)*.

Fig. 43.12 Short Arm, Thumb Spica Splint. Common immobilization technique used for occult fractures of the scaphoid bone seen in a volar view. Note the optimal 10 degrees of wrist flexion and radial deviation, which assists in scaphoid immobilization.

Fig. 43.13 Avascular Necrosis of the Scaphoid Bone. A common complication of scaphoid fractures is avascular necrosis as a result of the distal to proximal osseous blood supply, displacement, or nonunion, resulting in chronic wrist pain and arthritis.

1 week. Recent evidence has questioned the practice of immobilizing the wrist in all patients with suspected scaphoid fractures, instead suggesting that the emergent use of advanced imaging modalities is more accurate and cost-effective. The cost of time off work, serial casting, repeat physician evaluation, and office visits was found to exceed that of advanced imaging for definitive diagnosis when these imaging modalities are readily available.[8] A recent trial in the United Kingdom demonstrated improved cost savings, diagnostic accuracy, and patient satisfaction associated with immediate MRI in patients with clinically suspected scaphoid fracture with normal radiographic imaging.[9] Importantly, the outcomes of these trials vary depending on MRI cost and accessibility. At this time, we advise thumb spica immobilization with urgent orthopedic follow-up within 1 week for any patient with clinically suspected scaphoid fracture and normal radiographs.

The definitive treatment for uncomplicated, nondisplaced distal pole and nondisplaced waist scaphoid fractures depends on various factors, although screw fixation portends a faster recovery time.[10,11] There is no current consensus as to whether the thumb should be included in the splint, but clinical trials are ongoing. Most surgeons terminate the thumb spica at the interphalangeal joint line. Some specialists use a long arm (above the elbow) cast or splint, which prevents wrist pronation and supination for the first few weeks, while others prefer short arm immobilization. In addition to flexion and extension, pronation and supination may produce fracture displacement in the proximal carpal row. We advise immobilization in a thumb spica short arm splint with urgent follow-up with an orthopedic specialist within 1 week (Fig. 43.12). The duration of total immobilization will vary relative to the location of the fracture. More proximal fractures commonly require longer durations to ensure adequate healing. Variability in healing time is related directly to the pattern of blood supply to the scaphoid, which flows from the distal to proximal portion of the bone through the scaphoid tuberosity. This pattern of blood flow also accounts for the higher incidence of AVN and nonunion seen in more proximal fractures (Fig. 43.13). As a result of these complications, scaphoid fractures require urgent orthopedic referral.

Lunate fractures

Foundations. Fractures of the lunate are relatively uncommon. This injury tends to occur in persons with a congenitally short ulna.

Clinical features. Patients will experience pain over the dorsum of the wrist, exacerbated by axial loading of the long finger metacarpal. On physical examination, tenderness may be elicited by palpation over the dorsum of the wrist in the depression felt just distal to

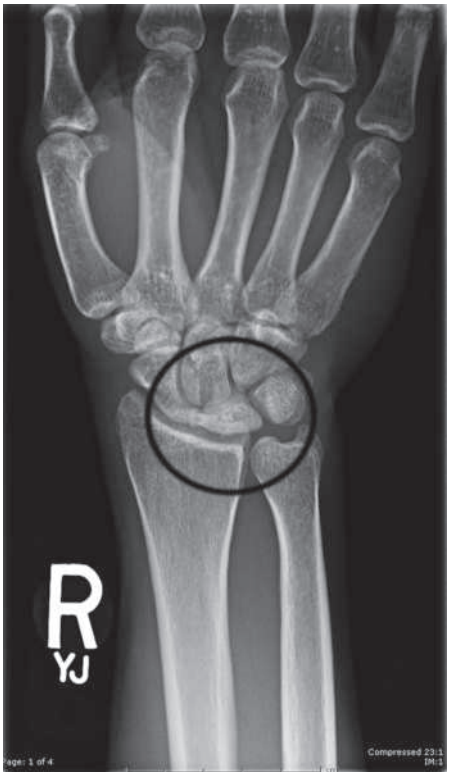

Fig. 43.14 Avascular necrosis of the lunate bone *(circle),* also known as *Kienbock disease.* Prevailing theories support fracture of the lunate bone or compromised circulation as the most likely cause of disease.

Lister tubercle. The usual mechanism of injury involves a fall on the outstretched hand causing extreme dorsiflexion, with transfer of the resultant force from the capitate to lunate. Complications of lunate fractures include progression to carpal instability, nonunion, and AVN. Kienbock disease, defined by AVN of the lunate, has a predictable pattern of bony collapse, carpal change, and degeneration. It results from a combination of vascular, anatomic, and traumatic mechanisms. In well-established cases of Kienbock disease, the lunate appears sclerotic and fragmented on radiographic examination, and ultimately the bone collapses, with resultant proximal migration of the capitate (Fig. 43.14). These changes cause secondary osteoarthritis of the radiocarpal joint, chronic wrist pain, and weakness at the wrist joint. Initial treatment involves a short arm cast, but patients may require operative intervention. In more severe cases, excision and prosthetic replacement of the lunate or arthrodesis may be necessary.

Diagnostic testing. In the ED, wrist radiographs are utilized to assess for lunate fractures; however, fractures of the lunate may be difficult to see on plain films because of overlap of the distal radius, ulna, and other carpal bones. CT or MRI can identify a fracture that is not visible on radiographic imaging. Arthroscopy remains the gold standard for assessing and diagnosing these injuries.

Management and disposition. To minimize the risk of AVN, clinically suspected lunate fractures should be immobilized due to the possibility of occult lunate injuries. Nondisplaced lunate fractures are treated with short arm immobilization with double sugar-tong splint or thumb spica splint with orthopedic follow-up in 5 to 7 days. Displaced injuries, open fractures, or those with neurovascular compromise require open reduction and internal fixation (ORIF) and warrant ED orthopedic consultation. Lunate and perilunate dislocations are discussed later, in the section on *Carpal Instability.*

Triquetral Fractures

Foundations. There are two main patterns of triquetral fractures that are observed: triquetral body and dorsal cortical chip fractures. An adequate blood supply to the triquetrum reduces the risk of AVN, but does not eliminate it.

Clinical features. Patients will experience local tenderness over the dorsal wrist (in the setting of dorsal cortical chips) or volar wrist (avulsion fracture). In addition, swelling and tenderness may be noted over the triquetrum on the ulnar aspect of the wrist. Triquetral body and volar avulsion fractures are commonly associated with perilunate and lunate dislocations, therefore, ligamentous injuries should be considered.

Diagnostic testing. A fracture to the triquetral body is best seen on the AP view. Dorsal triquetral chip fractures are best seen on the standard lateral view of the wrist as a small dorsal avulsion fragment, although a more oblique pronated view may be necessary for visualization (Fig. 43.15). CT or MRI can be used to identify a fracture not visible on radiographic imaging, but is generally not indicated in the ED.

Management and disposition. Treatment of triquetral fractures involves immobilization in a short arm volar splint. Urgent orthopedic referral within 5 to 7 days is suggested for non-displaced triquetral body fractures. Displaced triquetral body fractures will require ORIF and warrant ED consultation. Dorsal triquetral chips are avulsion-type fractures with a more benign clinical course, requiring routine orthopedic referral within 1 to 2 weeks. Neurovascular compromise and open fracture constitute additional indications for ED consultation.

Pisiform Fractures

Foundations. The pisiform is unique because it is the only sesamoid-like carpal bone and attaches to the FCU tendon, articulating on its dorsal surface with the triquetrum. Given the important role of forming the lateral wall of Guyon canal, ulnar arterial damage and neurapraxias may be associated with pisiform fractures.

Clinical features. Fractures of the pisiform usually occur from a fall on the outstretched hand but also may be seen after direct blows to the hypothenar eminence. This occurs from repetitive trauma when the palm of the hand is used in a hammer-like manner. On physical examination, there is tenderness over the ulnar aspect of the wrist, just distal to the volar crease. Paresthesias in the distribution of the ulnar nerve and hand "clumsiness" (or neurapraxia) from intrinsic muscle dysfunction can occur.

Diagnostic testing. Pisiform fractures are poorly seen on routine wrist radiographs and are likely underreported. A reverse (supinated) oblique and carpal tunnel view allow for better visualization (Fig. 43.16). CT scan or MRI can identify fractures that are radiographically occult.

Management and disposition. Nondisplaced fractures of the pisiform generally carry a good prognosis and are treated conservatively, with immobilization in a short arm splint in 30 degrees of wrist flexion with ulnar deviation and orthopedic referral within one week. Most pisiform fractures with evidence of ulnar neurapraxia will resolve, but orthopedic consultation for consideration of surgical decompression is warranted. Pisiform fractures complicated by displacement or nonunion may also require excision and orthopedic consultation in the ED.

Hamate Fractures

Foundations. The hook or hamulus is the most common site of hamate fracture, although articular surfaces and body fractures are also seen.

Clinical features. Fracture of the hook usually occurs from a fall on the outstretched hand or from a direct blow to the palm. A fracture

Fig. 43.15 Triquetral Avulsion Fracture. A minimally displaced triquetral avulsion or dorsal chip fracture *(arrow)* is seen on this lateral radiograph of the wrist.

Fig. 43.16 Pisiform Fracture. A reverse supinated oblique radiograph of the wrist profiling the pisotriquetral joint demonstrates minimally displaced pisiform fracture *(arrow)* not typically seen on traditional posteroanterior, lateral, and oblique views.

Fig. 43.17 Hamate Fracture. Fracture of the articular surface of the hamate bone *(arrow)* is seen on this posteroanterior radiograph of the wrist.

to the hook of the hamate typically occurs in patients participating in racket or club sports (e.g., tennis, golf, baseball). The repetitive use of hammers and vibration equipment (e.g., jack hammers) can predispose workers to hamate fractures and ulnar canal and hypothenar hammer syndrome. Patients may have isolated pain over the hypothenar eminence, decreased grip strength, or compromised distal perfusion. Pain may be localized directly on palpation of the hamate, 1 cm distal and radial to the pisiform. Hamate body and articular surface fractures are usually caused by increased load to the metacarpals of the ring and little fingers. Potential complications of hamate fractures include damage to the ulnar nerve, artery, and vein. Hook of hamate fractures may result in immediate or delayed ulnar arterial or nerve compromise, as well as flexor tendon rupture of the little finger.

Diagnostic testing. Hamate body and articular surface fractures are best seen on PA views of the wrist (Fig. 43.17). Standard wrist radiographs have poor sensitivity for hamate hook fractures, which are more readily seen on reverse, supinated oblique, and carpal tunnel views (Fig. 43.18). CT or MRI may be used to identify radiographically occult fractures. CT imaging may be slightly more accurate in identifying hook cortical fractures, but MRI is more accurate in identifying the integrity of the flexor digitorum profundus tendon as well as bone marrow edema and ulnar nerve injuries.

Management and disposition. Confirmed hook of hamate fractures should be immobilized in a volar splint that includes the fourth and fifth MCP joints in flexion to prevent tendon shortening. Displaced hook of the hamate fractures are frequently treated with operative resection, but immobilization has been successful for nondisplaced injuries. Vascular compromise, open fractures, or distal ischemia warrants emergent orthopedic consultation; otherwise, splinting and urgent orthopedic follow-up is recommended. Nondisplaced hamate body fractures can be treated with a short arm splint and orthopedic follow-up within one week. Displaced fractures or those associated with rupture of the flexor digiti minimi tendon should be referred to orthopedics urgently, within 3 to 5 days.

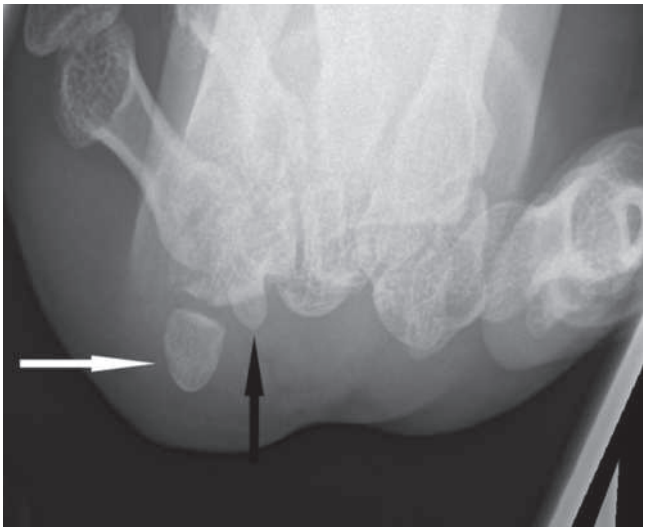

Fig. 43.18 Carpal Tunnel View of Wrist. The pisiform bone *(white arrow)* and hook of hamate or hamulus *(black arrow)* are better visualized on carpal tunnel views of the wrist when hypothenar palmar wrist pain is present, and a fracture is suspected.

Trapezium Fractures

Foundations. There are two main types of trapezium fractures, those involving the body and trapezial ridge.

Clinical features. A direct blow to the adducted thumb causes fracture through the body of the trapezium, with transmittal of the force by the base of the thumb metacarpal. Avulsion fractures of the trapezial ridge occur with forceful radial deviation or rotation of the wrist. On examination, patients report pain with movement of the thumb and on direct palpation of the trapezium, just distal to the scaphoid in the anatomic snuffbox. Complications of distal trapezium ridge fractures include nonunion, median nerve irritation, CMC arthritis, carpal tunnel syndrome, flexor carpi radialis tendinopathy, and loss of pinch strength.

Diagnostic testing. Although trapezium fractures may be seen on the AP view of the wrist, they are typically better visualized on oblique views (Fig. 43.19), a Bett view, and a carpal tunnel view to evaluate for ridge fractures. Trapezium fractures can be radiographically occult. CT scanning or MRI can be used to identify fractures that are not evident on X-ray.

Management and disposition. Nondisplaced trapezium fractures are treated with immobilization in a short arm thumb spica splint, with orthopedic referral within one week. Displaced fractures, comminuted fractures, intra-articular fractures, distal ridge fractures, and involvement of the carpometacarpal joint warrant urgent orthopedic consultation for ORIF within 2 to 3 days. Neurovascular compromise or open fractures warrant emergent consultation.

Capitate Fractures

Foundations. The capitate lies in a central position in the distal carpal row and, because of this protected location, it is rarely fractured.

Clinical features. The mechanism generally is a direct blow to the dorsum of the wrist. Fractures may also be seen in association with perilunate dislocations after a fall on the outstretched dorsiflexed hand. Clinical examination reveals dorsal wrist pain and swelling, with localized tenderness over the capitate. Complications of nonunion and AVN of the proximal fragment are rare but do occur because the capitate receives blood supply through its distal half.

Fig. 43.19 Trapezium Fracture. An oblique view of the wrist shows an isolated, comminuted, intraarticular fracture of the trapezium body *(arrow)*.

Diagnostic testing. Fractures usually are visible on the standard PA view of the wrist, although the lateral and oblique views may be helpful in determining the presence of rotation or displacement of the fracture fragment. CT scan or MRI can be useful in identifying radiographically occult fractures.

Management and disposition. Identified or suspected nondisplaced fractures of the capitate should be managed with immobilization in a short arm thumb spica splint with routine orthopedic referral within one week. Urgent orthopedic referral within 2 to 3 days is recommended for fractures with displacement. ED consultation is indicated for associated carpal dislocation, open fractures, or neurovascular compromise.

Trapezoid Fractures

Foundations. Trapezoid fractures are rare, usually seen in association with other carpal injuries.

Clinical features. The typical mechanism of injury is a direct blow down the long axis of the index metacarpal, which may result in isolated fracture to the trapezoid or cause a dorsal fracture-dislocation. On clinical examination, pain and tenderness are localized over the dorsum of the wrist at the base of the second metacarpal.

Diagnostic testing. The fracture may be visible on routine PA views of the wrist; however, oblique views may be superior for visualization of the injury. CT scan or MRI can be used in identifying radiographically occult fractures.

Management and disposition. Confirmed or suspected nondisplaced trapezoid fractures should be immobilized with a short arm thumb spica splint with urgent orthopedic referral in 2 to 3 days. Displaced fractures or fracture dislocations warrant orthopedic consultation in the ED for reduction and fixation. Trapezoid fractures have a high rate of nonunion and AVN.

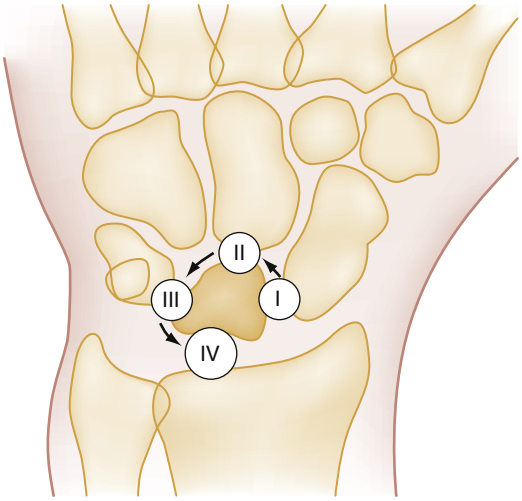

Fig. 43.20 Sequential stages of carpal dislocation. Each of four stages (I–IV) represents a sequential intercarpal ligament injury proceeding around the lunate. (From Greenspan A. *Orthopedic radiology: a practical approach*. 2nd ed. New York: Gower Medical; 1992.)

Carpal Instability

Foundations. The Mayfield classification of carpal instability is comprised of four distinct stages. Each stage represents a sequential intercarpal injury, beginning with scapholunate joint disruption and proceeding around the lunate, creating progressive carpal instability (Fig. 43.20). Each stage also may be associated with specific bony fractures, which, if present, should alert the emergency clinician to the possibility of an occult perilunate ligamentous injury. These associated injury patterns include fractures of the radial styloid, scaphoid, capitate, and triquetrum.

Clinical features. Carpal ligamentous injury is caused by wrist hyperextension, ulnar deviation, and intercarpal supination. Patients with these carpal dislocation injuries typically have a history of a fall on the outstretched hand. They complain of pain and swelling over the dorsum of the wrist, with limited range of motion. On physical examination, tenderness to palpation is noted over the dorsum of the wrist. Delayed scapholunate instability may be clinically elicited by a provocative maneuver, such as the *Watson scaphoid shift test*, which will increase pain and produce a clunk or snap. The test is performed by placing upward pressure on the scaphoid tuberosity while the hand is in ulnar deviation. In scapholunate instability, this action will cause the scaphoid to ride out of the radial fossa over the dorsal rim and, as the hand is moved back radially, a painful snap is produced. In the setting of acute trauma, this test is often too painful to perform. With perilunate and lunate dislocations, visible deformity of the wrist also is apparent, and two-point sensation in the median nerve distribution often is diminished. Complications of carpal dislocation injuries include median nerve injury and chronic carpal instability, with resultant degenerative arthritis.

Diagnostic testing. A stage I injury, or scapholunate dissociation, results in a characteristic widening of the scapholunate joint on the PA view, which has been called the *Terry Thomas sign* after the British comedian with a gap between his front teeth. This radiographic sign has been updated to reference more current celebrity figures and is also referred to as the *David Letterman sign*. This injury pattern may be associated with a rotary subluxation of the scaphoid. Radiographically, the scaphoid is seen end-on, with the cortex of the distal pole appearing as a ring shadow, referred to as the *signet ring sign* (Fig. 43.21). Scapholunate dissociation may not be demonstrated on routine radiographs, so when there is clinical suspicion for this injury, additional stress views could be considered. Radiographs taken with a clenched fist and with ulnar deviation (the clenched fist AP view) accentuate widening of the scapholunate joint and are suggestive of disease when a gap larger than 3 mm is measured.

Fig. 43.21 Scapholunate Dissociation With Scaphoid Subluxation. Posteroanterior view of the wrist shows characteristic widening of the scapholunate joint *(black arrow)*, known as the *Terry Thomas sign*, and a ring shadow over the scaphoid *(white arrow)* secondary to subluxation, known as the *signet ring sign*.

A stage II injury, or perilunate dislocation, is seen best on the lateral view of the wrist. Although the lunate remains articulated to the distal radius, the capitate is dorsally dislocated. The PA view shows overlap of the distal and proximal carpal rows and also may show an associated scaphoid, radial styloid, or capitate fracture (Fig. 43.22).

A stage III injury appears identical to a stage II injury but includes a dislocation of the triquetrum that is seen best on the PA view, with overlap of the triquetrum on the lunate or hamate. This injury may be associated with a volar triquetral fracture.

A stage IV injury, or lunate dislocation, results in a characteristic triangular appearance of the lunate on the PA view caused by the rotation of the lunate in a volar direction. This triangular appearance is commonly referred to as the *piece of pie sign*. This rotation also is visible on the lateral view of the wrist, in which the lunate looks like a cup tipped forward and spilling its contents, referred to as the *spilled teacup sign*. On the lateral view, the capitate is seen to lie posterior to the lunate and often has migrated proximally to contact the distal radius (Fig. 43.23). MRI can identify these injuries in the setting of negative radiographs but is rarely indicated in the ED. Arthroscopy remains the gold standard for definitive diagnosis.

Management and disposition. Carpal dislocation injuries need emergent orthopedic consultation in the ED for reduction and stabilization. ED management of dissociations without evidence of dislocation or neurovascular injury consists of immobilization and urgent orthopedic follow up within one week.

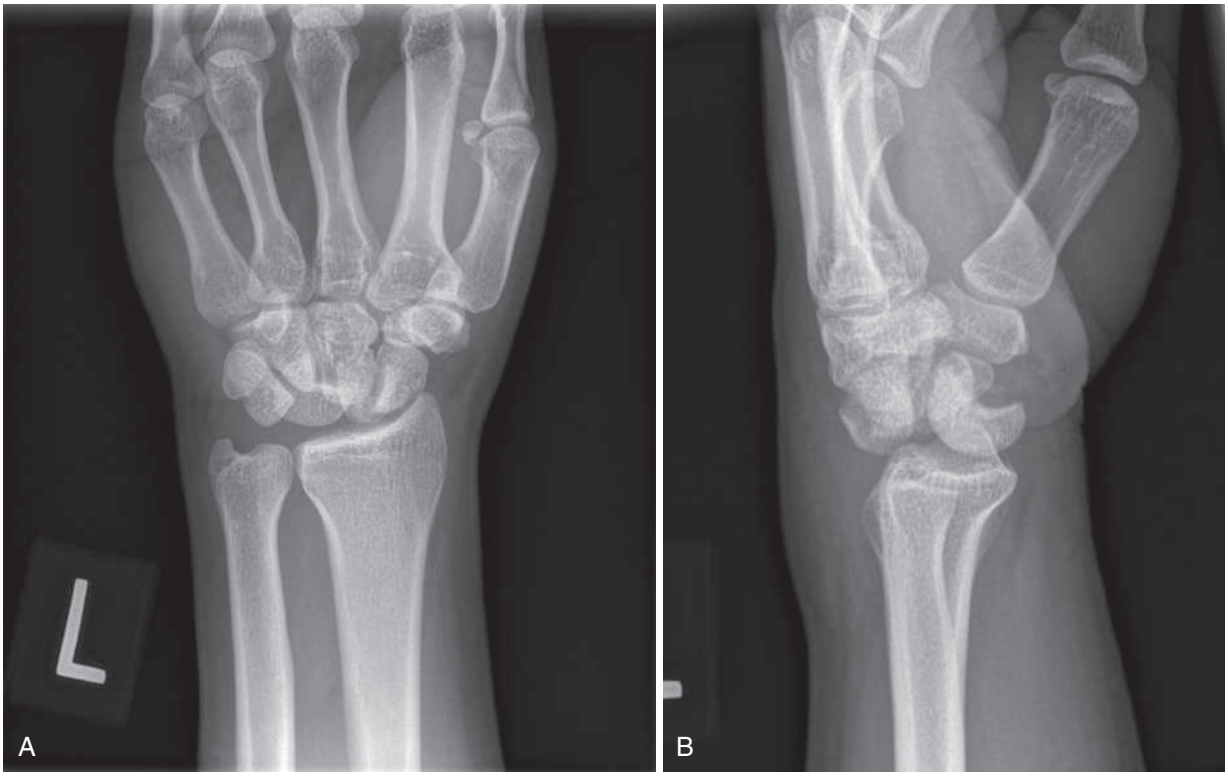

Fig. 43.22 Perilunate Dislocation. (A) This posteroanterior view of the wrist shows an abnormal-appearing lunate bone, obvious disruption of the normal carpal arcs, and commonly associated and, in this case, displaced scaphoid fracture. (B). Lateral view shows a dislocated and dorsally displaced capitate bone in relation to the lunate. Of note, the lunate maintains its articular connection and alignment with the radius, suggesting a perilunate dislocation.

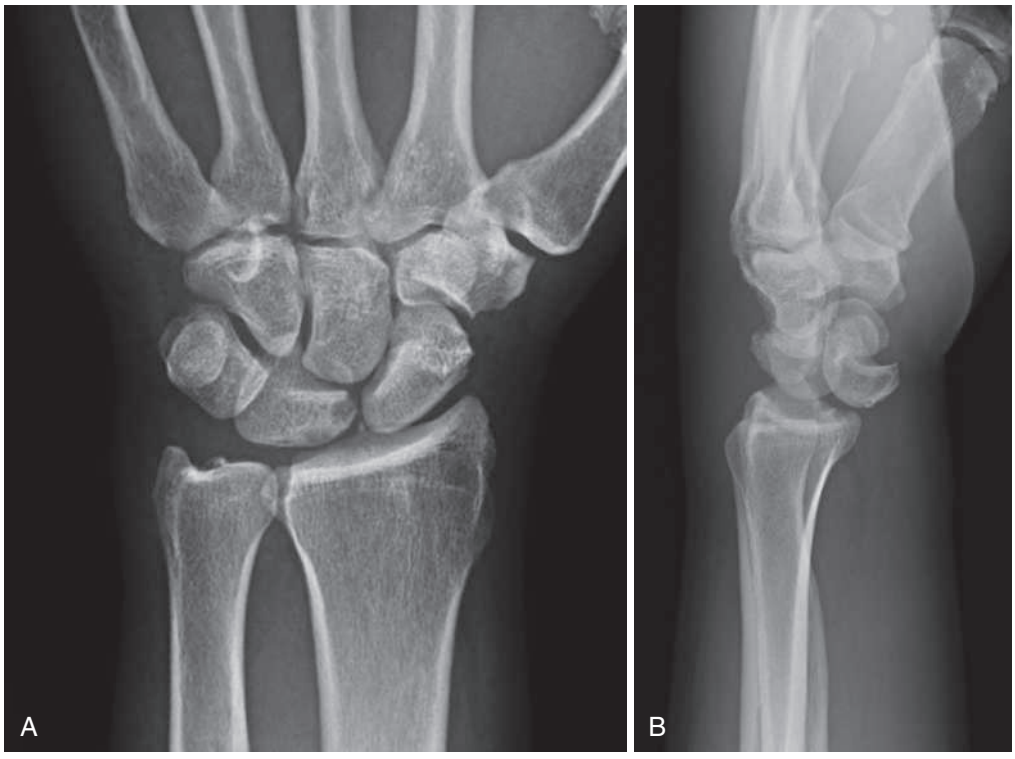

Fig. 43.23 Lunate Dislocation. (A). This posteroanterior view shows the characteristic triangular shape of the lunate bone during dislocation. (B) Volar displacement of the lunate resembles a spilled teacup on the lateral view. Note the disrupted articulation between the lunate and distal radius and realignment of the radius, capitate, and metacarpals, suggesting lunate dislocation.

Radiocarpal Dislocation

Foundations. Radiocarpal dislocations and fracture dislocations are considered extremely rare and are typically associated with high-energy trauma.

Clinical features. Patients are commonly involved in polytrauma scenarios. Dislocations may be volar or dorsal, although ulnar translation of the carpal bones is much more common than radial translation.

Diagnostic testing. Radiographs of the wrist are typically sufficient to identify radiocarpal dislocations.

Management and disposition. Emergent reduction of these injuries is paramount because of the extensive soft tissue damage and commonly associated neurovascular compromise. Reductions may be difficult to maintain in these complex and unstable injuries, which usually require ORIF. Emergent orthopedic consultation in the ED is indicated.

Distal Radius and Ulna Injuries

Distal radius and ulna fractures typically occur from a ground-level fall on the outstretched hand in older patients and from high-energy trauma in younger patients. These injuries are commonly closed and may have intraarticular involvement and displacement. They frequently require ED closed reduction, splinting, and orthopedic referral. Plain radiographs are generally adequate for the diagnosis and management of these injuries; rarely is advanced imaging indicated in the ED. A neurovascular examination should be performed to exclude any median, radial, or ulnar neurapraxia and radial or ulnar arterial compromise caused by the deformity or fracture fragments. Post-reduction radiography and a neurologic examination are also recommended. Open fractures, instability, or an acute carpal tunnel syndrome (ACTS) are indications for emergent orthopedic evaluation. Vascular compromise should prompt immediate reduction in conjunction with orthopedic consultation. Patients with open fractures should receive tetanus immunization prophylaxis and tetanus immune globulin (if unvaccinated), and 2 g of cefazolin intravenously, prior to surgical intervention. Numerous classification patterns have been devised, and the most commonly encountered fractures are discussed in the following sections.

Colles Fracture

Foundations. A Colles fracture refers to a transverse fracture of the distal radial metaphysis, which is dorsally displaced and angulated.

Clinical features. Patients classically present with a "*dinner fork deformity*" on physical examination. The fracture usually is located within 2 cm of the radial articular surface and may be associated with comminution and intraarticular extension into the radiocarpal or radioulnar joints. Carpal instability may also occur. Complications of Colles fractures are seen most often in older patients and those with comminution, displacement, and inadequate fracture reduction. Although radial and ulnar nerves may be compromised, median nerve injury is most common and may occur acutely from contusion, traction from displacement, transection from fracture fragments, nerve compression after closed reduction, overlying cast pressure, or secondary to ACTS. Thus, it is important to evaluate neurologic function before and after fracture reduction and splint application.

Diagnostic testing. The PA view may show extension of the fracture into the radioulnar or radiocarpal joints and the amount of intraarticular step-off and radial shortening present. The degree of dorsal displacement and angulation is best seen on the lateral view, with loss of the normal volar tilt of the distal radial articular surface (Fig. 43.24).

Management and disposition. Most Colles fractures require ED reduction for restoration of radial length, correction of dorsal angulation (especially when greater than 20 degrees), restoration of

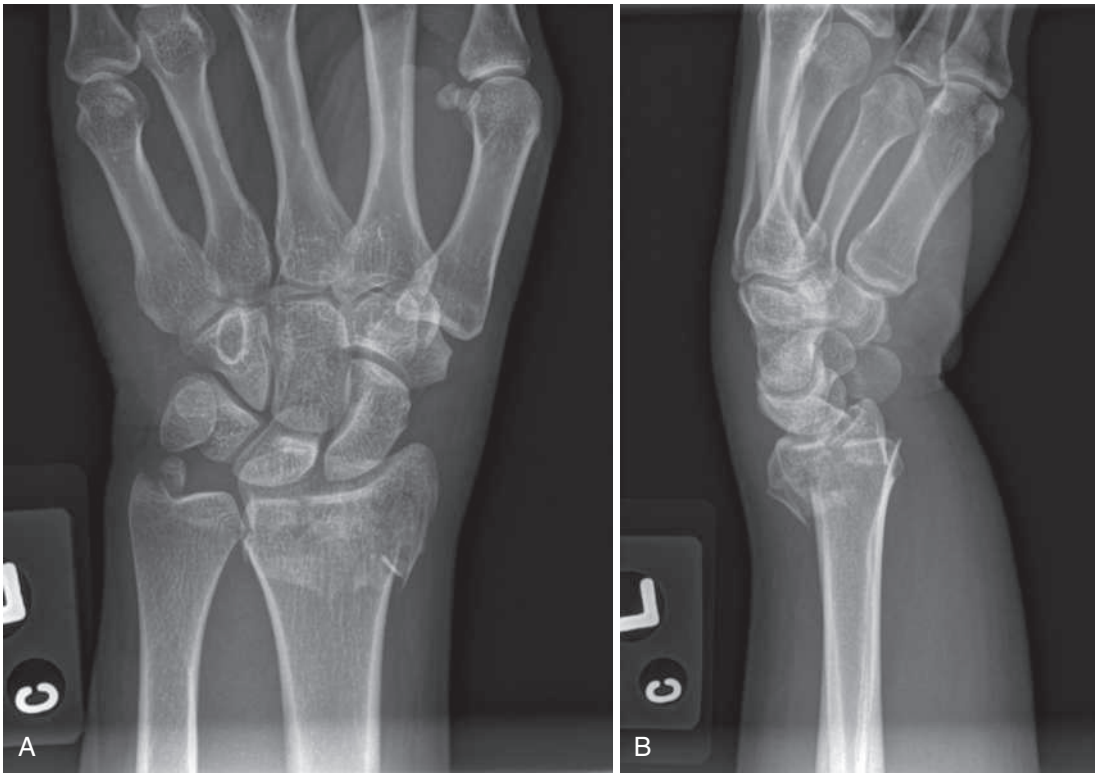

Fig. 43.24 Colles Fracture. (A) Posteroanterior view shows fracture and shortening of the radius, intraarticular extension, and associated ulnar styloid fracture. (B) Lateral view shows typical dorsal displacement and angulation of the radial fracture known as the *dinner fork deformity*.

anatomic volar tilt. Closed reductions should be performed under procedural sedation, local or regional anesthesia, or a combination of these options followed by immobilization in a double sugar tong splint. Splinting should immobilize the wrist but allow for finger movement. Immediate circumferential casting, as well as overly tight splinting, should be avoided for at least 24 hours because edema from this injury may induce subsequent pain or neurovascular compromise. Successful reduction allows for urgent outpatient orthopedic referral within 2 to 3 days in most cases.

Methods of local and regional anesthesia for distal radius fracture reduction include the classic hematoma block, IV regional anesthesia, known as the *Bier block*, and regional nerve blocks, including median, radial, ulnar, and brachial plexus approaches. The hematoma block remains an easy and effective method of anesthesia and may be performed by placing a 22-gauge needle in the dorsum of the distal radius, withdrawing until a fracture hematoma is encountered and then instilling 5 to 10 mL of 1% or 2% lidocaine, with or without the addition of a longer-acting agent such as bupivacaine (Fig. 43.25).[12] Hematoma blocks may avoid the requirement for procedural sedation and decrease ED length of stay. For pediatric distal radial fractures, local anesthesia should not be injected into the growth plate but is otherwise acceptable. Use of finger traps is another effective means of obtaining reduction to allow positioning for splinting (Fig. 43.26). The more comminuted and displaced the fracture, the higher the likelihood that operative reduction will be necessary.

Indications for emergent Colles fracture reductions include any neurovascular compromise, significant deformity, soft tissue tension, tenting of the skin, and loss of volar tilt, with significant dorsal angulation (>20 degrees). Loss of reduction will occur in many of these patients before orthopedic follow-up, especially intra-articular fractures, and in older adults, for whom the long-term benefits of anatomic restoration appear less beneficial. The American Academy of Orthopedic Surgeons has suggested surgical fixation of fractures with more than 3 mm of shortening, 10 degrees of dorsal tilt, and intra-articular step-off of more than 2 mm post-reduction. ED orthopedic consultation is recommended if a reduction is unable to be maintained, or if there is evidence of open fracture, severe comminution, neurovascular compromise, compartment syndrome, or skin tenting.

Smith Fracture

Foundations. Smith fracture is a transverse fracture of the metaphysis of the distal radius, with associated volar displacement and angulation. The fracture may extend into the radiocarpal joint.

Clinical features. The typical mechanism of injury involves a direct blow to the dorsum of the wrist or a fall onto the dorsum of the hand resulting in extreme palmar flexion. This fracture also may be seen after a backward fall on an outstretched hand, with the forearm in supination. The patient has a swollen painful wrist, which is deformed, with fullness visible on the volar aspect. On physical examination, a "*garden spade deformity*" will classically be observed. Because the displacement is opposite to that seen with a Colles fracture, Smith fractures are often called a "reverse Colles fracture."

Diagnostic testing. The fracture is visible on PA and lateral radiographs of the wrist, but the lateral view best shows the degree of volar displacement and angulation (Fig. 43.27).

Management and disposition. Treatment of this fracture involves closed reduction and immobilization in a splint if the fracture is extra-articular, as discussed for Colles fracture. Unlike Colles fracture, however, Smith fracture is more likely to be unstable and to require operative repair; it also has an increased tendency to cause neurovascular compromise, specifically median nerve compression. Urgent orthopedic referral within 2 to 3 days or emergent consultation is indicated based on the severity of angulation, neurovascular compromise, or associated soft tissue complications. Delayed tendon complications, including EPL entrapment and rupture, have been documented. Prognosis is most favorable in patients with successful reduction and restoration of the normal radial length and volar tilt. ED consultation is warranted for similar indications to the Colles fracture.

Barton Fracture

Foundations. Barton fracture is an oblique intraarticular fracture of the rim of the distal radius, with displacement and dislocation of the radiocarpal joint along with the fracture fragment.[13] The fracture may involve the dorsal rim of the radius with dorsal carpal subluxation (classic Barton fracture) or may involve the volar rim with volar carpal

Fig. 43.25 Hematoma Block. Sterile preparation of the fracture area is performed, and local anesthetic is then introduced to the hematoma that surrounds the fracture site to assist with pain control during reduction.

Fig. 43.26 Finger Traps. The distal radius reduction method typically involves traction followed by manipulation facilitated by the finger traps. Ten pounds of weight are hung from the elbow at 90 degrees of flexion for approximately 10 minutes before the reduction attempt.

Fig. 43.27 Smith Fracture. (A) Posteroanterior view shows a metaphyseal fracture of the radius, with shortening and associated ulnar styloid base fracture. (B) Lateral view shows volar displacement of the distal fracture fragment along with the carpus.

Fig. 43.28 Volar Barton Fracture. Lateral radiograph of the wrist shows typical oblique intraarticular fracture of the volar rim of the radius, with associated displacement of the distal radial fragment and carpus dislocation.

subluxation (volar Barton fracture). While these fractures are rare, the volar-anterior margin fracture is seen more often than the dorsal-posterior margin fracture.

Clinical features

The mechanism of injury for these fractures is a high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in volar flexion (causing a volar rim fracture) or dorsiflexion (causing a dorsal rim fracture). Complications include posttraumatic arthritis of the radiocarpal joint and delayed carpal instability. Both complications are seen more commonly when reduction fails to achieve or maintain anatomic realignment of the radiocarpal joint surface.

Diagnostic testing. Volar and dorsal rim fractures are visible on PA and lateral wrist radiographs; however, the lateral view best shows the degree of articular surface involvement and amount of associated fracture displacement (Fig. 43.28).

Management and disposition. Treatment of these unstable fractures requires emergent orthopedic consultation for reduction and fixation. Closed reduction may be successful when performed under fluoroscopy, although most fractures require percutaneous pinning or ORIF to restore the articular surface of the radius and stabilize the carpus.

Hutchinson Fracture

Foundations. Hutchinson fracture, or *chauffeur's fracture*, is an intra-articular fracture of the radial styloid.

Clinical features. The mechanism of injury is usually a direct blow or fall resulting in trauma to the radial side of the wrist. The term *chauffeur's fracture* originated in the era of hand-cranked automobiles, when this injury occurred because of direct trauma to the radial side of the wrist from the recoil of the motor crank. Posttraumatic arthritis is a common complication of radial styloid fractures and more common with displacement and scapholunate ligament disruption.

Diagnostic testing. The fracture is seen best on the PA view of the wrist as a transverse fracture of the radial metaphysis, with extension through the radial styloid into the radiocarpal joint.

Management and disposition. Nondisplaced fractures may be immobilized in a sugar tong splint, with the patient given urgent orthopedic referral within 2 to 3 days. Displaced fractures, which are frequently associated with scapholunate ligament disruption, require emergent open or closed reduction and fixation (Fig. 43.29). Because the radial styloid is the primary site of attachment for many of the ligaments of the wrist, accurate fracture reduction and union are crucial for proper wrist function.

Distal Radioulnar Joint Disruption

Foundations. Acute dislocation of the DRUJ can occur as an isolated injury, which is rare, or in association with a fracture to the distal radius *(Colles fracture)*, radial diaphysis *(Galeazzi fracture)*, or radial head *(Essex-Lopresti injury)*.

Clinical features. Certain characteristic findings on clinical examination may constitute the only clue to the presence of this injury. The typical mechanism of injury is a fall on the outstretched hand with hyperpronation, resulting in dorsal dislocation, or hypersupination, causing volar dislocation of the ulna. Dorsal ulna dislocations are more common than volar dislocations. Another mechanism known to cause DRUJ dislocation is the catching of the hand in rotating machinery, resulting in the same forcible hyperpronation or supination. This forcible rotation of the wrist causes disruption of the TFCC, the major stabilizer of the DRUJ, and may result in an associated avulsion fracture of the ulnar styloid.

Patients with this injury have a history of sudden onset of pain with a snapping sensation in the wrist, swelling, and limited range of

Fig. 43.29 Hutchinson Fracture. Posteroanterior radiographic view shows intraarticular fracture of the radial styloid with displacement and scapholunate dissociation, a common complication of untreated Hutchinson fracture.

Fig. 43.30 Distal Radioulnar Joint Dislocation. Posteroanterior radiographic view shows an ulnar styloid base fracture suggestive of triangular fibrocartilage complex disruption and widening of the radius and ulna, consistent with distal radioulnar dislocation.

motion. On examination, tenderness is present over the ulnar aspect of the wrist, with palpable crepitus on supination and pronation. On examination, the *piano key test* may be used to assess for DRUJ instability. The test is positive when the ulnar head springs back like a piano key after being depressed volarly and then released. The *ballottement test* also evaluates stability of the DRUJ. With this test, the radius is grasped firmly by the examiner while the ulna is fixed between the examiner's other thumb and index finger. Pressure is then applied to the ulna in dorsal and volar directions with respect to the radius. Increased displacement relative to the contralateral wrist suggests instability.

With a dorsal dislocation of the ulna, the ulnar styloid appears more prominent than on the unaffected side, and significant pain and limitation of movement are noted on supination of the wrist. With a volar dislocation of the ulna, there is loss of the normal ulnar styloid prominence, with pain and limitation of movement on pronation. These characteristic clinical findings should alert the emergency clinician to the possibility of DRUJ disruption and prompt the appropriate imaging studies to confirm the presence or absence of injury.

Diagnostic testing. Diagnosis often is difficult because when the injury occurs in isolation or is not suspected, plain radiographs commonly are reported as normal. Well-positioned lateral radiographs of the wrist may show the presence of a DRUJ dislocation with more than 20 degrees of dorsal angulation or volar displacement, but pain and inability of the patient to rotate the wrist fully may cause a false-negative result because a true lateral view cannot be obtained. Fractures of the ulnar styloid base increase suspicion for a DRUJ disruption. It also is important to assess for radial head fractures because this injury is commonly associated with DRUJ disruption and interosseous membrane rupture (see below, "Essex-Lopresti Lesion"). A DRUJ dislocation may be seen on the PA view of the wrist radiograph showing significant overlap or widening of the distal radius and ulna (Fig. 43.30). If there is significant clinical suspicion of injury, and the radiographic appearance is normal, a CT scan or MRI may assist in the diagnosis.

Management and disposition. Treatment of DRUJ dislocations commonly requires emergent orthopedic consultation for reduction and stabilization. Closed reduction with the forearm in supination followed by application of a long arm splint is indicated. Alternatively, open reduction is often necessary with volar dislocations because the ulnar head may be locked on the distal radius. Operative reduction is also necessary in dorsal dislocations to repair the associated injury to the TFCC. Any associated bony injuries should be managed with immobilization as indicated.

SOFT TISSUE INJURIES OF THE WRIST

Carpal Tunnel and Acute Carpal Tunnel Syndrome

Foundations

Carpal tunnel syndrome (CTS) is the most common entrapment neuropathy; it occurs at the wrist and results in compression of the median nerve. CTS is typically a chronic, progressive, repetitive overuse syndrome with a female preponderance. The transverse carpal ligament and volar surfaces of the carpal bones form the carpal tunnel. It is a rigid compartment that contains nine flexor tendons (flexor pollicis longus, four flexor digitorum superficialis, and four flexor digitorum profundus tendons) and the median nerve.

Clinical Features

The classic symptoms include a gradual onset of numbness, paresthesia, and pain in the median nerve distribution (thumb, index, long and radial aspect of the ring finger; see Table 43.1). These symptoms often are bilateral and are worse during the night and after strenuous activities. Typically, patients report numbness and paresthesias on awakening that lessens when the hands are shaken or held in a dependent

position. Pain may actually radiate proximal to the carpal tunnel, and symptoms may progress to include decreased grip strength, hand clumsiness, thenar atrophy, and trophic ulceration of the fingertips.

Differential Diagnoses

CTS can be associated with numerous systemic conditions, such as rheumatoid arthritis, hypothyroidism, diabetes mellitus, renal failure, congestive heart failure, acromegaly, and collagen vascular diseases. Each of these systemic diseases is thought to produce an increase in pressure within the carpal tunnel from thickening of the flexor synovia or transverse carpal ligament. Hormonal changes associated with pregnancy and menopause also are known to be associated with CTS. Differential diagnoses also include cervical radiculopathy (especially the C6 or C7 nerve root) and Raynaud syndrome. The median nerve may also be compressed at other sites including the pronator teres. A brachial plexopathy may also produce similar symptoms.

Diagnostic Testing

The most common provocative test supporting the diagnosis of CTS is the wrist flexion or *Phalen test* (Fig. 43.31). This test is performed by asking the patient to flex the wrists fully for 60 seconds while holding the forearms in a vertical position. The test result is positive if paresthesia or numbness develops in the median nerve distribution. Other tests suggesting CTS are weakness observed on thumb abduction testing and *Tinel sign*, which demonstrates pain or paresthesias elicited by light tapping over the median nerve at the wrist. *Durkan test*, or the median nerve compression test, consists of the application of pressure directly over the median nerve at the carpal tunnel and may have the highest sensitivity and specificity for disease. However, no physical examination maneuver is completely reliable in making the diagnosis and is therefore more supportive when used in combination. Nerve conduction studies have traditionally been used to confirm the diagnosis. MRI and ultrasound are also being used for confirmation, but emergently the diagnosis of CTS is primarily clinical.

Management and Disposition

Conservative (nonoperative) treatment for CTS yields variable results. Specific measures include splinting the wrist in a neutral position and administering cortisone injections in the carpal tunnel as an outpatient in an orthopedic clinic. Splinting initially may be prescribed full time and then reduced to immobilization at night only. Five factors that lessen the likelihood of successful nonoperative treatment are (1) age older than 50 years, (2) symptom duration longer than 10 months, (3) constant paresthesias, (4) stenosing flexor tenosynovitis, and (5) positive Phalen test result at less than 30 seconds. Nonsteroidal antiinflammatory drugs (NSAIDs) have proved to be of little benefit. Open or endoscopic surgical release of the flexor retinaculum to unroof the carpal tunnel is indicated when medical management fails.

Fig. 43.31 Phalen Test.

ACTS, which occurs over hours rather than weeks or months, is much less common than the chronic, gradually progressive presentations of CTS. ACTS is more often directly related to fractures, fracture-dislocations, hemorrhagic conditions, infections, vascular disorders, and edema involving the wrist. Although the carpal tunnel is open at both ends, it has the physiologic properties of a closed compartment. Distal radius fractures are the most common cause of ACTS; however, lunate and perilunate dislocations are associated, and even isolated carpal fractures and rupture of the EPL tendon have been found to be associated with ACTS as well. Trauma resulting in an ACTS is typically relieved by closed reduction, and no reliable clinical method currently exists for differentiating acute median nerve compression in ACTS from concussive insult. In the absence of trauma, ACTS has occurred secondary to hemorrhagic, vascular, and bleeding disorders, and anticoagulant use. When ACTS has been diagnosed, ED orthopedic consultation is recommended for surgical decompression and release of the transverse carpal ligament.

De Quervain Disease

Foundations

De Quervain disease and intersection syndrome, like CTS, have been grouped into the overuse or repetitive strain injury pattern category, sometimes referred to as work-related cumulative trauma. The APL and EPB, both within the first dorsal extensor compartment of the wrist, are the tendons affected in de Quervain disease. Traditionally known as a stenosing tenosynovitis or tendinitis, de Quervain disease involves enlarged tendons, which may reach five times their original size, creating a stenosing tendinopathy.

Clinical Features

Clinically, patients report pain on the radial side of the wrist, with ulnar deviation, thumb movements, weakened grip strength, or a combination of these symptoms. Onset is gradual and typically the result of increased use. De Quervain disease is thought to be common, affecting women six times more frequently than men, typically at an age older than 40 years.

Diagnostic Testing

Radiographs are useful in ruling out bony pathology, but the diagnosis may be made with physical examination alone. *Finkelstein test* and radial styloid tenderness have long been considered to be a pathognomonic signs of de Quervain disease. Ultrasound reveals fluid in the first dorsal extensor tendon compartment tendon sheath with associated thickening of the APL and EPB tendons.

Management and Disposition

Conservative interventions of rest, splinting, and NSAIDs are the first-line treatments for mild to moderate disease. Thumb spica splints effectively immobilize the APL and EPB, but pain may return when the inciting activities are resumed. ED management should consist of rest, thumb spica splint immobilization, and nonsteroidal antiinflammatory agents. Orthopedic consultation is warranted within a few weeks. Injection of corticosteroid preparations into the dorsal extensor compartment of the wrist may be offered at follow-up with an orthopedic physician within 3 to 5 weeks. Patients with refractory or severe cases that interfere with activities of daily living may undergo surgical release of the first dorsal extensor compartment of the wrist, with decompression of the APL and EPB tendons.

Intersection Syndrome

Foundations

Intersection syndrome is another overuse tendinopathy that clinically manifests with pain on the radial side of the wrist, approximately 4 to 8 cm proximal to the site of de Quervain disease. Pathophysiologically, intersection syndrome occurs secondary to inflammation where the muscle bellies of the APL and EPB cross over the muscle bellies of the extensor carpi radialis longus and brevis, proximal to the retinaculum.

Clinical Features

The condition is also known as *crossover or oarsman syndrome*. The mechanism of injury is secondary to rowing, weightlifting, or a repetitive resistance pulling action.

Diagnostic Testing

Physical examination findings include significant pain, soft tissue swelling, and crepitus with movement in more severe cases. Ultrasound findings may include thickened tendons or effusion, and radiographs are generally negative for pathology.

Management and Disposition

The treatment for this disease is immobilization with a wrist splint and antiinflammatory medications. Although surgical treatments have been described, this syndrome is typically self-limited. Orthopedic follow-up is recommended within 3 to 5 weeks.

FOREARM

FOUNDATIONS

Forearm injuries are common encounters in the ED. There is a bimodal age distribution of patients who suffer forearm injuries—children aged 6 to 15 years and adults older than 50 years.[14] In children, forearm fractures account for nearly 50% of all pediatric fractures and are on the rise due to an increase in sporting activities and body mass index (BMI). Refer to pediatric fractures referenced in Chapter 160.

Anatomy, Physiology, and Pathophysiology

Mechanisms of injury for forearm fractures include falls on outstretched hands, direct blows to the area, or high-energy trauma, such as involvement in a motor vehicle collision. Evaluation of forearm injuries requires an understanding of the interdependent biomechanical relationship between the radius and ulna. These two bones articulate at the proximal and distal ends, which allows the radius to rotate around the ulna to provide pronation and supination. Because fractures of the radius or ulna can result in dislocation at the wrist or elbow, emergency clinicians should be vigilant when treating forearm fractures. Early diagnosis and prompt treatment of these injuries are critical to prevent loss of function.

The forearm is a unique two-bone structure with the radius and ulna being bound at both ends by a ligamento-capsular structure. The proximal radioulnar joint (PRUJ) consists of an articulation between the radial head and ulna. The radial head, the primary stabilizer of the forearm, combined with the annular, quadrate, radial, and ulnar ligaments, provides strong support at the PRUJ. At the DRUJ, the TFCC and anterior and posterior radioulnar ligaments support the articulation of the distal radius and ulna. The interosseous membrane further stabilizes the forearm by providing a strong interconnection between the radius and ulna. The ulna is relatively straight and provides the rotational axis for the bowed radius to rotate around through various planes of motion. The supinator, pronator teres, and pronator quadratus muscles insert along the shaft of the radius and ulna to provide their named function, but they also are responsible for the deforming forces in forearm fractures.

The forearm is typically divided into three compartments—volar, dorsal, and mobile wad of Henry. The interosseous membrane divides the volar and the dorsal compartments, and the mobile wad is located laterally (Fig. 43.32). The volar compartment, which can be further divided into superficial and deep layers, contains the pronators and flexor muscles of the hands. The radial, ulnar, and anterior interosseus arteries and median, ulnar, and superficial radial nerves are also contained within the volar compartment. The dorsal compartment consists of the extensor muscles of the hand and posterior interosseous artery and nerve. The mobile wad is located in the proximal lateral aspect of the forearm and contains the brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis.

CLINICAL FEATURES

Obtaining the mechanism of injury is important in the initial assessment of a forearm injury. The most common mechanism of injury is an axial load applied to the forearm through the hand, which often leads to rotational displacement. Patients may present with obvious deformity and a significant amount of pain.

Physical examination of the forearm injury begins with visual inspection by evaluating for swelling along the injured area, obvious deformity, and evidence of lacerations. Gentle palpation can assist in localization of the injury, reveal crepitus in grossly unstable fractures, and allow assessment of skin turgor in the evaluation of compartment pressure. Significant swelling, as well as disproportionate pain, paresthesia, and paleness of skin, should alert emergency clinicians to the potential development of compartment syndrome. Neurologic evaluation should include careful examination of motor and sensory function of the radial, ulnar, and median nerves. Assessment of the brachial, radial, and ulnar arteries should be performed. See pediatric trauma and compartment syndromes referenced in Chapter 160.

DIFFERENTIAL DIAGNOSES

When approaching a patient with forearm pain, differential diagnoses will be determined by the mechanism of injury, location of pain, and chronicity of the symptoms. Acute trauma associated with inability to supinate will raise suspicion for acute fracture involving radius or ulna depending on the location. Other differential diagnoses include straining of the forearm muscles and tear of the ligaments stabilizing radius and ulna. For patients with chronic forearm pain without acute trauma, repetitive strain injury due to overuse and repetitive movement should be considered.

DIAGNOSTIC TESTING: RADIOLOGY

The radiologic evaluation of the forearm injury should begin with the AP and lateral views. It is necessary to include wrist and elbow in the x-ray examination of the forearm to exclude any concomitant injuries to the DRUJ or PRUJ.

On the normal AP view of the forearm, a medially pointing radial styloid and laterally projecting biceps tuberosity of the proximal radius are visible. On the lateral view, the coronoid process of the proximal ulna points volarly, and the ulnar styloid lies dorsally (Fig. 43.33). Any deviation suggests an abnormal rotational or axial deformity. The normal radiologic findings of the forearm, including radiocarpal articulation angle, relationship between radial styloid and ulnar styloid, and normal volar tilt of the radius, are described earlier in the *Radiology of the Wrist* section of this chapter.

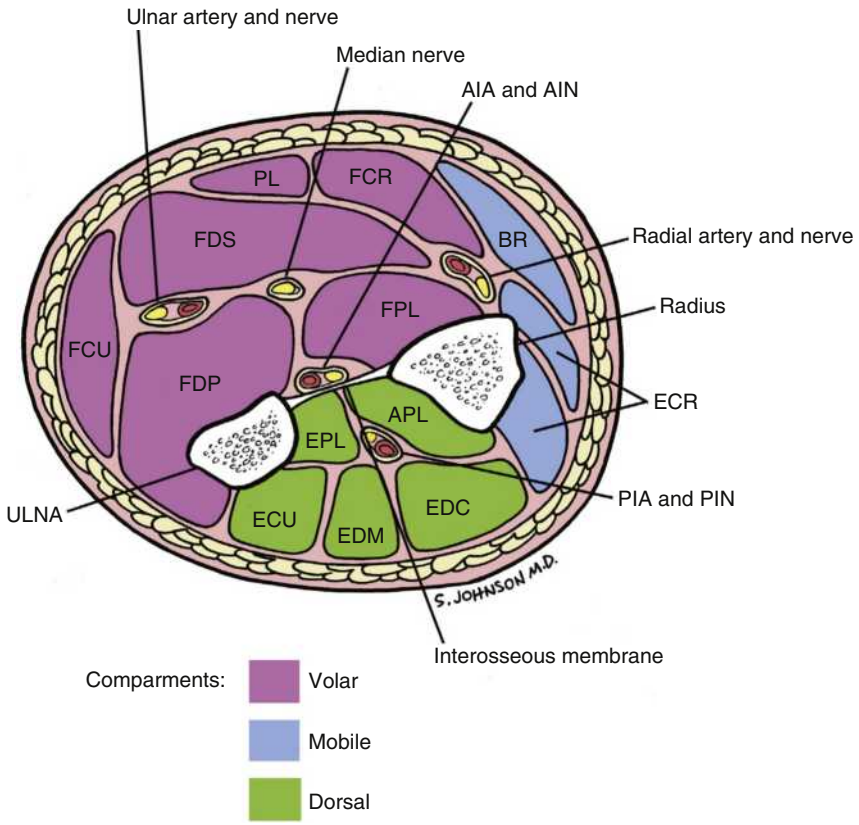

Fig. 43.32 Cross Section of the Forearm Demonstrating the Compartments and Neurovascular Structures. The volar compartment contains the flexors of hand and wrist, including the palmaris longus *(PL)*, flexor digitorum superficialis *(FDS)*, flexor carpi radialis *(FCR)*, flexor pollicis longus *(FPL)*, flexor digitorum profundus *(FDP)*, and flexor carpi ulnaris *(FCU)*, as well as the ulnar nerve, ulnar artery, median nerve, radial artery, superficial branch of the radial nerve, anterior interosseous artery *(AIA)*, and anterior interosseous nerve *(AIN)*. The dorsal and volar compartments are bordered by the interosseous membrane. The dorsal compartment contains finger extensors and long thumb abductor, as well as the posterior interosseous artery *(PIA)*, posterior interosseous nerve *(PIN)*, abductor pollicis longus *(APL)*, extensor digiti minimi *(EDM)*, extensor carpi ulnaris *(ECU)*, extensor pollicis longus *(EPL)*, and extensor digitorum communis *(EDC)*. The mobile wad, which is often considered to be a third compartment, is composed of the extensor carpi radialis brevis and longus muscles *(ECR)* and brachioradialis *(BR)*. (Courtesy Dr. S. Johnson.)

Injury to the radial head can be evaluated by drawing a midaxis line through the radial shaft, neck, and head. This radial midaxis line should intersect the center of capitellum of the elbow on any radiologic view. Any variance from this alignment should raise suspicion regarding radial head dislocation (Fig. 43.34).

CT scans can be useful when there is a suspicion of extension of the fracture into the DRUJ or PRUJ on plain radiography. MRI is the study of choice for evaluation of soft tissues (e.g., muscle, tendon, ligament) of the forearm, including the interosseous membrane. Ultrasound can also help with evaluation of interosseous membrane injury and to determine when pediatric forearm fractures have been adequately realigned after closed reduction.[15]

Shaft Fractures of Radius and Ulna

Foundations

Fractures involving both the radius and ulna, also known as both bone fractures, are common forearm injuries.

Clinical Features

Patients often have pain and obvious deformity of the forearm as a result of blunt trauma. Physical examination includes assessing for any associated neurovascular injury or open fracture. Compartment syndrome should be considered in all patients with these types of injury. Common complications of combined radius and ulna fractures are nonunion, malunion, infection, and neurovascular injury.

Diagnostic Testing

The initial radiologic evaluation should include the AP and lateral radiographs of the forearm, as well as dedicated wrist and elbow radiographs.

Management and Disposition

After initial evaluation, any open fractures should be irrigated with sterile water or saline to decrease contamination, and a sterile dressing should be applied, along with parenteral antibiotics, while awaiting emergent operative management. Any grossly displaced fracture-dislocation should be reduced to improve alignment and prevent impending or ongoing neurovascular injury. Application of a sugar tong forearm splint should be made with an urgent referral within 7 days to an orthopedist, as long as there is no evidence of open fracture or neurovascular compromise.

Nondisplaced concurrent radius and ulna fractures are uncommon and most both bone fractures of the forearm in adults generally require operative management as soon as possible to achieve the alignment.

Fig. 43.33 Normal anteroposterior (A) and lateral (B) radiographic views of the forearm. Both bones should be visible for their entire length, and the radiograph should include the wrist and elbow joints.

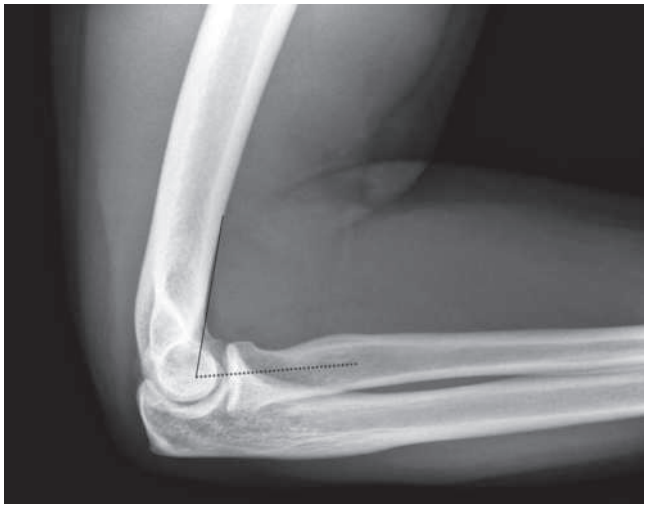

Fig. 43.34 Lateral Radiographic View of a Normal Elbow. A line bisecting the proximal radial shaft also bisects the capitellum *(dotted line)*.

Ulna Shaft Fractures

Foundations

Isolated fractures of the ulna shaft, known as nightstick fractures, are seen frequently in the ED.

Clinical Features

Patients often have pain and swelling over the medial aspect of the forearm, because the usual mechanism involves raising the arm overhead to protect it from a direct traumatic impact. Careful inspection

Fig. 43.35 Isolated Ulna Fracture *(Nightstick Fracture)*. Anteroposterior (A) and lateral (B) radiographic images show isolated ulnar fracture.

of the skin is necessary as many patients have open fractures, given the superficial position of the ulna directly under the subcutaneous skin. Examination should include wrist and elbow assessments to exclude any associated injuries involving the PRUJ or DRUJ. The emergency clinician should be aware of potential instability at either articulation associated with fractures involving the proximal or distal third of the ulna.

Diagnostic Testing

Diagnosis of an ulna fracture is made by obtaining AP and lateral radiographs of the full-length forearm (Fig. 43.35). Although most isolated ulna fractures are considered stable, those with more than 50% displacement, more than 8 degrees of angulation, involvement of the proximal third of the ulna, or instability at the DRUJ or PRUJ are considered unstable fractures.

Management and Disposition

There is a controversy regarding the indication for the operative management of isolated ulna shaft fracture; however, any unstable fractures should be referred to an orthopedist within 7 days for possible ORIF because they carry a high risk of function loss, nonunion, malunion, and radioulnar synostosis.[16]

Most stable ulna fractures heal without significant clinical sequelae. Stable fractures can be managed with 6 to 8 weeks of short arm, below-elbow immobilization with interosseous molding to limit radial angulation and prevent forearm rotation. Early mobilization with a removable forearm support achieves the earliest radiologic time to union and lowest rate of malunion. Above-elbow immobilization or long arm casting

may be detrimental to the healing process and have been associated with nonunion and delayed union.

Monteggia Fracture

Foundations

Ulna fractures associated with radial head dislocation are commonly known as Monteggia fractures. Monteggia originally described a traumatic lesion involving the fracture of the proximal third of the ulna and anterior dislocation of the radius. Bado later redefined the Monteggia fracture and classified it to encompass various ulna fractures with concomitant radial head dislocations. The Bado classification divides the injury into four types depending on the location and angulation of the ulna fracture, along with the direction of the radial head dislocation.

Clinical Features

Patients with a Monteggia fracture often have fallen on an outstretched hand, resulting in hyperpronation. Direct posterior force on the ulna or a fall on the flexed elbow has also been implicated in the mechanism of the injury. Typically, patients have swelling and tenderness along the fracture site accompanied by a limited range of motion at the elbow and pain with pronation of the forearm. A dislocated radial head may be appreciated on palpation. Initial assessment of a Monteggia fracture should include a focused neurologic examination because the posterior interosseous nerve (PIN), a deep branch of the radial nerve, can be injured. Because the PIN innervates the finger extensors along with the supinator, PIN injury is often manifested by weakness or paralysis of the thumb or finger extension. Complications of a Monteggia fracture include malunion, nonunion, synostosis, stiffness, and nerve palsy. Early diagnosis and treatment of a Monteggia fracture are crucial in achieving good outcomes.

Diagnostic Testing

The radiograph of the forearm reveals the obvious ulna fracture that often overshadows the subtle radial head dislocation (Fig. 43.36). A chronic, irreducible radial head dislocation can occur as a result of delay in diagnosis. Drawing the radiocapitellar line (RCL) through the head of the capitellum can prevent overlooking a proximal dislocation. The line should intersect the distal third of the capitellum on all views and confirm correct alignment. In young children however, an RCL may not reliably bisect the capitellum in normal pediatric patients. An abnormal RCL is suggestive of, but not pathognomonic for an injury.

Management and Disposition

Treatment of a Monteggia fracture depends on the age of the patient. Pediatric patients with this type of injury can be treated conservatively, with long arm casting in supination with acceptable reduction. Conversely, most adult patients with this type of fracture should have orthopedic evaluation to arrange for urgent ORIF.

Fig. 43.36 *Monteggia Fracture-Dislocation.* A fracture of the ulna diaphysis with anterior dislocation of the radial head *(arrow)* is shown in this lateral view of the forearm.

Galeazzi Fracture

Foundations

Galeazzi fracture refers to a fracture of the middle to distal third of the radius associated with injury to and dislocation of the DRUJ.

Clinical Features

Typically, a Galeazzi fracture results from a fall or motor vehicle collision as the patient attempts to brace for impact by stretching out the hand in hyperpronation. A direct blow to the dorsolateral aspect of the forearm is less common but also well recognized as a mechanism of injury for a Galeazzi fracture. Galeazzi fracture is often overlooked as a simple radius fracture, yet it often results in diminished forearm range of motion, loss of function, weakness, and chronic pain.

In addition to radiographic imaging, the mechanism of injury and focused examination play a critical role in the diagnosis of a Galeazzi fracture because injuries to the DRUJ may not be obvious. Patients with Galeazzi fracture have deformity at the site of the fracture associated with swelling and tenderness. The wrist should be meticulously examined to assess for stability of the DRUJ. Instability of the DRUJ can range from obvious prominence of the ulnar head (associated with the subluxation or dislocation) to tenderness elicited at the wrist, which can be a subtle sign of DRUJ ligament injury.

Diagnostic Testing

AP and lateral radiographs of the entire forearm and wrist are necessary to diagnose Galeazzi fracture. Besides the obvious fracture at the middle to distal third of the radius, there will be other subtle radiographic findings. On the AP view of the forearm, the space between the distal radius and ulna is widened (>2 mm) and the radius appears relatively shortened. In the lateral view, the dorsally angulated fracture of the radius can cause a dorsal displacement of the ulnar head. A fracture at the base of the ulnar styloid should raise the suspicion for DRUJ interruption (Fig. 43.37). Although not all radius shaft fractures are associated with DRUJ injury, previous studies have shown that at least 25% of all patients with radius fractures have DRUJ dislocation. Therefore, patients with radial shaft fractures should be referred to an orthopedist for further evaluation.

Management and Disposition

Conservative management of a Galeazzi fracture in adults has been associated with poor outcomes. Due to deforming forces from different forearm muscles and loss of stability at the DRUJ, displacement of the alignment in the cast occurs, despite successful initial reduction. A Galeazzi fracture has been termed a "*fracture of necessity*" to imply that surgical intervention is pivotal for achievement of an ideal anatomic position and acceptable functional outcomes. For any skeletally mature patients with this fracture, an orthopedist should be consulted emergently for ORIF of the radius and associated repair of the DRUJ to maintain the length and alignment. In contrast, conservative treatment with closed reduction and long arm casting has been successful in children and rarely necessitates surgical intervention. Along with the common complications associated with forearm fractures, such as malunion and nonunion, the occurrence of subluxation and dislocation of the DRUJ can result in limited motion and chronic pain.

Essex-Lopresti Lesion

Foundations

The Essex-Lopresti lesion, or longitudinal radioulnar disassociation, refers to an unstable forearm as a result of a triad of injuries to the radial head, disruption of the interosseous membrane, and violation of the DRUJ.

Fig. 43.37 Galeazzi Fracture-Dislocation. The anteroposterior (A) and lateral (B) views of the forearm show an obvious fracture of the distal third of the radius, with severe displacement and an associated dislocation of the distal radioulnar joint *(arrow)*.

Clinical Features

The patient often has fallen on an outstretched hand, resulting in transmission of a large axial loading force from the wrist to elbow. Consequently, the radial head, the primary forearm stabilizer, is fractured and displaced proximally. Disruption of the interosseous membrane and DRUJ also occurs and compromises the stability of the forearm. In addition to localized pain along the elbow from a radial head fracture, patients with the Essex-Lopresti lesion have wrist and forearm pain, along with grip and pronation weakness. Radioulnar synostosis and loss of forearm rotation can result from longitudinal disassociation. Early diagnosis of Essex-Lopresti injury and stabilization of DRUJ have been linked to favorable outcomes in comparison to delayed diagnosis.[17]

Diagnostic Testing

The diagnosis of an Essex-Lopresti lesion remains elusive because the standard AP and lateral views of the forearm often reveal an isolated radial head fracture. Thus, the incidence of the lesion may be higher than previously appreciated. The integrity of the interosseous membrane is difficult to assess based on a plain film. Subtle findings of positive ulna variance and a widened DRUJ are suggestive of longitudinal radioulnar dissociation. Obtaining a grip view and comparing the injured wrist with the contralateral wrist can be helpful in diagnosing an Essex-Lopresti lesion. MRI is the study of choice when clinical suspicion for an Essex-Lopresti lesion is high; however, ultrasound has recently been used more frequently to evaluate the integrity of the interosseous membrane. A CT scan (with three-dimensional reconstructions) of the elbow may be helpful in determining the degree of comminution and articular involvement of the radial head.

Management and Disposition

Once the diagnosis of an Essex-Lopresti lesion is confirmed, the patient should be referred to an orthopedic surgeon within 7 to 10 days for further surgical intervention. Many strategies have been proposed to repair Essex-Lopresti lesions, and the treatment option varies, depending on the chronicity of the injury.

ACKNOWLEDGMENT

We would like to thank David Williams, Karen G.H. Woolfrey, Michael Woolfrey, and Mary A. Eisenhauer for their contributions to previous versions of this chapter.

CHAPTER 43: QUESTIONS AND ANSWERS

1. In the setting of acute trauma and negative radiographs of the wrist, which clinical examination method(s) is (are) used to detect occult scaphoid fractures?
- **a.** Anatomic snuffbox tenderness
- **b.** Scaphoid tubercle tenderness
- **c.** Thumb metacarpal compression tenderness
- **d.** A positive Watson's scaphoid shift test
- **e.** All of the above

Answer: e. In the setting of acute trauma and negative radiographs, tenderness to palpation within the anatomic snuffbox, on the scaphoid tubercle, with thumb metacarpal compression, or a positive Watson's scaphoid shift test are all suggestive of occult scaphoid fracture.

2. A 45-year-old man complains of wrist pain after falling on an outstretched hand. What injury is shown in Figure 43.21 of the patient's wrist?
- **a.** Barton's fracture
- **b.** Lunate dislocation
- **c.** Perilunate dislocation
- **d.** Scaphoid fracture
- **e.** Scapholunate dissociation

Answer: e. The radiograph shows the signet ring, or cortical ring sign, which refers to the rotary subluxation of the scaphoid and oval appearance of the tubercle in the anteroposterior (AP) view of the wrist. On a properly positioned radiograph, this sign is typically associated with scapholunate widening, suggesting ligamentous laxity or dissociation. The signet ring sign is also used to describe pulmonary computed tomography (CT) imaging of bronchiectasis in relation to a dilated bronchus and associated pulmonary artery.

3. A 55-year-old man complains of wrist pain after a fall onto an outstretched arm. There is pain and swelling along the carpal bones. Also noted is decreased two-point sensation distally on the tips of the index and middle digits. Which structure is most likely injured?
- **a.** Median nerve
- **b.** Radial artery
- **c.** Radial nerve
- **d.** Ulnar artery
- **e.** Ulnar nerve

Answer: a. The median nerve courses through the carpal tunnel on the volar aspect of the wrist. It provides sensation to most of the palm and thumb, half of the ring finger and, specifically, the tips of the index and middle digits. The median nerve is the most common neurapraxia associated with Colles fractures.

4. Which nerve is commonly associated with a Monteggia fracture?
- **a.** Muscular branch of the radial nerve
- **b.** Posterior interosseous nerve
- **c.** Deep branch of the ulnar nerve
- **d.** Median nerve
- **e.** Ulnar nerve

Answer: b. Injury to the posterior interosseous nerve (PIN), a deep branch of the radial nerve, is commonly associated with a Monteggia fracture. Because the PIN innervates the finger extensors along with the supinator, associated injury is often manifested by weakness or paralysis of the thumb or finger extension.

5. A karate player presents with pain over the ulnar aspect of his hand. On physical examination, there is tenderness over the ulnar aspect of the wrist, distal to the volar crease. Paresthesias in the distribution of the ulnar nerve are present and the patient also complains of hand clumsiness. Standard X-rays are negative. What additional view might reveal the diagnosis?
- **a.** Clenched fist view
- **b.** Carpal tunnel view
- **c.** Scaphoid view
- **d.** External Oblique view
- **e.** Metacarpal view

Answer: b. Pisiform or hook of hamate fractures may cause the constellation of findings in the above scenario and are better appreciated on the carpal tunnel view. The clenched fist view is best for identifying scapholunate widening while the scaphoid view is optimal for identifying scaphoid fractures. The external oblique view would not optimize imaging of these two bones and the metacarpal view is not an actual view.

Humerus and Elbow Injuries

Matthew Salzberg and Kelly Bookman

KEY CONCEPTS

- Clinical decision rules for the elbow joint have not been validated. Radiographs should be obtained when there is limitation in range of motion, moderate to severe pain, obvious deformity, joint effusion, or significant tenderness or crepitus over any of the bony prominences or the radial head.
- The threshold for radiographic imaging should be lower in pediatric patients (with the exception of radial head subluxations), owing to the presence of open growth plates and limitations to the physical examination.
- Injuries that result in neurovascular compromise necessitate prompt intervention and consultation with an orthopedic specialist for reduction and potential operative intervention.
- In children with a traumatic wrist injury, normal radiographs should prompt consideration of an elbow injury causing referred pain to the wrist.
- On lateral elbow x-ray, a small anterior fat pad, parallel to the anterior surface of the humerus, can be a normal finding. Any convex ("sail sign") anterior fat pad and all posterior fat pads are pathological and indicate the presence of joint effusion.
- In the setting of trauma, patients with a radiological posterior fat pad sign of the elbow are assumed to have an intra-articular skeletal injury. In adults, a posterior fat pad sign is indicative of a radial head fracture, whereas in children, a supracondylar fracture is more likely. In the absence of trauma, inflammation and infection also cause effusions with positive fat pad signs.
- Radial nerve injury is the most common complication of humeral fractures. This is most often a benign neurapraxia that resolves spontaneously. Radial nerve injuries associated with penetrating trauma or open fractures are likely to represent anatomical disruption requiring operative exploration.
- The radius and ulna, bound together firmly by the annular ligament and interosseous membrane, typically displace as a unit and dislocate posteriorly following a traumatic injury.
- Biceps tendon rupture is more common in men, between ages 40 to 60, resulting from an unexpected extension force applied to the arm flexed at 90 degrees. Smoking, diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy may predispose to this injury.

FOUNDATIONS

Background and Importance

Injuries in the region of the elbow can be difficult to diagnose and have a high potential for complications and residual disability. Recognition of neurovascular and soft tissue complications improves the outcome in many of these injuries.

Anatomy, Physiology, and Pathophysiology

Knowledge of the relevant anatomy, mechanisms of injury, and appropriate management techniques, as well as knowing when to refer to or consult with orthopedic specialists will improve outcomes. The essential anatomy of the elbow region, as it relates to acute injury, is shown in Figs. 44.1–44.4.

GENERAL CLINICAL FEATURES

The history includes a description of the mechanisms of the traumatic event, pain characteristics including quality, duration, location, effects of movement, exacerbating or alleviating factors, severity, and radiation, in addition to concomitant injury or systemic complaint. Past medical history should include occupational factors and prior or chronic problems with the affected joint or other bones or joints. Numbness or weakness distal to the injury may indicate neurovascular injury. Pediatric orthopedic injuries, including those caused by abuse, are discussed in Chapters 160 and 172.

Examination begins with simple inspection and comparison with the contralateral limb. The position in which the extremity is held should be noted. Deformity may indicate fracture, dislocation, or hematoma. Range of motion may be evaluated, depending on the appearance of the extremity and suspicion of injury, but general manipulation of the acute injured extremity should be minimized. Bony prominences are palpated with notation of specific areas of tenderness. Crepitus, bony deformity, and pain in an acutely injured limb are virtually diagnostic of a fracture. The radial head specifically is palpated for tenderness. Intra-articular elbow fractures, including those of the radial head, are universally associated with effusion (hemarthrosis). Elbow effusions are notoriously difficult to discern on examination but are readily identified on lateral radiographs (Fig. 44.5). The extremity should be inspected for swelling, compromised circulation, or any wound that may indicate an open fracture.

In addition to the elbow region itself, focused examination incudes a thorough evaluation of the distal neurovascular status of the extremity. The presence of the brachial, radial, and ulnar pulses is confirmed by palpation. The ulnar pulse is more difficult to palpate than the radial pulse and may not be palpable in some normally healthy, uninjured patients. The radial, median, and ulnar nerve all transit the elbow in close proximity to major bony structures, so their motor and sensory functions require meticulous evaluation. The radial nerve can be tested by evaluating sensation to the dorsum of the hand and wrist extension. The median nerve should be tested for sensory function by assessing sensation at the lateral aspect of the thumb and for motor function by having the patient perform an "okay sign." The ulnar nerve provides sensation to the palmar aspect of the small digit and motor function to the medial interosseous muscles, which can be tested by having the patient abduct the small finger from the ring finger against pressure.

When movement of the elbow is possible without significant pain, the range of motion of the elbow in all planes (i.e., flexion-extension and pronation-supination) is determined. Inability to tolerate even

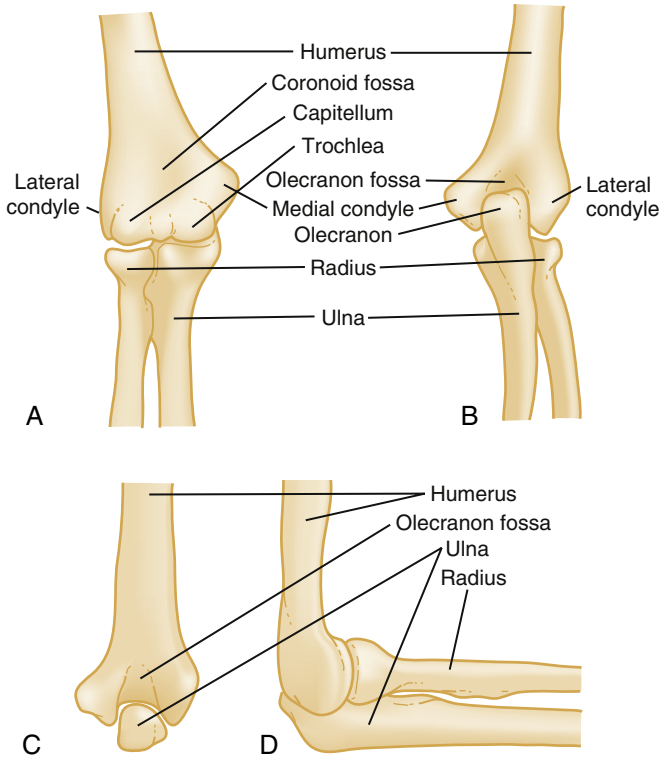

Fig. 44.1 Bony Anatomy of Distal Humerus and Elbow Region. (A) Anterior view. (B) Posterior view. (C) Posterior view, 90 degrees flexion. (D) Lateral view. Right elbow is shown. (Adapted from Connolly JF. *DePalma's management of fractures and dislocations*. Philadelphia, PA: WB Saunders; 1981.)

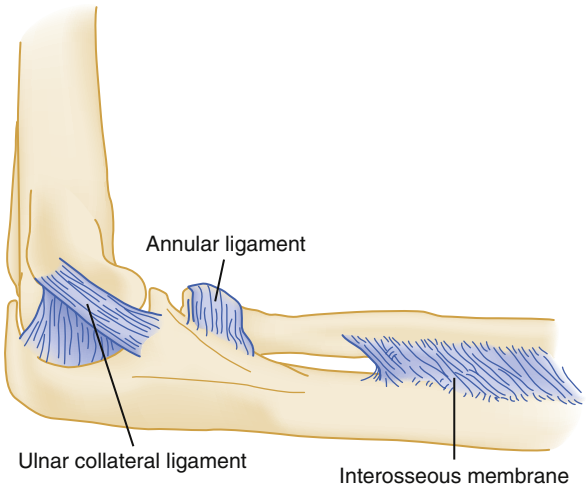
minimal passive movement often indicates dislocation or fracture. With the forearm supinated, the normal range of motion is 0 degrees in full extension to 150 degrees in full flexion. A mild degree of hyperextension is normal in some individuals and should be symmetric. With the elbow flexed at 90 degrees and the thumb facing up, the forearm normally supinates and pronates 90 degrees. Range-of-motion testing may be limited by pain and nearly impossible with severe injuries. These examination maneuvers can be delayed until after radiographic evaluation.

GENERAL DIFFERENTIAL DIAGNOSES

Injuries in the region of the shaft of the humerus and regions of the elbow fall into several categories including fractures, dislocations, subluxations, and soft tissue disorders (Table 44.1).

GENERAL DIAGNOSTIC TESTING

Most elbow and humerus injuries are evaluated radiographically, although on occasion, history and clinical examination alone are sufficient to make a diagnosis (e.g., minor mechanical fall with minimal pain, full range of motion, and no significant bony tenderness). There are no validated clinical decision rules for the elbow, so radiography should be performed when there is moderate to severe pain, significant limitation in range of motion, obvious deformity, swelling or effusion, or significant tenderness over any of the bony prominences or the radial head. With the exception of children with an apparent nursemaids' elbow (radial head subluxation), radiography should be used in virtually all pediatric elbow injuries with any bony tenderness on examination to assess for possible growth plate injury.



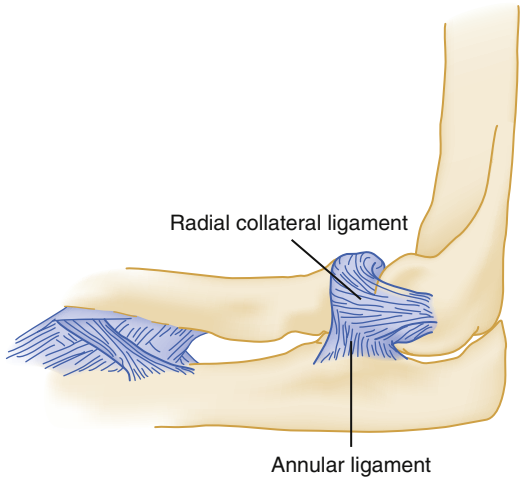


Fig. 44.2 Ligamentous Structures of Elbow. (From Simon R, Koenigsknecht S. *Emergency orthopaedics: the extremities*. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

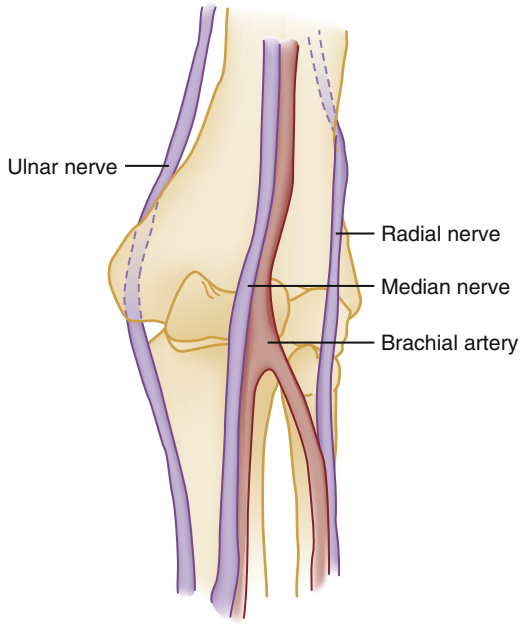

Fig. 44.3 Neurovascular Structures of Elbow Region. Volar surface of left elbow is shown.

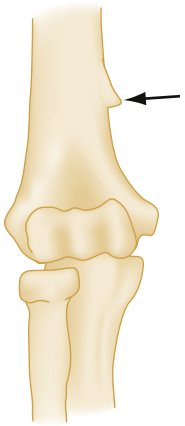

Fig. 44.4 Supracondylar process of the humerus *(arrow)* is present in approximately 2.5% of cases just proximal to the medial epicondyle. Volar surface of right elbow is shown.

Routine views of the elbow include at least the anteroposterior and lateral views, with oblique views when indicated. Anteroposterior and oblique views are taken with the elbow extended. The lateral view is taken with the elbow in 90 degrees of flexion and the thumb pointing upward. Positioning of the elbow is critical because anything other than a true lateral view makes accurate interpretation of soft tissue findings and alignment difficult.

Most fractures in the elbow region are identifiable on plain film, but radial head and subtle supracondylar fractures may be difficult to visualize. Radiographic examination of the elbow for the presence of fat pads secondary to traumatic effusion provides additional clues. The normal cortex of the radius is smooth and has a gentle continuous concave sweep. If consistent with history and physical findings, any disruption of this smooth arc is considered evidence of fracture. Abnormalities within the soft tissues on elbow films are particularly important and may be the only radiographic sign of a fracture. Normally, fat surrounding the proximal elbow joint is hidden in the concavity of the olecranon and coronoid fossae. The elbow normally has a narrow strip of lucency anteriorly, parallel to the anterior surface of the distal humerus (the anterior fat pad). The presence of a posterior fat pad is not considered a normal finding. Injuries that produce intra-articular hemorrhage cause distention of the synovium and displace the fat out of the fossa, making the posterior fat pad visible on lateral radiographic views. This intra-articular swelling displaces the anterior fat farther anteriorly, where it takes the shape of a main sail of a boat. Thus, this radiographic finding is commonly referred to as the "*sail sign*." Displacement of the posterior fat pad makes it visible on the lateral radiograph as a "posterior fat pad sign" (see Fig. 44.5). In the setting of trauma, more than 95% of patients with a posterior fat pad sign have an intra-articular skeletal injury. These soft tissue findings occur even with subtle fractures, and when present in the setting of trauma, an occult fracture should be suspected. In adults without an identifiable fracture on radiograph, fat pad signs most often indicate a radial head fracture, whereas in children a supracondylar fracture is the more likely. In the absence of trauma, the presence of a fat pad suggests other causes of effusion (e.g., inflammation or infection). Of note, the fat pad sign may be absent in fractures where the injury is severe enough to rupture the capsule.

Additional imaging modalities in the emergency department (ED), such as diagnostic ultrasound, computed tomography (CT) scanning, or magnetic resonance imaging (MRI) may be considered. Ultrasound may be considered as a quick bedside modality to assist in the diagnosis of fractures, most easily utilized on long bone injuries. This may

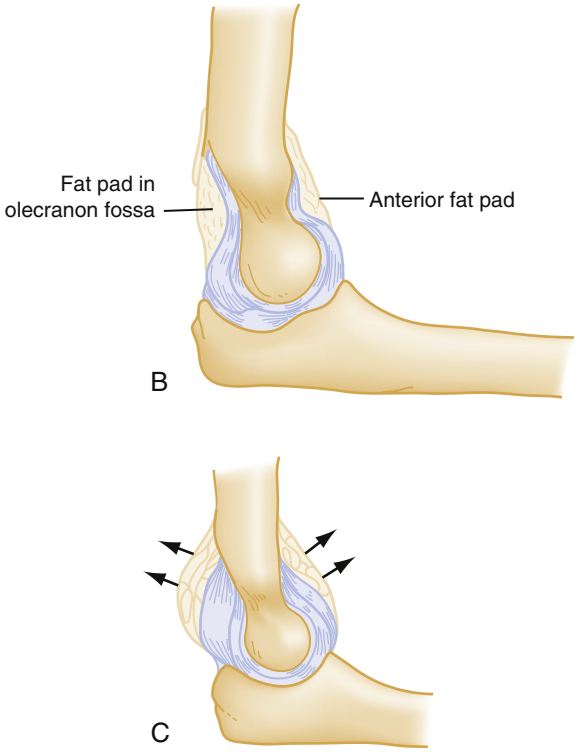

Fig. 44.5 (A) Anterior and posterior fat pads on lateral study *(arrows)*. (B) The anterior fat pad is normally a thin radiolucent stripe; the posterior fat pad is not visible. (C) An effusion displaces both fat pads. This posterior fat pad is now visible.

be especially useful in the hemodynamically unstable trauma patient during resuscitation.[1] MRI (or less commonly) CT imaging may be considered if there is high suspicion for a fracture on plain imaging that only reveals a traumatic effusion. Classically, this may be applied to pediatric elbow injuries to identify underlying fractures not visible on standard imaging.

GENERAL MANAGEMENT

General management should begin with an appropriate evaluation for additional traumatic injuries, pain control with appropriate analgesics, and attempt at providing patient comfort with support for the injured extremity. Once a potential fracture is identified, prompt neurovascular evaluation should be performed. Although a warm hand with

TABLE 44.1 Injuries to the Humerus and Elbow

Injury Site				Mechanism/Exam		Imaging
Humerus fractures	Shaft of the humerus fractures			Direct blow, severe twisting	Localized tenderness, may be shortened or rotated	Obvious fracture line
	Distal humerus fractures					
		Supracondylar (most common in children)				
			Extension	Fall on the outstretched hand when the elbow is either fully extended or hyperextended	Arm is held at the side and has a characteristic S-shaped configuration	Obvious fracture line or maybe the presence of a posterior fat pad or an abnormal anterior humeral line
			Flexion	Direct blow to the flexed elbow	Forearm is supported with the opposite hand with the elbow flexed to 90 degrees	Increase in the anterior angulation of the distal supracondylar fragment or gross displacement of the distal fragment proximal and anterior to the distal end of the proximal fragment
		Transcondylar (more common in elderly)		Mechanism of injury that is similar to that for supracondylar injuries	Localized tenderness	Fracture line, either transverse or crescent shaped, that passes through both condyles within the joint capsule just proximal to the articular surface
			Extension	Mechanism of injury that is similar to that for supracondylar injuries	Localized tenderness	Fracture line, either transverse or crescent shaped, that passes through both condyles within the joint capsule just proximal to the articular surface
			Flexion	Mechanism of injury that is similar to that for supracondylar injuries	Localized tenderness	Fracture line, either transverse or crescent shaped, that passes through both condyles within the joint capsule just proximal to the articular surface
		Intercondylar		Direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end	Localized tenderness	T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment
			Nondisplaced	Direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end	Localized tenderness	T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment
			Separated	Direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end	Localized tenderness	T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment
			Separated and rotated	Direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end	Localized tenderness	T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment

Injury Site				Mechanism/Exam		Imaging
			Combination with articular surfaces	Direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end	Localized tenderness	T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment
		Condylar			Localized tenderness	Widening of the intercondylar distance
			Medial	Valgus force on the extended elbow	Localized tenderness	Widening of the intercondylar distance
			Lateral	Direct blow to the lateral aspect of the flexed elbow or a force that results in adduction and hyperextension with avulsion of the lateral condyle	Localized tenderness	Widening of the intercondylar distance
			Articular surface		Localized tenderness	Widening of the intercondylar distance
		Capitellum		Fall on outstretched hand	Localized tenderness, pain worse with flexion	Fragment lying anterior and proximal to the main portion of the capitellum
		Trochlea		Fall on outstretched hand	Localized tenderness with limited ROM	Fragment visible lying on the medial side of the joint, just distal to the medial epicondyle, signs of joint effusion
		Epicondylar		Fall on outstretched hand, repetitive valgus stress, direct blow	Elbow is held in flexion and any movement is resisted	A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow dislocation; evaluate for fracture fragments
			Medial	Fall on outstretched hand, repetitive valgus stress, direct blow	Elbow is held in flexion and any movement is resisted	A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow dislocation; evaluate for fracture fragments
			Lateral	Fall on outstretched hand, repetitive valgus stress, direct blow	Elbow is held in flexion and any movement is resisted	A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow dislocation; evaluate for fracture fragments
Radius/ulnar fractures	Radial head fracture			Fall on outstretched hand	Localized tenderness over radial head or pain with passive rotation of forearm	Range from subtle disruption of the gradual sweep of the radial neck and head surface to obvious displaced or comminuted fracture, positive fat pad sign
		Nondisplaced		Fall on outstretched hand	Localized tenderness over radial head or pain with passive rotation of forearm	Range from subtle disruption of the gradual sweep of the radial neck and head surface to obvious displaced or comminuted fracture, positive fat pad sign
		Displaced		Fall on outstretched hand	Localized tenderness over radial head or pain with passive rotation of forearm	Range from subtle disruption of the gradual sweep of the radial neck and head surface to obvious displaced or comminuted fracture, positive fat pad sign
		Comminuted		Fall on outstretched hand	Localized tenderness over radial head or pain with passive rotation of forearm	Range from subtle disruption of the gradual sweep of the radial neck and head surface to obvious displaced or comminuted fracture, positive fat pad sign

TABLE 44.1 Injuries to the Humerus and Elbow—cont'd

Injury Site				Mechanism/Exam		Imaging
	Ulnar fracture					
		Olecranon fracture		Direct blow, forceful contraction of the triceps while the elbow is flexed during a fall can cause a transverse or oblique fracture through the olecranon	Localized tenderness, palpable separation at fracture site, inability to extend the elbow against force	Obvious fracture line
		Coronoid fracture		Direct blow, forceful contraction of the triceps while the elbow is flexed during a fall can cause a transverse or oblique fracture through the olecranon	Localized tenderness, palpable separation at fracture site, inability to extend the elbow against force	Obvious fracture line
Subluxations/ dislocations	Elbow dislocation					Obvious dislocation, must assess for concurrent fractures
		Posterior		Fall on the outstretched hand or wrist, the elbow being either extended or hyperextended	Elbow in flexion at approximately 45 degrees and have marked prominence of the olecranon	Obvious dislocation, must assess for concurrent fractures
		Anterior		Blow from behind to the olecranon while the elbow is in the flexed position	Upper arm appears shortened, the forearm elongated and supinated, the elbow is fully extended and the olecranon fossa is palpable posteriorly	Obvious dislocation, must assess for concurrent fractures
		Medial/lateral		Mechanism similar to that in posterior dislocations, with a vector of force displacing the ulna and radius as a unit either medially or laterally	Obvious deformity either medially or laterally	Obvious dislocation, must assess for concurrent fractures
	Radial head subluxation			Forearm pulled while in pronation with the elbow extended, direct blow, twisting	Arm held in passive pronation, with slight flexion at the elbow; refuses to move the arm, localized tenderness, swelling, ecchymosis and deformity are absent	Radiographs are not necessary and are rarely positive
Soft tissue	Epicondylitis			Repetitive pronation and supination of the forearm	Dull pain over lateral aspect of elbow, the lateral epicondyle or radiohumeral joint, increased by grasping or twisting motions	Radiographs normal or may have calcifications
	Olecranon bursitis			Repetitive minor trauma, inflammatory	Progressive pain, tenderness, and swelling over olecranon	None
	Bicep tendon rupture					
			Proximal	Repetitive microtrauma to the tendon	Visible defect at top of bicipital groove with bunching of the muscle distally, flexion of elbow produces pain at proximal insertion but flexion remains intact	None
			Distal	Extension force applied to the arm flexed at 90 degrees	Pain and tearing in the antecubital region, visible deformity and palpable defect of the biceps muscle belly with weakness of elbow flexion and supination	None

normal color suggests adequate tissue perfusion, a handheld Doppler device is often required to evaluate major vessel flow if significant swelling is present or if the pulses are not palpable. Poor perfusion may be the result of a direct arterial injury, compression or kinking from a fracture or dislocation, or compartment syndrome. Identification of arterial compromise or injury warrants consultation with an orthopedic or vascular surgeon (see Chapter 40). Compartment syndrome is discussed in Chapter 41. Orthopedic consultation and measurement of compartment pressures is indicated for patients who are suspected of having a compartment syndrome.

GENERAL DISPOSITION

General disposition for patients with humerus or elbow fractures depends on several considerations. Common fracture factors include need for emergent operative intervention and need for neurovascular checks or compartment checks. Additionally, patient-centered factors may include pain control, ability to perform activities of daily life, and ability to follow instructions regarding fracture care. Given the previous factors, a large proportion of upper extremity, humerus, and elbow injuries can be discharged home with appropriate orthopedic specialty follow-up.

Specific Fractures

Shaft of the Humerus

Clinical features of humeral shaft fractures. Fractures of the humeral shaft commonly result from a direct blow to the arm, severe twisting, or a fall on an outstretched hand. Rarely, fractures may be caused by abrupt muscle contraction, such as occurs when a javelin or baseball is thrown. The shaft of the humerus most commonly fractures in the middle third in a transverse fashion. The patient reports localized pain, which is often severe in nature, and the arm is visibly swollen and cannot be used. When a fracture is complete, bony crepitus is felt in the shaft of the humerus with the slightest manipulation of the arm. The arm may be shortened or rotated, depending on the displacement of the fracture fragments. When the fracture is incomplete, there is bony tenderness and swelling without obvious deformity.

Diagnostic testing for humeral shaft fractures. Imaging studies should routinely include the shoulder and elbow joints. The humerus is a common site for benign tumors, unicameral cysts, and primary bone malignancies, as well as a common site for metastatic disease. Thinning of the cortex and abnormal osteoblastic or osteoclastic activity are evidence of a pathologic fracture (Fig. 44.6). Pathologic lesions may require orthopedic surgical intervention, though once a fracture occurs, a multidisciplinary approach with oncology should occur to determine the best course of surgical intervention. While these fractures may be stabilized with treatment such as plates, pins, intramedullary nails, cement, and joint replacement, these underlying fractures do not heal well without concomitant treatment of the underlying pathologic condition.[2]

Management of humeral shaft fractures. Isolated, closed fractures are treated with a high degree of success. Attempts at fracture reduction and external immobilization are generally unnecessary and may be detrimental to healing. Fractures that are nondisplaced or minimally displaced are immobilized by adding a coaptation, or "sugar-tong" splint, to the sling and swathe (Fig. 44.7). The coaptation splint is often replaced by a functional brace after the first 10 to 14 days. If the fracture is grossly displaced or comminuted, the hanging cast technique is preferable. This technique is especially effective with spiral fractures (Fig. 44.8). Care is taken not to make the cast too heavy because this would distract fracture fragments or too tight as this may compromise circulation. The hanging cast has the disadvantage of using gravity for traction and requires that the patient remain upright at all times, including during sleep, a situation that many patients find intolerable. Neurovascular examination should be repeated and documented before and after the application of any splint or cast because entrapment of the nerve between fragments can occur after these interventions. Open reduction and internal fixation (Fig. 44.9) are necessary for open fractures, presence of multiple injuries that preclude mobilization, bilateral fractures, poor reduction, poor patient compliance, failure of closed treatment, and fractures through pathologic bone. Although the success rate with nonoperative intervention is about 80%, patients should be included in treatment decisions regarding nonoperative versus operative intervention because operative intervention may decrease recovery time resulting in earlier return to work.[3]

Fig. 44.6 Pathologic Fracture of Proximal Humerus.

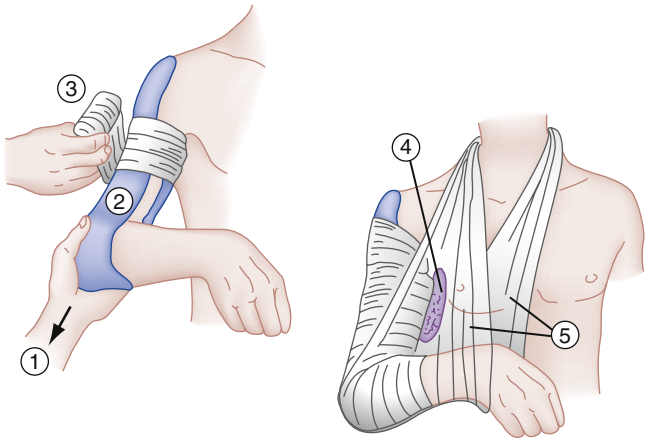

Fig. 44.7 Sugar-Tong Splint for Humeral Shaft Fractures. Gentle traction is applied (1) as the splint is placed (2) from over the deltoid laterally, under the elbow, and up into the axilla. An elastic wrap holds the splint in place (3). The axilla must be padded (4), and a sling is used (5). (Adapted from Connolly JF. *DePalma's management of fractures and dislocations.* Philadelphia, PA: WB Saunders; 1981.)

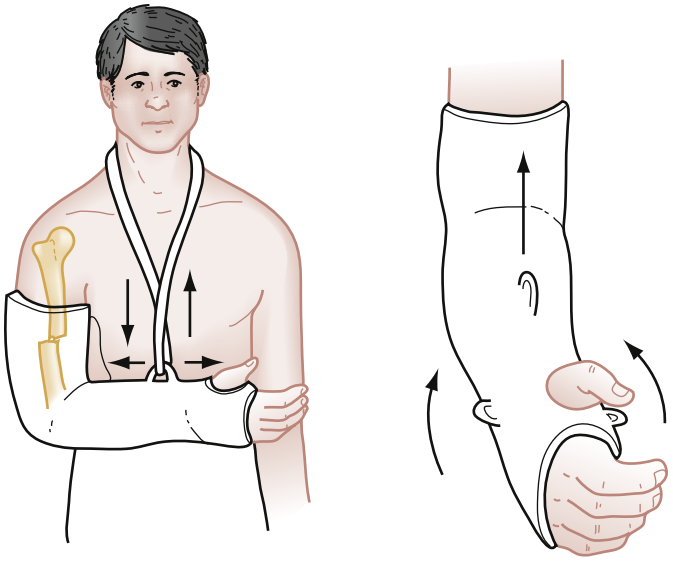

Fig. 44.8 Hanging Cast Technique.

For open fractures, the wound should be covered with normal saline soaked gauze. Splinting can be done for comfort during patient manipulation but should be limited. Cefazolin (2 g intravenously) is given, and consultation is obtained by orthopedic surgery for emergent operative washout. Additional antibiotics, such as an aminoglycoside or quinolone may be used as an alternate for gram negative coverage. For potential clostridial infection (e.g., contaminated farm injuries), clostridial coverage including clindamycin or metronidazole may also be indicated.[4]

The most common complication, radial nerve injury, occurs in up to 15% of humerus fractures.[5] Radial nerve injury causes wrist drop with loss of the ability to extend the fingers and thumb.[6] This nerve injury is most often a benign neurapraxia that resolves spontaneously in approximately 80% to 90% of cases without operative intervention, although recovery may take 6 to 9 months.[6] Of those with radial nerve palsy who fail conservative treatment, upwards of 90% of patients will recover.[5] Patients should be advised of this possible complication prior to discharge, and follow-up with an orthopedic surgeon should be arranged from the ED. Exploration and internal fixation are indicated if the radial nerve palsy develops after manipulation, because this is highly suggestive of nerve entrapment. Radial nerve injuries associated with penetrating trauma or open fractures are likely to be caused by anatomical nerve disruption and generally warrant operative exploration. Median and ulnar nerve injuries are rare and usually secondary to penetrating trauma. Injuries to the brachial artery occur rarely and, if suspected, vascular surgery consultation is indicated, often with angiography or other vascular studies.

Disposition of humeral shaft fractures. All patients with humeral shaft fractures should be referred to an orthopedic surgeon for further evaluation within 48 hours after treatment in the ED to ensure that the alignment has been maintained, no neurological deficits have emerged, and pain is adequately controlled. Emergent referral to an orthopedist is recommended for patients with evidence of radial nerve injury, severely displaced or comminuted fractures, open fractures, or fractures associated with forearm fractures in the same injured extremity.

Distal Humerus

Supracondylar fractures. Distal humerus fractures that occur proximal to the epicondyles are called supracondylar fractures. This type of fracture is almost exclusively an injury of the immature skeleton, with a peak incidence in children 5 to 10 years old.[7] This injury rarely occurs after age 15 and accounts for approximately one half of all elbow fractures and one third of pediatric limb fractures. In children, the tensile strength of the collateral ligaments and joint capsule of the elbow is greater than that of bone. In adults, the reverse is true, and a fall or accident that would result in a supracondylar fracture in children would likely result in a posterior elbow dislocation

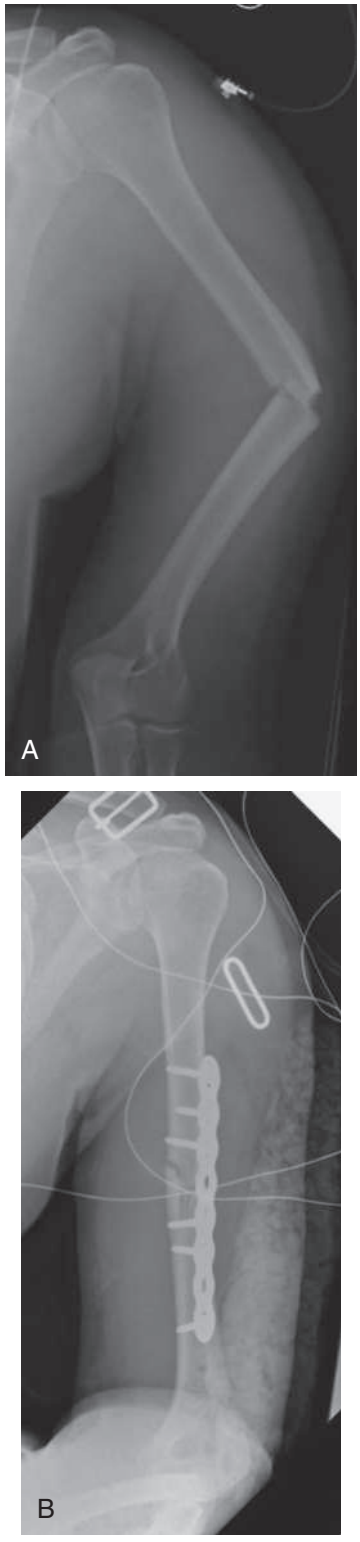

Fig. 44.9 Midshaft humerus fracture before (A) and after (B) open reduction and internal fixation.

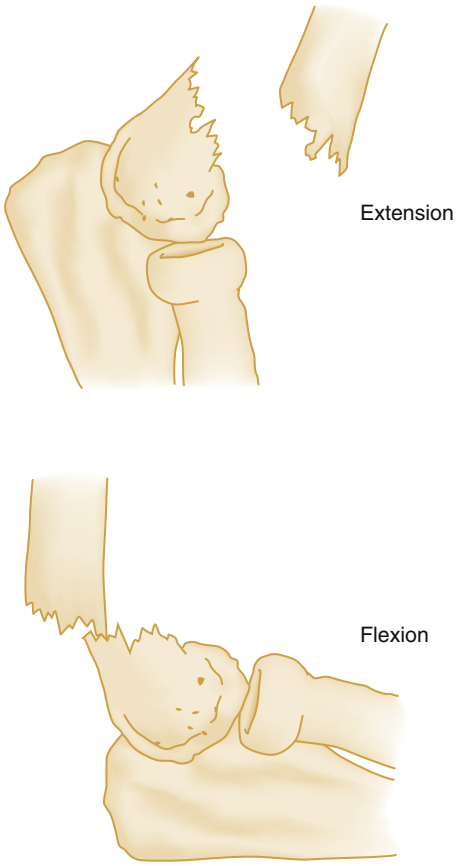

Fig. 44.10 Supracondylar Fractures, Extension and Flexion. (Adapted from Simon R, Koenigsknecht S. *Emergency orthopaedics: the extremities*. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

in an adult. Supracondylar fractures are classified as either extension or flexion fractures, depending on the mechanism of injury and the displacement of the distal fragment. Of these injuries, 98% are of the extension type.

Extension type supracondylar fractures.

Clinical features of extension type supracondylar fractures. Extension supracondylar fractures occur as a consequence of a fall on the outstretched hand when the elbow is either fully extended or hyperextended (e.g., a fall off the playground "monkey bars"). The strong action of the triceps tends to pull and displace the distal fragment in a posterior and proximal direction. In children with extension-type supracondylar fractures, the arm is held at the side and has a characteristic S-shaped configuration, whereas with flexion-type supracondylar fractures, the forearm is supported with the opposite hand with the elbow flexed to 90 degrees. There may be anterior angulation of the sharp distal end of the proximal fragment into the antecubital fossa, which could injure the brachial artery and median nerve (Fig. 44.10). In most cases, however, the brachialis muscle protects the anterior neurovascular structures from injury. Because this fracture primarily occurs in children, 25% of supracondylar fractures are of the greenstick variety, with the posterior cortex remaining intact. Subtle changes (e.g., the presence of a posterior fat pad or an abnormal anterior humeral line) may be the only radiographic clues to the presence of a fracture (Fig. 44.11). Ten percent of children lose the radial pulse temporarily, most often as a result of swelling and not direct brachial artery injury. Fracture reduction, avoiding flexing the elbow more than 90 degrees, and elevating the arm help prevent secondary obstruction to arterial flow. Nerve injuries occur in approximately 10% of these injuries,

Fig. 44.11 Supracondylar fracture *(arrow)* with anterior and posterior fat pad.

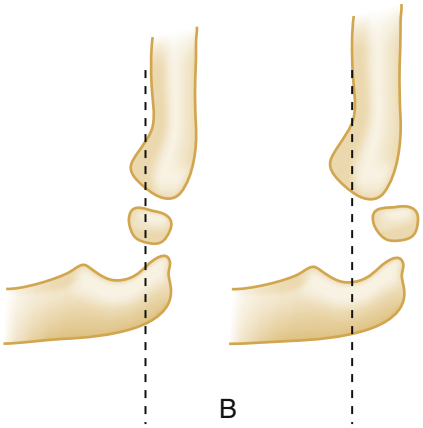

Fig. 44.12 (A) A line drawn down the anterior surface of the humerus on a lateral film should transect the middle third of the capitellum. (B) With an extension supracondylar fracture, the line passes more anteriorly. (From Simon R, Koenigsknecht S. *Emergency orthopaedics: the extremities*. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

but the incidence increases to a range of 20% to 50% with increasing severity of fracture displacement.[8,9] The anterior interosseous nerve is the most commonly injured, followed by the radial, median, and ulnar nerves. Most deficits seen at the time of injury are neurapraxias that resolve with rest and conservative management. Motor function returns within 7 to 12 weeks, whereas recovery of sensation may take over 6 months, though the recovery of injuries with multiple nerve injuries may take longer than that of isolated nerve injuries.[8,10]

Diagnostic testing of extension-type supracondylar fractures. Two diagnostic aids in evaluating for possible supracondylar fractures include using the anterior humeral line and evaluation of Baumann's angle. The *anterior humeral line* is a line drawn on a lateral radiograph along the anterior surface of the humerus through the elbow. Normally, this line transects the middle third of the capitellum (Fig. 44.12). With an extension supracondylar fracture, this line either transects the anterior third of the capitellum or passes entirely anterior to it. An abnormal relationship between the anterior-humeral line and capitellum may be the only radiographic evidence of a minimally displaced supracondylar fracture and is a presumptive finding of a

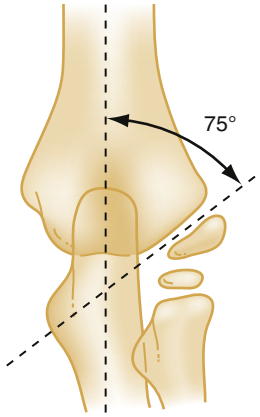

Fig. 44.13 Baumann's Angle as Measured on Anteroposterior Film. (From Worlock P. Supracondylar fractures of the humerus. *J Bone Joint Surg Br.* 1986;68:755.)

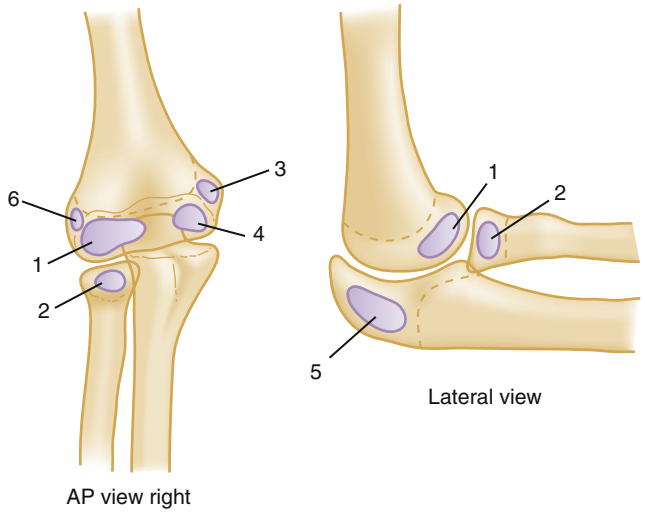

Fig. 44.14 Secondary Growth Centers of the Elbow. 1, Capitellum. 2, Radial head. 3, Medial epicondyle. 4, Trochlea. 5, Olecranon. 6, Lateral epicondyle. (From Townsend DJ, Bassett GS. Common elbow fractures in children. *Am Fam Physician.* 1996;53:2031.)

fracture. *Baumann's angle* is the intersection of a line drawn on the anteroposterior film through the midshaft of the humerus and the growth plate of the capitellum defines an angle of approximately 75 degrees (Fig. 44.13).[11] Radiographic evaluation of the elbow in children is challenging because of the presence of multiple ossification centers (Fig. 44.14). Comparison views of the uninjured elbow are often helpful in distinguishing fractures from the normal epiphyses and ossification centers. Table 44.2 lists the typical age of first appearance and fusion of ossification centers.

Based on radiographic findings, supracondylar fractures are classified into four types: type I, minimal or no displacement; type IIA, displaced fracture, posterior cortex intact with no rotational component; type IIB, displaced fracture, posterior cortex intact with a rotational component; type III, totally displaced fracture, anterior and posterior cortex disrupted; and type IV, multidirectionally unstable due to complete circumferential periosteal disruption.[12]

Management and disposition of extension type supracondylar fractures. Current treatment recommendations for supracondylar fractures from the American Academy of Orthopedic Surgeons remain based on the modified Gartland classification (Box 44.1). Nondisplaced extension supracondylar fractures (type I) are immobilized primarily

TABLE 44.2 Ossification Centers of the Elbow: CRITOE

Ossification Centers	Age of Appearance
Capitellum	1–2
Radial head	4–5
Internal (medial) epicondyle	4–5
Trochlea	8–10
Olecranon	8–9
External (lateral) epicondyle	10–11

BOX 44.1 Gartland Classification for Supracondylar Fractures in Children

Type I: Minimal or no displacement
Type II: Displacement of the fracture but with the posterior cortex intact
  Type IIA: No rotational component
  Type IIB: Some rotational component
Type III: Displaced, no cortical contact, periosteal contact
  Type IIIA: No rotation of the fracture
  Type IIIB: Rotation present
Type IV: Complete disruption/displacement

for comfort and protection, because they are inherently stable. They are treated in a splint or cast flexed to 75 to 80 degrees with the forearm in neutral rotation.[8] Protected active range of motion is begun in approximately 3 weeks. Even without definite radiographic findings, a child with localized tenderness consistent with a supracondylar fracture should be splinted and referred for follow-up examination within 24 to 48 hours. A plain radiograph performed a few weeks after the injury may reveal periosteal new bone formation in the supracondylar region. Patients with a type I fracture can be discharged safely from the ED with instructions to elevate the extremity, apply ice, and have a follow-up evaluation in 1 to 2 days. Fractures that require manipulation usually warrant admission to the hospital to ensure compliance and for neurovascular monitoring. Minimally displaced (type II) fractures that are stable after reduction can be treated with splinting or casting with the elbow flexed. We recommend flexion to 110 to 120 degrees for this injury.[7] This position uses the intact posterior periosteum as a tension band to hold the reduction; however, if swelling or circulatory obstruction prevents this amount of flexion, it should not be used. The greater the flexion at the elbow, the greater is the chance of vascular impairment. When swelling peaks at 24 to 48 hours, the risk of vascular obstruction and compartment syndrome is highest. Occasionally, these injuries require percutaneous pinning to maintain stability, especially if a significant rotational component is present.[8] Percutaneous pinning of fractures after reduction has grown in popularity in recent years and is recommended for type IIB fractures with some studies showing better outcomes with pinning than without.[8,13] Type III totally displaced fractures generally are the result of more severe injuries that produce more swelling than type I or type II injuries. Displacement necessitates the reestablishment of length, increases the chance of varus deformity, and increases the chances of interposed soft tissues and neurovascular injury. For all these reasons, patients with type III fractures require emergency orthopedic consultation in the ED and should be admitted to the hospital for frequent neurovascular checks and closed reduction and percutaneous pinning. Open reduction may be necessary if closed reduction is unsuccessful.[8] Reduction in the ED is indicated only when the displaced fracture is associated with vascular compromise

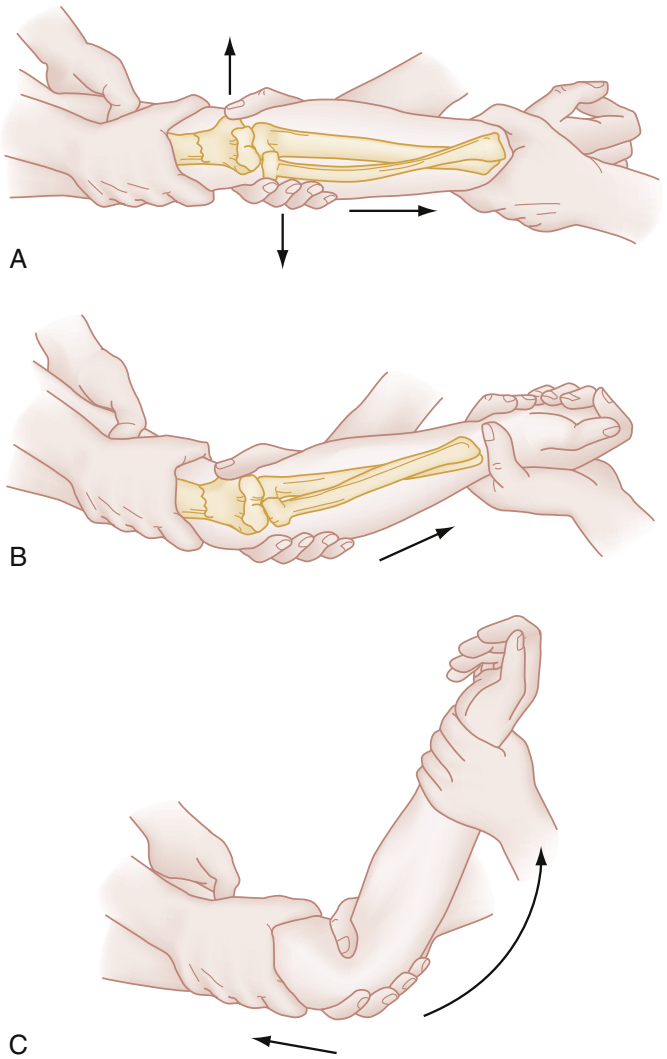

Fig. 44.15 (A) to (C) Steps in reduction of displaced supracondylar fracture.

that threatens the viability of the extremity. Under these conditions, closed reduction should be attempted. After appropriate procedural sedation, an assistant fixes the arm of the patient. The clinician grasps the patient's wrist and applies steady, firm traction in line with the long axis of the limb (Fig. 44.15A). The forearm is kept in the neutral, thumb-up position. While traction is maintained, correction of any medial or lateral displacement is accomplished with the other hand at the elbow (see Fig. 44.15B). If the distal fragment is displaced laterally, it is pushed inward; if it is displaced medially, it is pushed outward. After the length has been restored and the angular deformity has been corrected, the thumb of the free hand is placed over the anterior surface of the proximal fragment with the fingers behind the olecranon. While traction is maintained, the elbow is gently flexed to just beyond 90 degrees (see Fig. 44.15C). Angulation is corrected to a normal carrying angle. Only one attempt should be made at this manipulation technique. Multiple attempts increase the likelihood of neurovascular injury and swelling. If reduction is unsuccessful, simple traction on the extended elbow may restore vascular supply. When reduction is performed, follow-up radiographs are obtained to ensure adequate reduction and neurovascular function is checked at frequent (hourly) intervals. Cylinder casts are not applied initially because they increase the risk of forearm ischemia; a posterior plaster splint

Fig. 44.16 Type III supracondylar fracture with significant displacement of distal fragment.

provides safe and adequate immobilization. Type IV injuries require emergent orthopedic consultation for operative intervention. These injuries represent a surgical challenge, but recent studies show that a satisfactory outcome can be achieved.[12]

Flexion type supracondylar fractures

Clinical features of flexion type supracondylar fractures. Flexion-type supracondylar injuries are much less common, with a reported frequency of about 2% of all supracondylar fractures. The mechanism of injury is a direct blow to the flexed elbow.

Diagnostic of flexion type supracondylar fractures. Plain films may reveal a simple increase in the anterior angulation of the distal supracondylar fragment or gross displacement of the distal fragment proximal and anterior to the distal end of the proximal fragment. In the latter case, the distal end of the proximal fragment protrudes posteriorly. A line drawn down the anterior humeral shaft (see earlier discussion in the extension type supracondylar fractures section) intersects the capitellum either normally or posteriorly in these fractures, depending on whether there is anterior displacement. The most common complication is nerve injury with injury to the ulnar nerve, occurring in over 90% of cases.[8] The radial and median nerves are rarely injured.

Management of flexion type supracondylar fractures. For flexion-type supracondylar injuries, when the posterior periosteum is torn, the anterior periosteum functions as a tension band with the arm in extension. In type I fracture, the periosteum is minimally displaced. These injuries do not need to be immobilized in extension. The elbow can be comfortably flexed and should be immobilized in a splint as with extension injuries. Type II and III injuries require emergent orthopedic consultation. Type II injuries are manipulated into extension and then either in a long arm cast or with percutaneous pins. Type III injuries are treated with closed reduction and percutaneous pinning but will require open reduction if closed reduction fails (Fig. 44.16).[8]

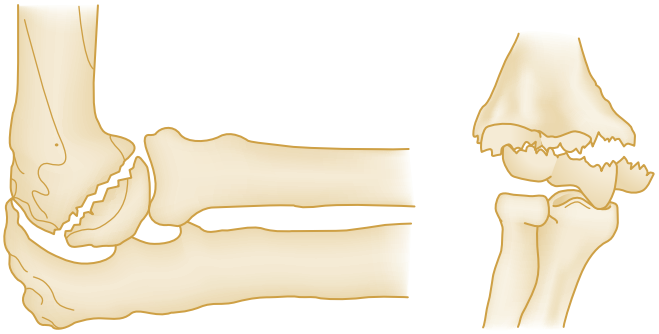

Fig. 44.17 Transcondylar Fracture of Distal Humerus. (*Left*, From Ruiz E, Cicero J. *Emergency management of skeletal injuries*. St Louis: Mosby; 1995. *Right*, Adapted from Simon R, Koenigsknecht S: *Emergency orthopaedics: the extremities*. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

Transcondylar Fractures

Clinical features of transcondylar fractures. Both extension and flexion types of transcondylar fractures have been described based on the position of the elbow when fractured. Extension types are the most common with a mechanism of injury that is similar to that for supracondylar injuries. In contrast to supracondylar fractures, however, the injury is more common in elderly individuals with fragile, osteoporotic bone.

Diagnostic testing of transcondylar fractures. Transcondylar (or dicondylar) fractures have a fracture line, either transverse or crescent shaped, that passes through both condyles within the joint capsule just proximal to the articular surface (Fig. 44.17).

Management and disposition of transcondylar fractures. Transcondylar (or dicondylar) fractures are difficult to treat because the small distal fragment possesses little extra-articular bone, and only a small amount of bone contact is available for union. Orthopedic consultation in the ED should be obtained for these injuries. Both internal fixation and elbow arthroplasty are viable operative options, with internal fixation now supplanting primary elbow arthroplasty as the mainstay of treatment for most cases.

Intercondylar Fractures

Clinical features of intercondylar fractures. These injuries are rare and generally are seen in adults aged 50 to 70 years. The common mechanism of injury is direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end. Patients with intercondylar fractures complain of pain at the elbow, which on examination is tender to palpation. Neurovascular complications are not common with these injuries.

Diagnostic testing of intercondylar fractures. Good-quality anteroposterior and lateral radiographic views are essential in evaluating fracture displacement and comminution (Fig. 44.18). Intercondylar fractures are usually T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment (Fig. 44.19). The distal portion of the fracture extends to the articular surface of the distal humerus. CT may be used to delineate fracture patterns further.

Management and disposition of intercondylar fractures. Treatment of intercondylar fractures is challenging. The goal of treatment is to reestablish articular congruity and alignment and to begin active motion as soon as possible, most often through open reduction with rigid internal fixation. Closed treatment is typically restricted to elderly patients, patients with medical conditions that prohibit surgery, and certain patients with nondisplaced fractures; although recent literature

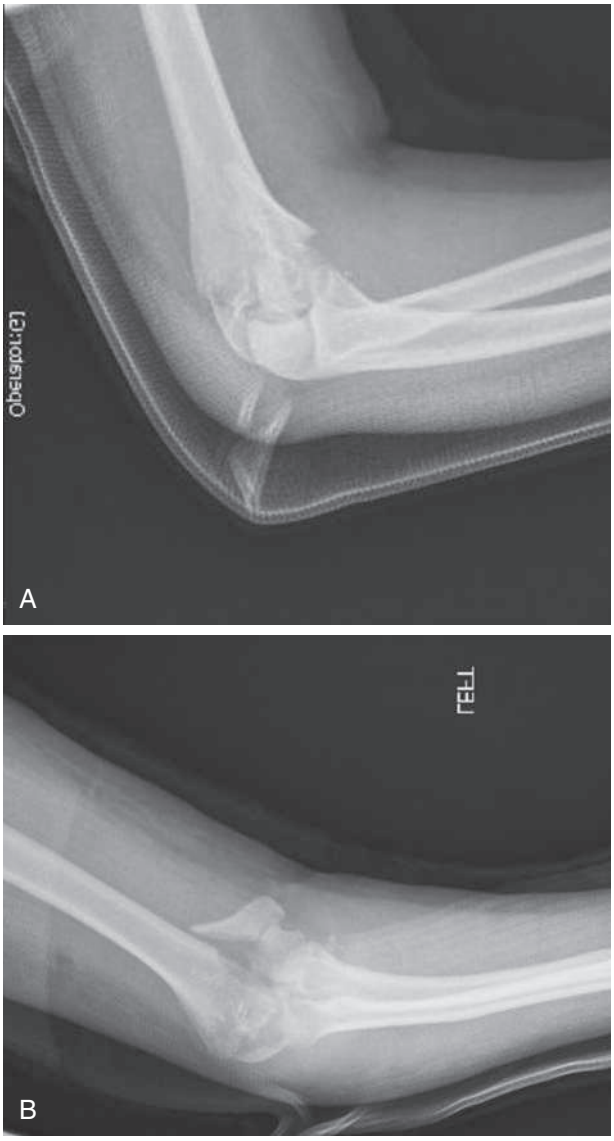

Fig. 44.18 Intercondylar fracture, type III. Lateral (A) and anteroposterior (B) views.

shows that both closed and open methods may have similar results in children.[14] These injuries require emergent orthopedic consultation. As with supracondylar fractures, manipulation should be avoided unless limb-threatening ischemia is present. Traction across the elbow

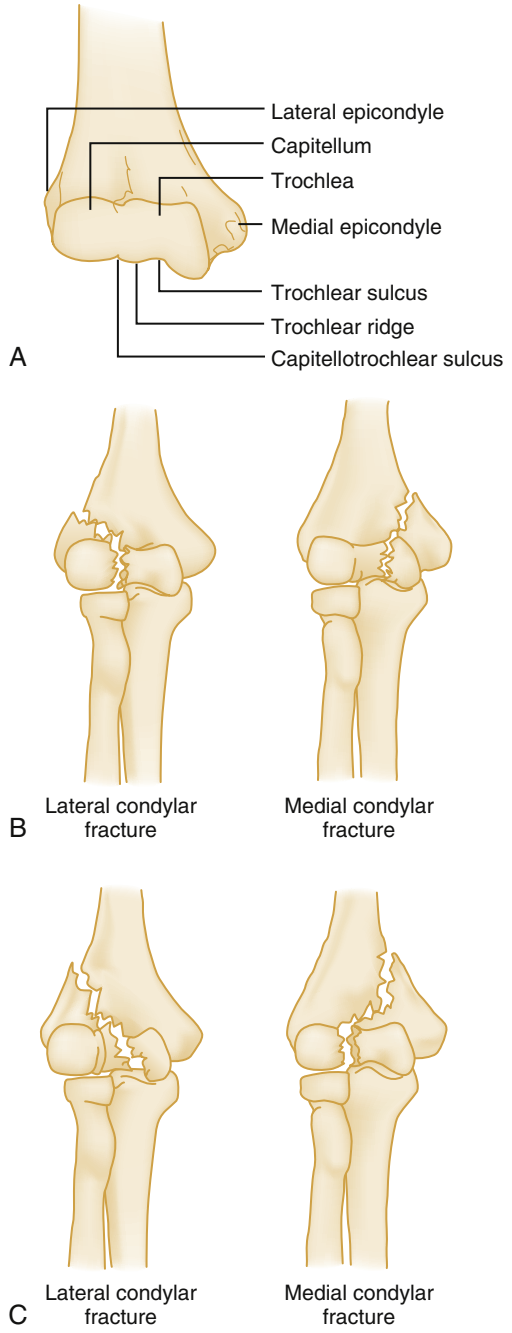

Fig. 44.20 Condylar Fractures. (A) Normal anatomy. (B) Lateral trochlear ridge not in fracture fragment (stable). (C) Lateral trochlear ridge included with fracture fragment (unstable). with the arm extended is helpful in restoring blood flow to an ischemic forearm.

Condylar Fractures

Clinical Features of condylar fractures. Condylar fractures are rare in adults and typically involve the articular surface and the nonarticular portion of the distal humerus, including the epicondyle (Fig. 44.20). Lateral condylar fractures are uncommon, although more frequent than fractures of the medial condyle. The mechanism of injury is either a direct blow to the lateral aspect of the flexed elbow or a force that results in adduction and hyperextension with avulsion of the lateral condyle. Medial condylar fractures are rare and result from either a direct blow to the apex of the flexed elbow or a fall on the outstretched hand with the elbow forced into a varus angulation. The presentation of condylar fractures is similar to that of other distal humerus fractures, with swelling, tenderness, and crepitus localized over either the medial or the lateral elbow. On palpation, independent motion of the involved condyle may be appreciated. In lateral condylar fractures, findings may be accentuated with movement of the radius. In children, lateral condyle fractures are the second most common fractures involving the elbow, after supracondylar fractures. The fracture has an age distribution similar to that of supracondylar fractures and occurs after a fall on the outstretched hand, with a varus stress applied to the extended arm. Tenderness and swelling are noted over the lateral aspect of the elbow. In general, children exhibit less swelling than with supracondylar fractures and neurovascular compromise is uncommon. Because of the location of the ulnar nerve, it is vitally important to test its function when this fracture is present. Medial condylar fractures are associated with tenderness over the medial condyle and pain with flexion of the wrist against resistance. Medial condyle fractures are rare in children, comprising 1% to 2% of pediatric elbow fractures.[15] When they do occur, medial condyle fractures are considered type IV Salter-Harris injuries, possibly a physeal injury. The mechanism of injury is believed to be a valgus force on the extended or overhead elbow.[14] The patient has tenderness and swelling over the medial aspect of the elbow.

Diagnostic testing of condylar fractures. Diagnosis is usually made on standard anteroposterior and lateral views, although an oblique view also may be helpful. These fractures are notoriously difficult to diagnose because fractures with minimal displacement are difficult to see radiographically and are often misdiagnosed as supracondylar humerus fractures. The status of the lateral trochlear ridge is the key to analyzing humeral condyle fractures. It may be involved with either medial or lateral condylar fractures and, when incorporated into the distal fragment, is far more likely to result in instability. On radiographic examination, lateral condylar fractures show a widening of the intercondylar distance. The distal fragment is often displaced, most commonly posteriorly and inferiorly. Displaced distal fragments tend to be anterior and inferior because of the pull of the forearm flexors. For medial condoyle fractures, anteroposterior, lateral, and oblique films may show the fracture in older children, but because the trochlea does not ossify until about age nine, plain films in younger children may not clearly demonstrate the fracture. MRI is often necessary to confirm the diagnosis in these patients.

Management and disposition of condylar fractures. For condylar fractures, treatment depends on radiographic findings, but controversy exists about the accuracy of these findings.[16] For nondisplaced or minimally displaced condylar fractures, immobilization of the flexed elbow in a long arm posterior plaster splint is sufficient. Surgical intervention is recommended for a fragment incarcerated within the elbow joint, open fracture, nerve injury, or gross elbow instability.[16] For fractures displaced more than 3 mm, surgical fixation is traditionally recommended, but there is some controversy around this with acceptable displacement ranging from more than 2 to 15 mm.[16] Due to the high rate of complications, we recommend orthopedic consultation be sought for all adult condylar fractures. For lateral condylar fractures, the forearm should be supinated and the wrist extended to relieve the tension on the extensor muscle attachments. For medial condylar fractures, the forearm should be pronated and the wrist flexed). Nondisplaced lateral condyle fractures are treated nonoperatively with a cast, whereas fractures with any displacement require closed or open reduction with percutaneous pin fixation for 3 to 4 weeks. For medial

Fig. 44.21 Fracture of the Capitellum.

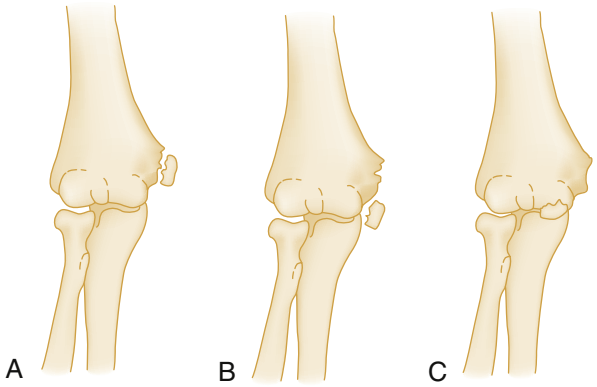

Fig. 44.22 Fractures of Medial Epicondyle. (A) Minimal displacement. (B) Marked displacement. (C) Displacement into joint. (From Connolly JF. *DePalma's management of fractures and dislocations*. Philadelphia, PA: WB Saunders; 1981.)

condyle fractures, operative treatment is indicated if displacement is greater than 2 mm; otherwise, conservative treatment is sufficient.

Capitellum and Trochlea Fractures

Clinical features of capitellum and trochlea fractures. Fractures of the capitellum and trochlea typically occur together, usually as a result of posterior dislocation of the elbow, with isolated fractures being less common. Injury to the capitellum occurs when the patient falls on an outstretched hand, forcing the radial head upward, similar to the motion of a piston, shearing off the capitellum into the radial fossa. Because the capitellum has no muscular attachments, the fragment may remain nondisplaced. More often, the fragment is displaced, usually anteriorly and occasionally posteriorly. A radial head fracture also may be present and should be clinically suspected because of this mechanism. The development of significant signs and symptoms may be delayed with capitellum fractures. Eventually, swelling within the capsule results in severe pain that manifests as well-localized tenderness on examination and flexion of the elbow. Isolated fractures of the trochlea are exceedingly rare because of the structure's protected position deep within the elbow joint. The shearing force of the ulna against the trochlea is associated more commonly with posterior elbow dislocation. The elbow is painful, with an effusion and limited range of motion because this is an intra-articular injury.

Diagnostic testing of capitellum and trochlea fractures. For capitellum fractures, a lateral plain film usually shows the fragment lying anterior and proximal to the main portion of the capitellum (Fig. 44.21). In an isolated trochlear fracture, the radiograph shows a fragment visibly lying on the medial side of the joint, just distal to the medial epicondyle, and signs of joint effusion are visible. The fracture may extend into the distal portion of the medial epicondyle.

Management and disposition of capitellum and trochlea fractures. Treatment of capitellum and trochlea fractures begins in the ED with a posterior splint, ice packs, elevation, compression, and analgesia. Accurate anatomic alignment, rigid internal fixation, and early mobilization are prerequisites for a good functional result.[17] Fractures of the articular surfaces can be treated non-surgically, but only if radiographs show perfect anatomic alignment. Nondisplaced trochlea fractures may be treated with a posterior splint for 3 weeks, followed by early range-of-motion exercises. Displaced fractures (> 2 mm) should be treated operatively; fragments that can be internally fixed are repaired, whereas small fragments are excised. Immobilization should be minimized to 10 to 14 days.

Epicondylar Fractures

Clinical features of epicondylar fractures. Most epicondylar fractures involve the medial epicondyle. Medial epicondyle fractures are most common in children and adolescents and often involve the apophysis, which is the last ossification center to fuse in the distal humerus, usually after age 15. Fractures through this ossification center usually occur in adolescence and constitute 10% of pediatric elbow fractures. These are not Salter-Harris injuries, because the apophysis is involved rather than the physis. The lateral epicondyle is almost level with the flattened outer surface of the lateral condyle giving it only minimal exposure to a direct blow and fracture is rare. Medial epicondyle injuries occur from a variety of mechanisms. First, avulsion fractures are associated with posterior elbow dislocations in patients younger than 20 years in up to 50% of cases. Avulsion fractures also may occur with severe or repeated stress, such as from arm wrestling or pitching (also known as "*Little Leaguer's elbow*"). Finally, a direct blow to the medial epicondyle can cause this injury. The elbow is held in flexion and any movement is resisted. Isolated fractures are associated with focal tenderness over the medial epicondyle. The use of the forearm flexors increases pain because their attachment is along the medial epicondyle. Ulnar nerve function should be evaluated as an associated ulnar nerve palsy may be present with an entrapped fragment.

Diagnostic testing of epicondylar fractures. Simple fractures of the medial epicondyle are extra-articular injuries with limited soft tissue injury.[18] They generally do not produce a fat pad sign on the lateral radiographic view of the elbow. A posterior fat pad or significant swelling of the joint suggests concurrent injuries, such as elbow dislocation. Meticulous radiographic evaluation is especially important because fracture fragments may migrate into the joint space. If the fragment is overlying the joint line on radiographic examination, it should be considered intra-articular (Fig. 44.22). Radiographic detection of the intra-articular fragment may be subtle.[14] Fragments are often difficult to see on radiographs and a true anteroposterior view is challenging to obtain because of severe pain on extension. In an adolescent patient, there is a tendency to confuse the normal radiolucent epiphyseal growth plate with a fracture. In addition, minimally displaced fractures may be difficult to appreciate with

radiographs and comparison films of the uninjured elbow may assist in making the diagnosis. If dislocation is present, repeat radiographs after reduction should be evaluated for fragment location.

Management and disposition of epicondylar fractures. For epicondylar fractures, if the fracture fragment is minimally displaced (< 5 mm), treatment with a posterior splint is appropriate. To minimize distraction of the fragment by the forearm flexors, the elbow and wrist are flexed with the forearm pronated. Treatment of displaced fractures is controversial. The degree of displacement will dictate the need for surgery but results of operative and nonoperative treatment are generally good regardless of the amount of displacement. Some experts advocate surgery for patients who participate in high-performance athletic activities that involve the injured extremity, but controlled studies are lacking. Intra-articular fragments that cannot be removed from the joint by manipulation are an indication for surgery. Emergent orthopedic consultation should be sought for these types of injuries. The rare lateral epicondylar fracture in adults was traditionally treated with immobilization; however, more recent experience indicates that operative management is more successful.

Olecranon

Clinical features of olecranon fractures. Fractures of the olecranon commonly occur from a direct blow as a result of a fall, a motor vehicle or motorcycle crash, or an assault. Less commonly, indirect force applied by forceful contraction of the triceps while the elbow is flexed causing a transverse or oblique fracture through the olecranon. Olecranon fractures are uncommon in children. The anatomic integrity of the olecranon is essential for triceps strength and normal function of the elbow. Physical findings may include tenderness and pain over the olecranon, a palpable separation at the fracture site or the inability to extend the elbow against force. This last finding indicates complete discontinuity of the pulling mechanism and the consequent failure of triceps function. The neurovascular status should be examined with special attention given to the ulnar nerve distribution. Loss of sensation over the palmar aspect of the fifth digit and hypothenar eminence or motor weakness in the interossei muscles of the hand suggests ulnar nerve injury. Symptoms of ulnar nerve injury occur in 10% of patients, and in most cases, the injury is an ulnar contusion that resolves spontaneously.

Diagnostic testing of olecranon fractures. Lateral radiographic views provide the most information. In addition to the fracture, the degree of comminution, the extent of articular surface disruption and the amount of displacement in the 90-degree flexion position should be noted.

Management and disposition of olecranon fractures. In olecranon fractures, non-displacement in the 90-degree flexion position indicates that the triceps aponeurosis tendon is still intact and prolonged immobilization is not indicated. Displacement of more than 2 mm is considered an indication for surgery (Fig. 44.23A). A fracture line that increases in separation with flexion of the elbow is also considered a displaced fracture. When this fracture is associated with elbow dislocation, the plane of instability is located through the fracture site and the radiohumeral joint. This results in posterior displacement of the proximal fragment of the ulna and anterior dislocation of the radius and ulna as a unit (see Fig. 44.23B). Nondisplaced fractures can be treated conservatively on an outpatient basis with ice, compression, immobilization in 45 to 90 degrees of flexion and analgesia. Follow-up radiographs should be performed to ensure that subsequent displacement does not occur. In many cases, range-of-motion exercises can be started within 3 weeks. Displaced fractures or fracture-dislocations require open reduction and internal fixation and patients should be referred urgently to an orthopedist. Displaced fractures in elderly patients can be treated conservatively but this should be left to the discretion of the consultant. Orthopedic referral is also necessary when ulnar nerve compromise is present.

Fig. 44.23 (A) Olecranon fracture with displacement. (B) Fracture accompanied by radial head dislocation.

Radial Head and Neck

Clinical features of radial head and neck fractures. Radial head and neck fractures, in general, are produced by an indirect mechanism, typically a fall on an outstretched hand. The radius transmits the force upward, driving the radial head against the capitellum and resulting in fracture of the weaker radial head or neck. Although the fracture of the radial head may be the only radiographic finding, damage to the articular surface of the capitellum and injury to the collateral ligament may also occur. Displacement of the radial head fragment suggests considerable force and significant soft tissue injury. This injury is characterized by localized tenderness over the radial head or pain with passive rotation or supination and pronation of the forearm.

Diagnostic testing of radial head and neck fractures. Radiographic findings range from a subtle disruption of the usual gradual sweep of the radial neck and head surface to an obvious displaced or comminuted fracture (Fig. 44.24). Nondisplaced fractures are notoriously difficult to detect on radiographs. Tenderness coupled with a positive fat pad sign on the radiograph indicates that the injury should be treated as a radial head fracture even in the absence of a visible fracture.

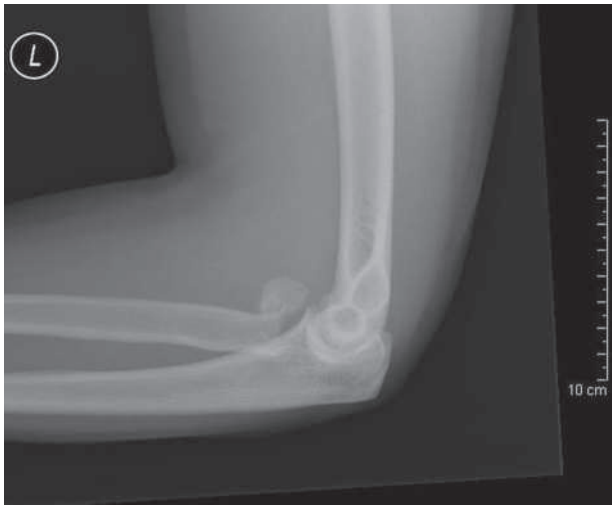

Fig. 44.24 Radial Head Fracture with Displacement.

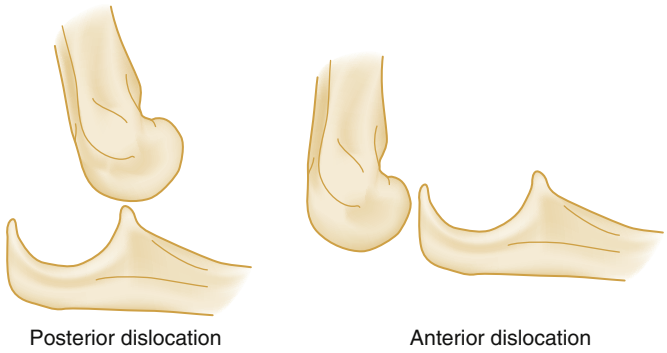

Fig. 44.25 Elbow Dislocation, Posterior and Anterior. (Adapted from Simon R, Koenigsknecht S. Emergency orthopaedics: the extremities. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

Radial head fractures are classified into four types: type I, nondisplaced fractures; type II, fractures involving less than 30% of the articular surface with more than 2 mm displacement, including impaction or angulation; type III, comminuted fractures of the entire radial head; and type IV, any of the previous types with elbow dislocation.[19]

Management and disposition of radial head and neck fractures. Radial head and neck fractures are classified by Manson criteria. Type I nondisplaced fractures are treated symptomatically with a brief period of sling support and early range-of-motion exercises (within 24 to 48 hours). Aspiration of the hemarthrosis from the joint space may give relief of pain and improve the range of motion, though this should be considered only as an adjunct to conservative splinting management.[19] Based on a prospective randomized study, which found no benefit to bupivacaine instillation compared with simple aspiration, we do not recommend injection of bupivacaine into the joint. Most patients with this injury recover well in 2 to 3 months. A few heal poorly however, with long-term pain, contracture, or inflammation. Type II injuries are usually treated similarly, with aspiration and immobilization in the ED, followed by a trial period of range-of-motion exercises. Radial head excision is sometimes performed later if the patient fails to improve. Early excision is advised for type II fractures when a mechanical block is present and for most type III fractures, though the management between excision, open reduction internal fixation, and arthroplasty remain controversial. Long-term functional results after radial head excision are acceptable in most patients with few having some functional disability after this procedure with up to 96% having good long-term outcomes.[19] Treatment of type IV injuries is directed at the elbow dislocation as described next and for specific radial head injuries.

Dislocations/Subluxations

Elbow

Clinical features of elbow dislocations/subluxations. The elbow is inherently subject to mechanical instability because of its anatomic structure and dislocations are common. *The elbow is second only to the shoulder as the most commonly dislocated large joint.* Elbow dislocation is a term usually used to describe a disruption of the relationship between the humerus and the olecranon. In general, the radius and ulna, bound together firmly by the annular ligament and interosseous membrane, displace as a unit. Most classifications refer to the abnormal position of the ulna relative to the humerus. The elbow most often dislocates posteriorly, although it may dislocate anteriorly, medially, or laterally (Fig. 44.25). Although rare, a divergent dislocation, which is a dislocation between the radius and ulna concurrently with the ulnohumeral type, can occur. Dislocation of the elbow requires considerable energy and is often associated with fractures of adjacent bony structures and a fracture-dislocation injury is referred to as a complex elbow dislocation.

The mechanism of injury of a posterior elbow dislocation is a fall on the outstretched hand or wrist, causing hyperextension of the elbow with a valgus stress at the time of impact. Patients hold the elbow in flexion at approximately 45 degrees and have marked prominence of the olecranon. Some elbow dislocations may reduce spontaneously prior to presentation in the ED where obvious swelling and tenderness may be the only findings. Because elbow dislocations are associated with brachial artery and median nerve injuries, neurovascular examination is important especially prior to any manipulation or reduction and should be documented and repeated after reduction. Radiographic evaluation is crucial before manipulation to rule out fractures that can mimic dislocation on examination. Several fractures, including fractures of the distal humerus, radial head, and coronoid process commonly occur in conjunction with dislocation, which need to be identified and treated when present. The most serious complication of elbow dislocation is vascular compromise. Severe disruption results in injury to the brachial artery in 5% to 15% of cases.[20] Vascular injury should be considered when a wide opening between the tip of the olecranon and the distal humerus is palpated or seen on a radiograph. Of note, the presence of distal pulses is not proof of an intact artery; and if a question of vascular compromise exists, emergent vascular studies and consultation is indicated. Median nerve traction injuries and entrapment have been reported. Unlike the shoulder, recurrent dislocation of the elbow is rare. Medial and lateral elbow dislocations are produced by a mechanism similar to that in posterior dislocations, with a vector of force displacing the ulna and radius as a unit either medially or laterally. Anterior dislocations are rare and occur as a result of a blow to the olecranon from behind while the elbow is in the flexed position. Severe associated soft tissue trauma is often present, including avulsion of the triceps mechanism or vascular disruption, and these dislocations are frequently open. On examination, the upper arm appears shortened, the forearm elongated and supinated, the elbow is fully extended, and the olecranon fossa is palpable posteriorly.

Diagnostic testing of elbow dislocations/subluxations. A radiographic example of posterior elbow dislocation before reduction is provided in Fig. 44.26. The anteroposterior view is important for visualization of either medial or lateral dislocations.

Management and disposition of elbow dislocations/subluxations. Rapid reduction of complete elbow dislocations is important to relieve pain and to prevent circulatory injury or cartilaginous damage.

Fig. 44.26 Characteristic posterior dislocation of elbow, lateral (A) and anteroposterior (B) views.

Reduction should be attempted as soon as possible, especially if there is neurovascular compromise. Because of the time sensitivity, delayed orthopedic consultation should not be waited upon to proceed. Intra-articular injection of local anesthetic may provide adequate analgesia to allow for closed reduction, but procedural sedation is often required to facilitate reduction. Posterior dislocations are reduced with an assistant immobilizing the humerus and applying counter traction while traction is applied to the distal forearm. The ideal position is for the elbow to be flexed at 30 degrees with the forearm supinated while distal traction is applied. When the capitellum slides over the coronoid process, a coupling sound occurs as the articular surfaces mesh. If reduction is unsuccessful with this technique, the clinician should apply downward pressure at the proximal forearm and apply pressure behind the olecranon while maintaining in-line traction. This downward force may help "unlock" the coronoid process, which may be trapped in the olecranon fossa. The joint is gently moved through its normal range of motion to check stability. As with all reductions, neurovascular status should be checked before and after any reduction attempt. Post-reduction radiographs are required to access concomitant fractures of the coronoid process or radial head or, in children, separation of the medial epicondylar apophysis. Post reduction management includes immobilization in a posterior splint with the elbow in as much flexion as circulation allows along with a sling. Circular casting should initially be avoided in the ED. Patients can be discharged with instructions to apply ice, elevate, and watch for signs of vascular impairment. If the elbow is stable after reduction, gentle range-of-motion exercises may be initiated in 3 to 5 days. Unstable joints may require either prolonged immobilization in the presence of ligamentous instability or internal fixation if associated with fracture. For medial and lateral elbow dislocations, reduction is carried out with the arm in slight extension but otherwise is similar to that for posterior dislocation. Care should be taken not to convert these to posterior dislocations during reduction. Complications and aftercare are the same as for posterior dislocations. Reduction of closed anterior dislocations is performed with distal traction of the wrist and a backward pressure on the forearm while the distal humerus is grasped. A clicking sound usually indicates that reduction has been achieved. These injuries have a higher incidence of vascular impairment than the more common posterior dislocation although ulnar nerve injuries are unusual. Emergent orthopedic referral is standard for open injuries or when vascular disruption is suspected.

Radial Head Subluxation

Clinical features of radial head subluxation. Subluxation of the radial head (or "*nursemaids' elbow*") is a common injury, representing more than 20% of upper extremity injuries in children. Children 1 to 4 years old are most often affected, although cases have been reported in children 6 months to 15 years old. Girls are affected more commonly than boys, and the left arm is more commonly affected than the right. The classic history, which is present approximately half of the time, is that of the forearm being pulled while in pronation with the elbow extended with stretching of the annular ligament, allowing fibers to slip between the capitellum and the head of the radius, resulting in an inability of the child to supinate the arm.[21] By the age of 5, the annular ligament becomes thick and strong and thus is far less likely to tear or be displaced. Other mechanisms include direct trauma to the elbow or a twisting motion of the arm. In children younger than 6 months old, the mechanism of subluxation involves rolling over in bed that may trap the involved forearm under the body with resulting longitudinal traction on the joint. Clinically, the arm is held in passive pronation, with slight flexion at the elbow. The child is unable or unwilling to move the arm. Resistance to supination and tenderness on direct palpation over the head of the radius are present. Swelling, ecchymosis, and deformity are generally absent.

Diagnostic testing of radial head subluxation. When the history is suggestive of radial head subluxation, radiographs are not indicated and are rarely useful. If there is swelling or deformity, if there is an uncharacteristic history, if the child does not resume use of the arm after reduction, or if there is a possibility of nonaccidental trauma, appropriate radiographic studies are recommended. If palpation of the forearm, wrist, or humerus away from the elbow elicits reproducible tenderness, radiographs should be taken to exclude other diagnoses.

Management and disposition of radial head subluxation. Reduction may be attempted in children with typical presentations and is safe even when the classic history is absent. Although historically, supination-flexion has been the reduction technique most commonly used, hyper-

pronation has a significantly higher reported success rate of reduction on the first attempt and is the recommended method for reduction.[21] With the hyperpronation method, the child's elbow is supported with moderate pressure applied to the radial head. The examiner then grips the child's distal forearm and hyperpronates the forearm, resulting in a click felt over the radial head (Fig. 44.27). In the supination-flexion method, reduction is achieved either by supination or pronation of the forearm while applying direct pressure over the radial head. With the supination method, the forearm is supinated while slight pressure on the radial head is applied with the examiner's thumb. In one continuous motion, the elbow is supinated and flexed with gentle axial pressure applied. A click often, but not always, is felt as the radial head reduces (Fig. 44.28). Many patients are asymptomatic within 5 to 10 minutes; 90% of patients regain use of the arm within 30 minutes. Because a fearful child often does not use even the successfully reduced limb, it is a good idea for the physician to leave the room and for parents to distract the child to demonstrate a return of normal function. If function does not return within 24 hours, the patient should be reevaluated. After successful reduction, no additional treatment, immobilization, or activity reduction is necessary. Parents and caregivers should be instructed to avoid excessive traction on the child's forearm to prevent recurrent radial head subluxation. The recurrent radial head subluxation rate is approximately 20%.[22]

Soft Tissue Disorders

Epicondylitis

Clinical features of epicondylitis. Epicondylitis is a term first introduced to describe an inflammatory process that involves the radiohumeral joint or lateral epicondyle of the humerus. Commonly called "*tennis elbow*" to describe lateral epicondylitis or "*golfer's elbow*" for medial epicondylitis, it is a common exercise-related syndrome, and the mechanism is thought to be repetitive pronation and supination of the forearm. Radiohumeral bursitis or synovitis, tendinitis of the common extensor tendon, periostitis of the lateral epicondyle, and entrapment by scar tissue of the radial nerve all have been suggested as causes of this syndrome. Histologically, the abnormality has been described as angiofibroblastic hyperplasia, a term subsequently modified to angiofibroblastic tendinosis. It is thought to be a degenerative process because of the paucity of acute inflammatory cells seen histologically. Most cases are lateral (tennis elbow), but medial epicondylitis (golfer's elbow) and posterior epicondylitis have been reported; the former involving the pronator teres and flexor carpi radialis insertions and the latter involving the triceps tendon. Onset is usually gradual, and patients report dull pain over the lateral aspect of the elbow over the lateral epicondyle or radiohumeral joint, increased by grasping or twisting motions. Supination and pronation against resistance may be painful, and pain can be elicited by stretching the wrist extensors. To test this, the elbow is extended, the forearm pronated, and the wrist fully dorsiflexed.

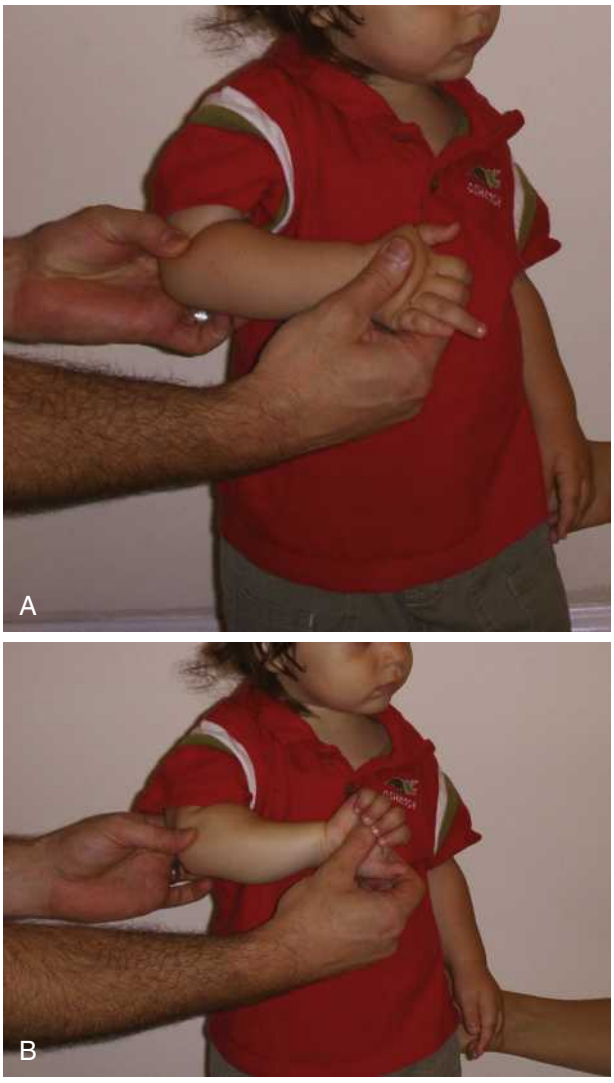

Fig. 44.27 Hyperpronation Method of Radial Head Subluxation Reduction. (A) Support elbow with pressure to radial head. (B) Then hyperpronate the arm distally.

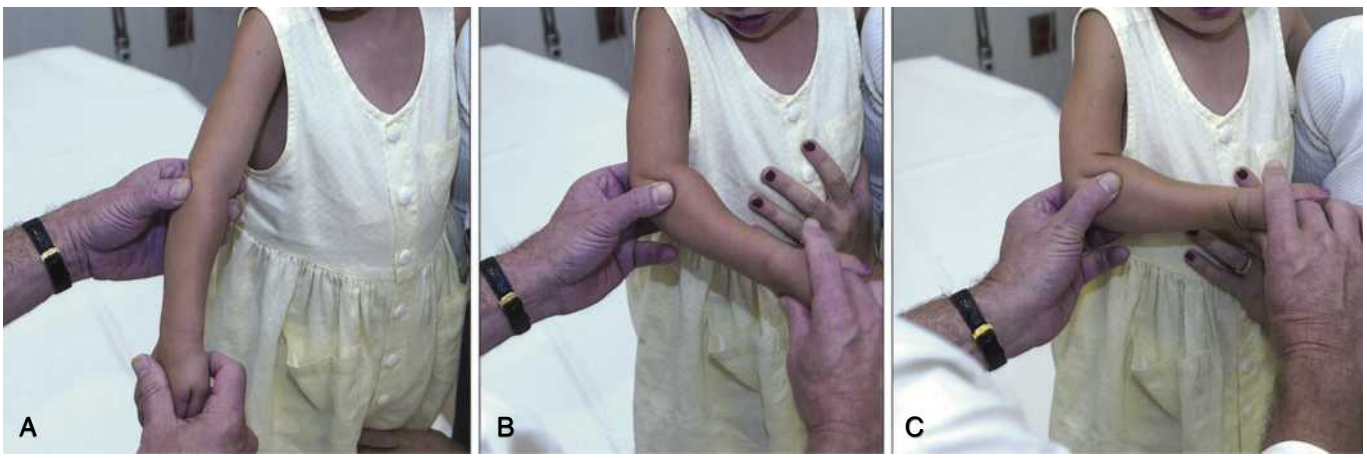

Fig. 44.28 Subluxation of the Radial Head. Method of reduction: Apply pressure to radial head (A) supinate the forearm (B) and flex elbow (C) in one continuous motion.

Diagnostic testing of epicondylitis. Radiographic findings may be normal, although with chronicity, calcifications may be present over the lateral epicondyle. Characteristic MRI findings also have been described, although MRI is not indicated emergently.

Management and disposition of epicondylitis. Treatment includes protection, rest, ice, compression, elevation, and analgesics. Initial therapy includes avoidance of the inciting activity and immobilization with a sling. Nonsteroidal antiinflammatory drugs (NSAIDs) are often used, but their efficacy is limited to their analgesic rather than their antiinflammatory properties. Injection of a corticosteroid at the point of tenderness provides some pain relief in most patients. Because corticosteroids weaken collagen, injection directly into the tendon and premature resumption of heavy loading of the tendon at the lesion should be avoided. Patients with pain that persists despite treatment and a rehabilitation program should be referred for possible surgery. Modification of athletic technique is recommended after the symptoms subside.

Olecranon Bursitis

Clinical features of olecranon bursitis. Olecranon bursitis is commonly caused by repetitive minor trauma, such as leaning on the elbow during work activities. It also may result from an inflammatory process, such as gout or an infectious process within the bursa (septic bursitis). Septic olecranon bursitis occurs most commonly in patients engaged in work that predisposes to repetitive trauma to the elbow, such as gardening or plumbing. Although several bursae are located in the elbow region, the olecranon bursa is the one most often involved in an isolated pathologic process. Patients usually have progressive pain, tenderness and swelling over the olecranon. Some patients with septic bursitis have an abrupt onset instead, with a rapid increase in pain over a few hours and on examination. The septic bursa is typically swollen, warm, erythematous, and tender. Flexion is limited by pain brought on by tightening of the skin over the inflamed bursa. Minor breaks in the skin, abrasions, or healing lacerations over the bursa may be present. Noninfectious bursitis usually manifests with less warmth and erythema. The skin is intact and swelling may be the only finding.

Diagnostic testing of olecranon bursitis. The most important aspect of evaluation is the differentiation of a septic process from a benign inflammatory one, and this differentiation may be difficult on clinical grounds because considerable overlap exists in the histories and physical findings. If suspicion exists, aspiration of the bursa should be performed and the fluid sent for crystals, white blood cell (WBC) count, Gram's stain, and cultures. Unless the aspirate is frankly bloody, traumatic non-septic olecranon bursitis usually has a leukocyte count lower than 1000 cells/mm^3, whereas septic bursal fluid usually has a count higher than 10,000 WBCs/mm^3.

Management and disposition of olecranon bursitis. Aspiration is diagnostic and therapeutic because relief of pressure relieves some of the pain. In cases of purulent bursitis, the bursa should be drained, and appropriate antibiotics to cover staph and streptococcal infections should be prescribed. Pending culture results, empirical antibiotics should include coverage for routine skin organisms, as well as methicillin-resistant *Staphylococcus aureus* (MRSA). Sulfamethoxazole/trimethoprim double-strength twice daily or doxycycline 100 mg should be used twice daily for 10 to 14 days. For patients with severe inflammation or who are immunocompromised, initial treatment with intravenous vancomycin at 15 to 20 mg/kg or intravenous or oral lineozlid 600 mg should be used. Bursitis refractory to aspiration and appropriate antibiotics may require incision and drainage. Noninfectious bursitis can be managed with a compression dressing, ice, NSAIDs, and avoidance of the inciting activity. Patients who have had their bursa aspirated should be rechecked within 24 to 48 hours to verify culture results and monitor their response to treatment.

Biceps Tendon Rupture

Clinical features of biceps tendon rupture. Biceps tendon rupture occurs most commonly in the proximal portion of the long head of the biceps. It is most common in middle-aged athletes or physical laborers who sustain repetitive microtrauma to the tendon. Patients experience a snapping sound and pain in the anterior shoulder during strenuous activities that produce rapid loading of the muscle. Rupture also occurs distally, usually as an avulsion from the insertion on the radial tuberosity, although ruptures at the musculotendinous junction occasionally occur. Rupture of the distal biceps tendon occurs almost exclusively in men, most commonly between the ages of 40 and 60, and most often involves the dominant arm.[23] The inciting event is usually an unexpected extension force applied to the arm flexed at 90 degrees. The pathophysiology of tendon rupture generally occurs in the setting of underlying tendinosis. Diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy all may result in tendinosis. Smoking has been shown to be strongly associated with distal biceps tendon rupture.[23,24] In proximal tendon rupture, the patient usually has a visible defect at the top of the bicipital groove with bunching of the muscle distally. Flexing of the elbow produces pain at the proximal insertion but flexion remains intact, because the short head of the biceps usually maintains its integrity. With distal ruptures, the patient reports pain and tearing in the antecubital region. Visible deformity and a palpable defect of the biceps muscle belly are present with weakness of elbow flexion and supination. If the tendon is completely ruptured, there is a bunching up of the muscle and this effect is accentuated when the patient attempts flexion.

Diagnostic testing for biceps tendon rupture. The patient's history and physical exam is often diagnostic of such an injury, and radiographs are not revealing and usually not necessary. MRI may be useful when a partial rupture is suspected but can be obtained in follow-up and is not indicated in the ED. The often-mentioned *Speed's and Yergason's tests*, while potentially useful, have poor diagnostic sensitivities and specificities for the diagnosis of biceps tendon rupture, and therefore should only be used in appropriate clinical contexts.

Management and disposition of biceps tendon rupture. All patients require referral to an orthopedist within 72 hours for evaluation for early anatomic repair of complete ruptures. Partial ruptures occasionally respond to conservative treatment but often require surgical repair. The upper extremity is splinted, and the patient advised to apply ice and take analgesics while awaiting orthopedic consultation.

ACKNOWLEDGMENTS

CHAPTER 44: QUESTIONS AND ANSWERS

1. A 4-year-old boy is brought to the emergency department (ED) by his mother after falling from a swing set. He complains of right wrist pain and resists detailed examination of the arm. Radiographs are normal. What is the most appropriate next step in this patient's management?

a. Computed tomography (CT) scan of the wrist
b. Elbow radiograph
c. Reassurance
d. Splinting for 3 to 6 weeks
e. Triple-phase bone scan after 7 to 10 days

Answer: b. In children with wrist pain and traumatic mechanism of injury, the absence of a clear-cut explanation for the pain (e.g., normal radiograph) should prompt suspicion for an elbow injury producing referred pain.

2. A 3-year-old girl comes in from home with arm pain after being playfully swung by her parents. The child appears uncomfortable and refuses the move her arm. After manipulation and a palpable click, the child appears more comfortable however after 30 minutes will not range her arm for the provider. What is the most appropriate next step for this patient?

a. Obtain an XR to evaluate for fracture
b. Continue to observe the patient with frequent re-evaluations
c. Observe for neurovascular check
d. Discharge home with parents with strict return precautions
e. Consult Orthopedics

Answer: d. In children with radial head subluxation, the child, fearful for eliciting a pain response, may continue to hold their arm in protection while appearing more comfortable. Appropriate comfort and discharge may be appropriate with reliable caregivers and with instructions to return within 24 hours if the child does not return to normal.

3. A 67-year-old right-hand dominant man fell onto his right arm and suffered an injury to his upper arm, with crepitus, gross deformity, and is diagnosed with a midshaft humerus fracture. 30 minutes after placement in a sling begins having difficulty extending the thumb and first finger. Repeat radiography shows improvement in alignment of prior fracture. What is the appropriate action?

a. Adjust splint and discharge to home
b. Do not adjust splint and discharge to home
c. Adjust splint and admit for surgery
d. Do not adjust splint and admit for surgery
e. Admit for compartment checks

Answer: c. The patient is now presenting with a radial nerve injury and palsy, likely after movement of the fracture fragments. The offending manipulation should be undone to potentially improve nerve function, and the patient should then be admitted for operative repair.

4. A 57-year-old man presents with acute left upper extremity pain while suffering an injury doing pullups. The patient has visible deformity of his proximal upper extremity and is splinting his arm and unable to supinate and flex his forearm. The patient is neurovascularly intact. X-rays of the shoulder and humerus are unremarkable. An ultrasound diagnoses a torn biceps tendon. What is the most appropriate treatment plan?

a. Orthopedics consultation for emergent operative repair of the ruptured tendon
b. Splinting and urgent orthopedic follow-up within 48 to 72 hours for operative repair
c. Splinting and follow-up with PCP in 1 week
d. Splinting and discharge with instructions for physical therapy

Answer: b. Patients with a biceps tendon rupture should be evaluated for fractures with plain radiography. If negative, consultation with orthopedics for urgent follow-up with possible operative repair is the most appropriate follow-up plan.

5. A 46-year-old construction worker falls onto an extended arm and has a sudden injury to their elbow. The patient arrives with a gross deformity to the distal humerus/elbow. Radiography reveals a posterior elbow dislocation with a wide humerus-olecranon space. The patient as 1+ radial pulses on the affected arm but is otherwise neurovascularly intact. What is the most appropriate next step?
   a. Manual reduction of the elbow dislocation and discharge to follow up with orthopedics
   b. Manual reduction of the elbow and a CT angiography to evaluate for brachial artery injury
   c. Orthopedics consultation for emergent operative reduction
   d. Vascular surgery consultation for management of potential brachial artery injury

Answer: b. The patient likely has a brachial artery injury. These are more common in elbow dislocations with a wide separation between the olecranon and humerus. While there may be persistent pulses distally, the presence of pulses does not eliminate the risk for brachial artery injury. The injury should be reduced, and the patient should undergo CT angiography for evaluation of potential vascular injury.

Shoulder Injuries

Charles Craig Rudy and Mohamud R. Daya

KEY CONCEPTS

- Axillary nerve function is best evaluated by testing the motor function of the deltoid muscle.
- The three-view trauma series of the shoulder (true anteroposterior, scapular Y, and axillary views) leads to an accurate radiographic diagnosis of most fractures and dislocations, although specialized views are sometimes necessary. Consider the presence of unfused epiphyses in adolescents and young adults.
- Most shoulder girdle fractures can be treated with simple immobilization with good functional outcomes.
- The most important aspect of scapular fractures, scapulothoracic dissociation, and posterior sternoclavicular joint (SCJ) dislocations is the high incidence of associated injuries to the ipsilateral lung, chest wall, mediastinum, or shoulder girdle complex.
- Type III acromioclavicular joint (ACJ) dislocations can be treated conservatively (immobilization, range of motion exercises, and strengthening).
- Recurrence is a common complication after anterior dislocation, especially in male patients younger than 30 years old, and such patients likely benefit from arthroscopic surgical repair.
- Posterior dislocation should be included in the differential diagnosis of any shoulder injury, particularly in patients who report shoulder pain after a seizure.
- Ultrasound can be a useful technique for diagnosing tendon tears, selected soft tissue conditions, fractures, and dislocation, as well as for confirming successful reduction.
- Early initiation of passive shoulder range-of-motion exercises reduces the risk of adhesive capsulitis when the shoulder is immobilized for any reason.

FOUNDATIONS

Background and Importance

The shoulder joint is a unique and complex articulation unit. It has the largest range of motion of any appendicular joint in the body and can be moved through a space that exceeds a hemisphere.

Shoulder injuries are commonly encountered in emergency medicine and dislocations account for more than 50% of all major joint dislocations seen in the emergency department (ED). The shoulder can be injured by trauma (indirect or direct) or by overuse.

In general, children are vulnerable to the same injuries as those incurred by adults; however, the presence of the epiphysis and its growth plate changes the pattern of injuries. The strength of the joint capsule and its ligaments is two to five times greater than that of the epiphyseal growth plate. An injury that produces a sprain or dislocation in an adult often causes a fracture through the hypertrophic zone of the growth plate in a child. Most shoulder injuries in children can be treated conservatively, with a good prognosis for full return of function.

Anatomy, Physiology, and Pathophysiology

The shoulder girdle connects the upper extremity to the axial skeleton and the sternoclavicular joint (SCJ) represents the only true articulation point (Fig. 45.1). The SCJ participates in all movements of the upper extremity and is the most moved joint in the body (Fig. 45.2). The superior mediastinum containing the great vessels, trachea, esophagus, thoracic duct, lung apices, and other important structures is immediately posterior to the SCJ.

The clavicle is an S-shaped bone that acts as a strut to support the upper extremity and keep it away from the chest wall, also protecting the subclavian vessels and brachial plexus. The middle third, which is thin and untethered, is the most commonly fractured segment.

The acromioclavicular joint (ACJ) connects the lateral end of the clavicle with the medial aspect of the acromion process (Fig. 45.3). The ACJ has little or no bony stability and is dependent on associated ligaments and muscles for support.

The scapula is a flat triangular bone that forms the posterior aspect of the shoulder girdle. The thin body of the scapula lies flat against the posterior thorax and widens laterally to form the glenoid fossa. The scapula's thickened borders are the attachment sites for 18 muscle origins and insertions. The thick muscle coat and ability to recoil along the posterior chest wall protect the scapula from both direct and indirect trauma.

The glenohumeral articulation is a ball-and-socket–type joint that depends largely on associated capsule, muscles, and ligaments for stability (Fig. 45.4). The absence of bony stability permits a range of motion greater than any other joint.

The proximal humerus articulates with the glenoid fossa and is the site for the attachment of many important muscles. The rotator cuff stabilizes the glenohumeral joint (GHJ) and consists of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles (Fig. 45.5). The long head of the biceps tendon originates from the supraglenoid tubercle and ascends over the humeral head to enter the arm via the bicipital groove (see Fig. 45.5).[1] Long muscles that cross the articulation are involved primarily in movements of the GHJ. The pectoralis major, latissimus dorsi, and teres major muscles all insert into the humeral intertubercular groove. Displacements encountered with fractures of the humerus usually reflect the pull of these attached muscle groups. The proximal humerus is composed primarily of trabecular bone with a thin cortical shell. Changes in bone density with age increase the risk of fractures.

The brachial plexus and subclavian vessels enter the shoulder girdle superiorly between the clavicle and the first rib, traverse under the coracoid process, and exit anterior to the inferior aspect of the GHJ as the median, ulnar, radial, musculocutaneous, and axillary nerves and axillary vessels. These nerves represent the final branches of the upper brachial plexus (nerve roots C5 to T1).

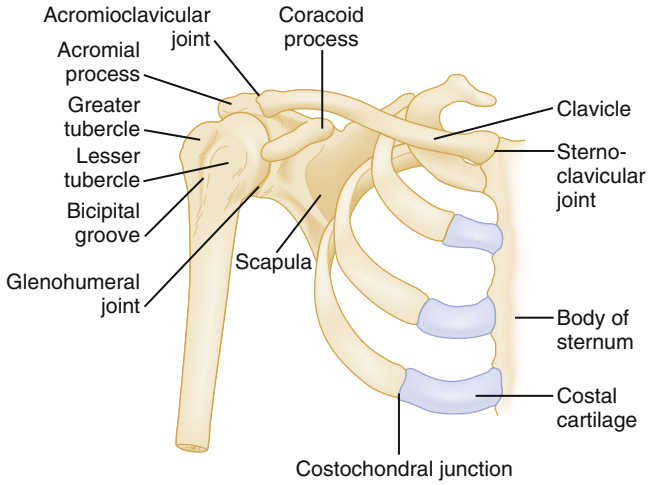

Fig. 45.1 Anatomy of the Shoulder Girdle. It consists of three bones: the clavicle, humerus, and scapula; three joints: the acromioclavicular, glenohumeral, and sternoclavicular joints; and one pseudoarticulation: the scapulothoracic pseudoarticulation. (From Roy S, Irwin R. *Sports medicine: prevention, evaluation, management and rehabilitation*. Englewood Cliffs, NJ: Prentice Hall; 1983.)

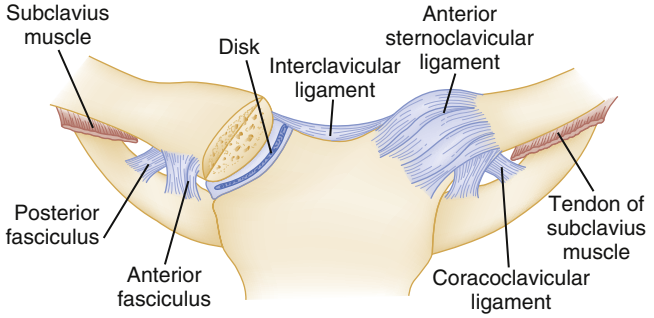

Fig. 45.2 The sternoclavicular joint is stabilized by several ligaments. (Redrawn from DePalma AF. *Surgery of the shoulder*. 3rd ed. Philadelphia: JB Lippincott; 1983.)

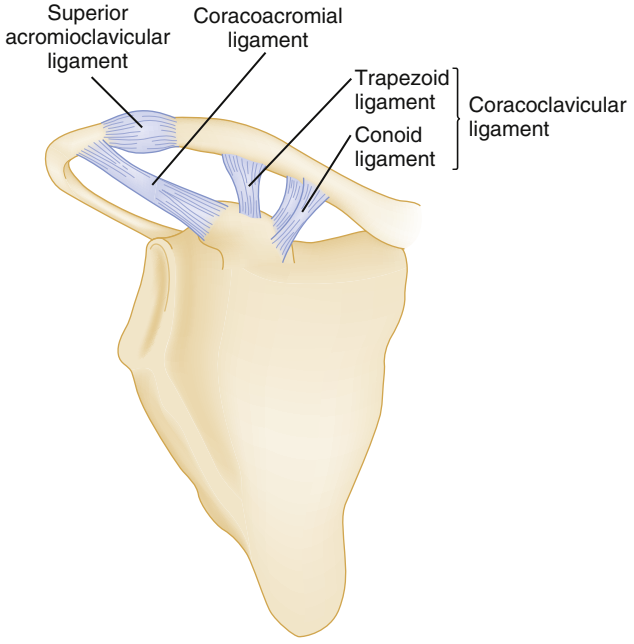

Fig. 45.3 Ligaments of the Acromioclavicular Joint. (Redrawn from DePalma AF. *Surgery of the shoulder*. 3rd ed. Philadelphia: JB Lippincott; 1983.)

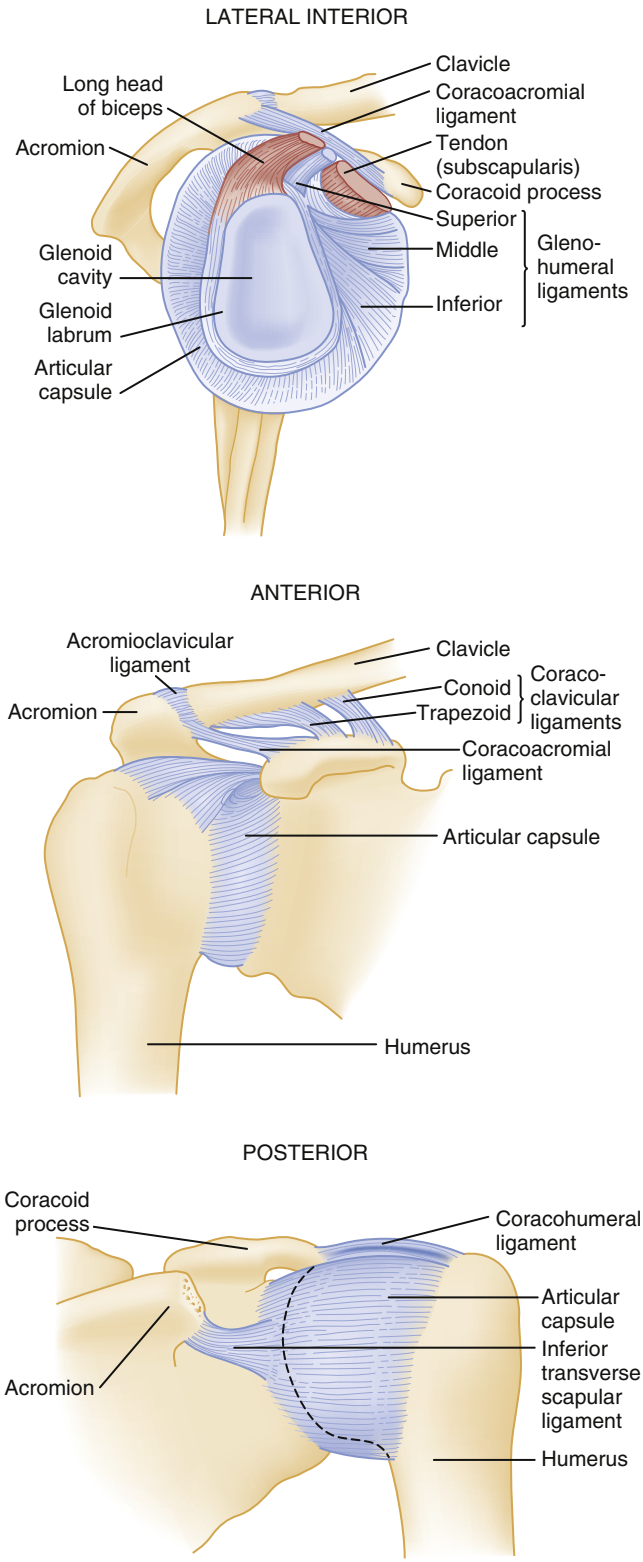

Fig. 45.4 Anatomy of the Glenohumeral Joint. Synovial membrane extends from the glenoid fossa to the humeral head. Overlying the synovial membrane is a loose and redundant fibrous capsule. Anteriorly, the capsule is thickened to form the superior, middle, and inferior glenohumeral ligaments. The anterior band of the inferior glenohumeral ligament is the most important restraint to anterior glenohumeral dislocations.

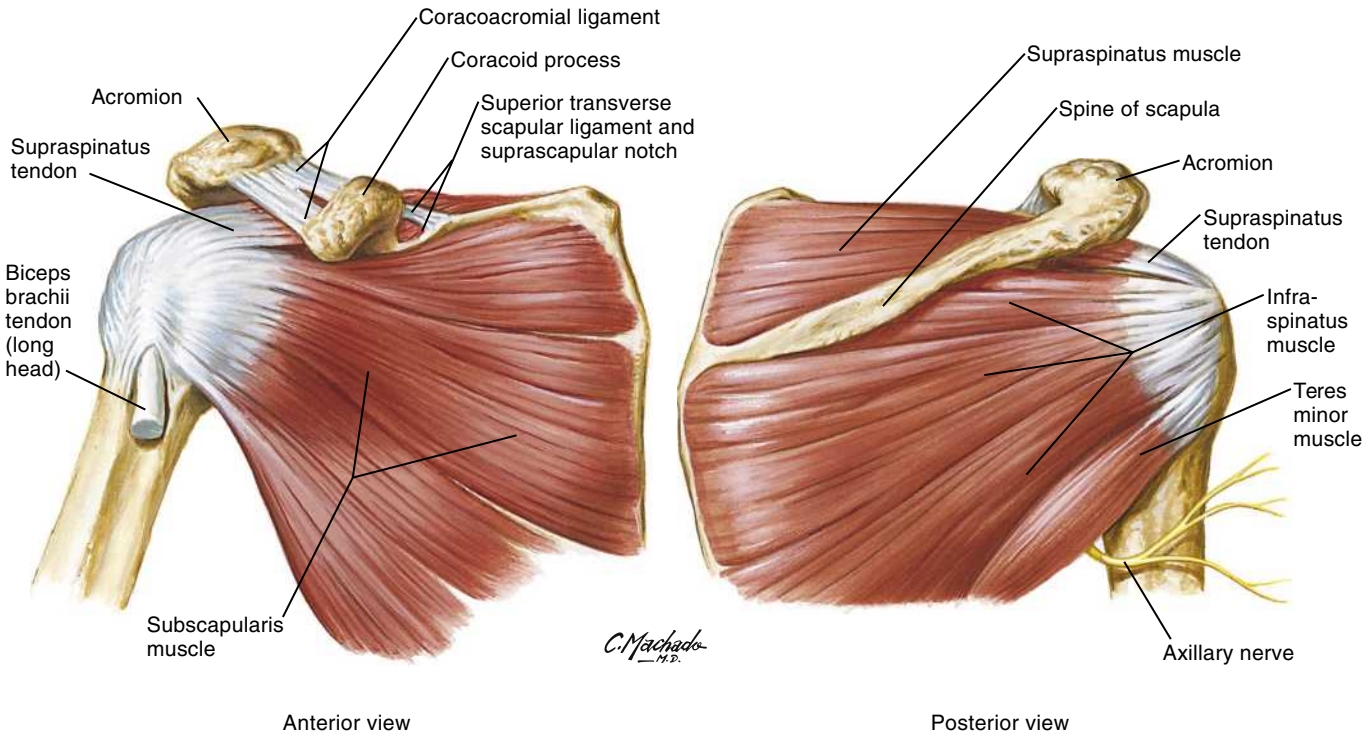

Fig. 45.5 The four rotator cuff muscles: anterior view (subscapularis) and posterior view (supraspinatus, infraspinatus, and teres minor). (Netter illustration from www.netterimages.com. Copyright 2016 Elsevier Inc. All rights reserved.)

CLINICAL FEATURES

History

Most complaints involve some combination of pain, stiffness, instability, or weakness. Pain can result from many different conditions extrinsic and intrinsic to the shoulder. Extrinsic sources of shoulder pain include disorders of the cervical spine, thoracic outlet, and myocardium, as well as symptoms referred from processes causing diaphragmatic irritation.

For intrinsic conditions, the most important factors to determine are the time and mechanism of injury (traumatic or overuse), location of the pain, and associated sensorimotor complaints. Shoulder pain also can manifest in an insidious manner, unrelated to any precipitating factor. In these instances, the duration, location, character, and aggravating and alleviating factors of the pain should be noted.

Stiffness usually manifests as a restricted range of motion resulting from an underlying painful condition of the shoulder. Instability can be chronic or acute and seen in the form of an obvious subluxation or dislocation or a sensation of the shoulder almost "going out of joint." Significant shoulder weakness is usually the result of an underlying nerve lesion or rotator cuff tear.

Physical Examination

The shoulder should be inspected from the anterior, posterior, and lateral positions, in addition to the axilla. Any obvious deformity, ecchymosis, laceration, swelling, or hematoma should be noted.

Palpation of the shoulder should be performed systematically, beginning at the SCJ and moving laterally to the ACJ. Next, the scapula, GHJ, and humerus are palpated. Any point tenderness, crepitus, swelling, or deformity should be noted.

Active and passive range of motion should be tested, although this may be limited due to pain. Active range of motion is best determined with the patient in the sitting position to eliminate the contributions of the lumbar spine and lower extremity joints. Passive range of motion is best evaluated in the supine position. The degrees of abduction, forward flexion, extension, and internal and external rotation should be compared with those of the unaffected extremity. In addition, observe the motion of the scapulothoracic articulation. After 45 degrees of abduction, the scapula moves approximately 1 degree for every 2 degrees of glenohumeral motion. Specific strength tests for the rotator cuff include resisted internal rotation (subscapularis), resisted external rotation (infraspinatus and teres minor), and the "empty can" test (supraspinatus). The empty can test is performed with the patient resisting downward pressure with their arm raised forward to 90 degrees, with arm extended and pronated, such that the thumb is down (as if pouring out a can of liquid).

The examination is completed with an assessment of neurovascular function. A complete neurologic examination of the brachial plexus includes sensory (light touch and pinprick) and motor assessment (Table 45.1). The radial pulse should be checked, although collateral circulation may preserve this, despite an underlying vascular injury.

TABLE 45.1 Sensory and Motor Components of the Brachial Plexus

Spinal Level	Sensory Area	Muscle
C2 to C4	—	Trapezius
C5	Lateral arm	Deltoid
C6	Lateral forearm and thumb	Biceps
C7	Tip of long finger	Thumb extensors
C8	Tip of little finger and medial forearm	Finger flexors
T1	Medial arm	Hand interossei

The presence of pallor, paresthesias, or a significant hematoma raises concern for a vascular injury. The neurovascular examination should be repeated and documented after any ED manipulation.

DIFFERENTIAL DIAGNOSES

Differential diagnoses for shoulder injuries are summarized in Table 45.2.

DIAGNOSTIC TESTING

Radiology

The initial assessment of traumatic injuries includes a three-view trauma series of radiographs consisting of true anteroposterior (45-degree lateral), trans-scapular lateral ("Y" view), and axillary lateral views. The true anteroposterior view is preferred over standard anteroposterior views, because it shows the GHJ without any bony overlap. Standard anteroposterior views obtained with the joint in internal and external rotation profile the lesser and greater tuberosity and are more useful in the evaluation of soft tissue conditions.

Orthogonal views include the axillary lateral, trans-scapular lateral, and apical oblique. The preferred view is the axillary lateral, which projects the GHJ in a cephalocaudal plane, helping to define the position of the humeral head with in the glenoid fossa and identify lesions of the coracoid process, humeral head, and glenoid rim. This view can be particularly helpful in identifying a posterior shoulder dislocation. If pain or post-reduction instability limits abduction, a modified axillary lateral view can be obtained by angling the central ray caudad with about 30 degrees of abduction. In the trans-scapular view, the scapula is projected as a Y, with the body forming the lower limb and the coracoid and acromion processes forming the upper limbs. The humeral head normally is superimposed over the glenoid, which is located at the junction of the three limbs. Advantages of this projection include its simplicity, reproducibility, and clear delineation of anatomic structures. Poor visualization of the glenoid is the primary disadvantage of the trans-scapular view. The apical oblique view (obtained by having the patient stand bending forward and angling the central ray 45 degrees caudally) shows the GHJ in a unique coronal projection. This view is useful in evaluating for Hill-Sachs lesions in shoulder dislocations, in addition to displacement and angulation of proximal humerus fractures.

Although plain radiographs suffice in most instances, additional bone and soft tissue details may be obtained via computed tomography (CT) or magnetic resonance imaging (MRI) in selected circumstances. Bedside point-of-care ultrasonography (POCUS) has emerged as a reliable screening and diagnostic imaging modality for selected conditions, in particular fractures of the clavicle, and soft tissue injuries, such as biceps tendon rupture and a rotator cuff tear.[2]

SPECIFIC INJURIES

Fractures

Clavicle

Foundations. The clavicle accounts for 3% to 5% of all fractures with a 2:1 male to female ratio. It is also the most commonly fractured bone in children. Clavicular fractures are classified anatomically and mechanistically into three groups. Fractures of the medial third are uncommon (5%) and occur as a result of a direct blow to the anterior chest. Fractures of the middle third are the most frequent (Figs. 45.6 and 45.9), accounting for 80% of all injuries. The usual mechanism of injury involves a direct force applied to the lateral aspect of the shoulder as a result of a fall, sporting injury, or motor vehicle collision (MVC). Fractures of the lateral third (15%) result from a direct blow to the top of the shoulder and are classified further into subtypes.[3] Type I fractures are stable and minimally displaced because the coracoclavicular ligament remains intact. Type II fractures are associated with a torn coracoclavicular ligament and have a tendency to displace because the proximal fragment lacks any stabilizing forces (Fig. 45.7). Type III injuries involve the articular surface.

Clinical features. The affected extremity is held close to the body as a result of the effect of gravity and the pull of the muscles

TABLE 45.2 Differential Diagnoses for Shoulder Injuries

Diagnosis	Differential Diagnoses
Clavicle fracture	Humerus fracture, AC joint injury, SC joint dislocation, soft tissue injury (contusion, sprain, strain)
Scapula fracture	Rib fracture, pneumothorax, hemothorax, glenohumeral dislocation, humerus fracture, and clavicle fracture
Humerus fracture	Glenohumeral dislocation, AC joint injury, rotator cuff tendon tear, soft tissue injury
Proximal humeral epiphysis	AC joint injury, humerus fracture, and glenohumeral dislocation
SC joint dislocation	Medial clavicle fracture, sternum fracture, rib fracture, mediastinal injury, and pneumothorax, soft tissue injury
AC joint dislocation	Distal clavicle fracture, acromion process fracture, coracoid process fracture, rotator cuff tear/strain, glenohumeral dislocation, soft tissue injury
Anterior glenohumeral dislocation	Proximal humerus fracture, proximal biceps tendon rupture
Posterior glenohumeral dislocation	Posterior glenohumeral subluxation, labral tear, glenoid fracture, proximal humerus fracture, scapula fracture
Inferior glenohumeral dislocation	Subglenoid anterior dislocation
Scapulothoracic dissociation	Glenohumeral dislocation, scapula fracture, proximal humerus fracture, and AC joint dislocation; brachial plexus injury
Impingement syndrome	Rotator cuff tendinopathy, rotator cuff tear, calcific tendinopathy, glenohumeral or acromio-clavicular osteoarthritis
Rotator cuff tear	Impingement syndrome, rotator cuff tendinopathy, biceps tendinopathy, AC joint osteoarthritis, GH or AC osteoarthritis
Biceps tendinitis	Proximal biceps tendon tear, rotator cuff tendon tear, rotator cuff tendinopathy, labrum tear, subluxing biceps tendon, and glenohumeral osteoarthritis
Biceps rupture	Subluxing bicep tendon, rotator cuff tendon tear, glenohumeral dislocation, and labrum tear
Calcific tendinitis	Rotator cuff tendinopathy, rotator cuff tear, impingement syndrome, and osteoarthritis
Adhesive capsulitis	Chronic dislocation, osteoarthritis, rotator cuff tendinopathy, calcific tendinitis, and rotator cuff tear

AC, Acromioclavicular; *GH*, glenohumeral; *SC*, sternoclavicular.

Fig. 45.9 Greenstick fracture of the clavicle *(arrow)*.

(pectoralis major, latissimus dorsi, sternocleidomastoid) on either side of the fracture site. The head is often tilted toward the injured side in an attempt to relax the effects of these displacing muscular forces. Tenderness, ecchymosis, crepitus, and a palpable or visible deformity may be present. Examine for any tenting of the skin, because this can cause progression to an open fracture. Furthermore, tenting of the skin is one of the indications for operative fixation and reduction. Although rare, it is prudent to evaluate for associated neurovascular and pulmonary injury due to close proximity of the subclavian vessels, brachial plexus, and lung apex. The most common complications are delayed union, nonunion, and symptomatic malunion. Displaced middle third fractures have a 15% to 20% rate of nonunion and up to 25% rate of symptomatic malunion.[4] Type III lateral clavicle fractures can lead to subsequent AC joint osteoarthritis.[3]

Differential diagnoses. In patients with direct fall onto lateral shoulder the differential diagnosis includes soft tissue injury (hematoma, contusion, strain, sprain), AC, GH, and SC joint injuries as well as rib, scapula, and humerus fractures.

Diagnostic testing. Clavicle-specific plain radiographs may be required to confirm the presence of a fracture, although most clinically significant fractures are diagnosed on chest or shoulder radiographs. Fractures in children can be reliably diagnosed or ruled out by POCUS, decreasing the exposure to radiation (Fig. 45.8).

Management. Principles of initial management for simple fractures include pain control, immobilization primarily for comfort, and proper follow-up care. In addition to oral analgesics, pain associated with clavicle fractures can also be managed with an ultrasound-guided superficial cervical plexus block in the ED.[5] Fractures of the clavicle are adequately immobilized with a simple sling since this results in similar functional outcomes and rates of union while providing greater pain relief than a figure-of-eight clavicular bandage.[6] Emergent orthopedic consultation should be sought for open fractures or fractures associated with neurovascular injuries, skin tenting, or interposition of soft tissues. More urgent orthopedic consultation (within 72 hours) is recommended for type II lateral clavicle fractures, because these fractures have up to a 30% incidence of nonunion and may require surgical repair.[3] Severely comminuted or displaced fractures of the middle third (defined as over 18 mm of initial shortening) are also associated with a higher incidence of nonunion and long-term functional deficits and deserve urgent orthopedic evaluation for consideration of operative reduction.[4,7]

Disposition. Most fractures of the clavicle heal uneventfully, and follow-up can be provided by a primary care physician. A sling should be worn until the patient is comfortable, which may precede radiographic evidence of callous formation. Early passive shoulder range-of-motion exercises (Fig. 45.10) are encouraged to reduce the risk of adhesive capsulitis (commonly referred to a "frozen shoulder"). Adolescents and adults generally require 4 to 8 weeks of immobilization. Contact sports should be avoided until the bone healing is solidified (6 to 8 weeks). Full range of motion of the shoulder and an absence of pain are two reliable clinical signs that the fracture has healed.

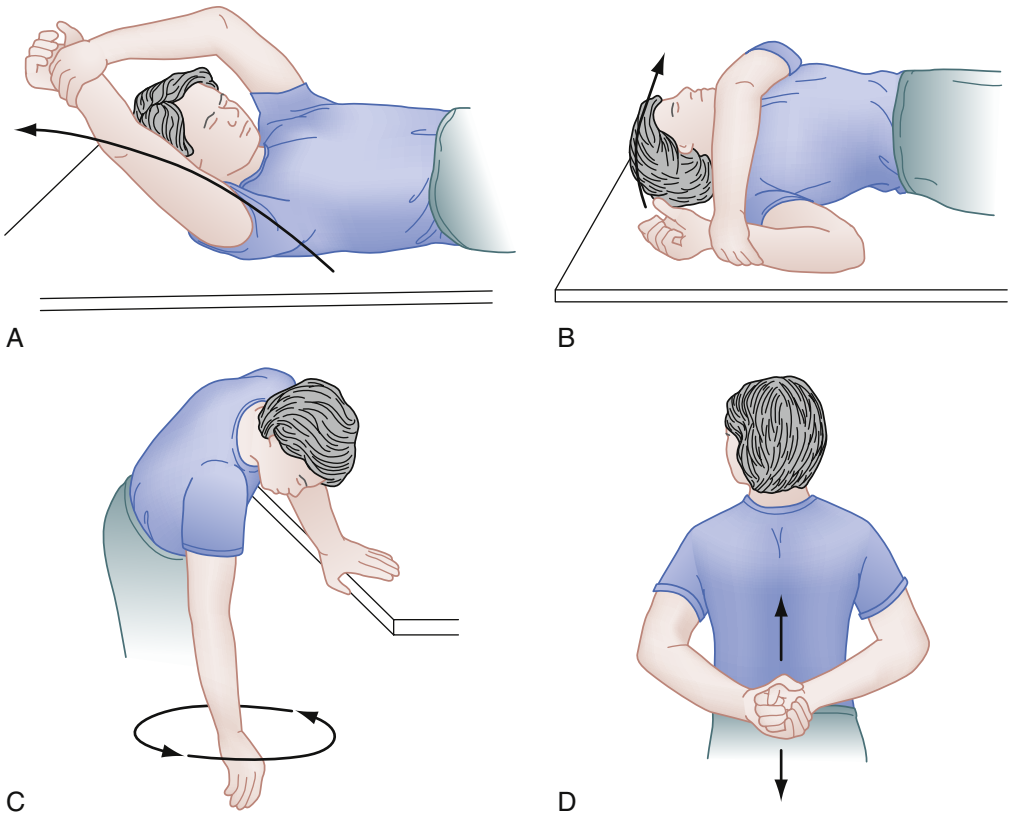

Fig. 45.10 Types of Active and Passive Shoulder Exercises. (A) Passive flexion. (B) Passive external rotation. (C) Pendular. (D) Passive internal rotation.

Scapula

Foundations. Fractures of the scapula are rare, accounting for approximately 1% of all shoulder fractures and caused by high-energy trauma, such as high-speed MVCs and falls from heights. Scapular fractures rarely require management but are associated with major injury (75% to 98%), specifically injuries to the ipsilateral lung, chest wall, and shoulder girdle complex. The most common associated orthopedic injuries are fractures of the ribs, proximal humerus, and clavicle. Associated lung injuries, including pneumothorax, hemothorax, and pulmonary contusion, usually occur acutely, but may manifest up to 2 to 3 days after the initial injury. Associated injuries of the head, spinal cord, brachial plexus, and subclavian or axillary vessels are less common.

Scapular fractures are divided into two main types: extra-articular (neck [Fig. 45.11], body, acromion process, coracoid process, spine) and intra-articular (with partial or total glenoid involvement).[8]

Clinical features. In a conscious patient, the shoulder is held in a position of most comfort, usually with the arm adducted and held close to the body. Any attempts at movement will result in significant pain. Tenderness, crepitus, or hematoma may be noted over the fracture site. The clinical findings occasionally mimic those seen with a rotator cuff tear. Associated injuries of the ipsilateral lung, chest wall, and shoulder girdle account for most complications. Neurovascular (e.g., brachial plexus, axillary artery, suprascapular nerve) injuries also have been reported with fractures of the acromial process, coracoid process, scapular neck, body, or spine fractures that extend into the suprascapular notch. Delayed complications include adhesive capsulitis and rotator cuff dysfunction.

Differential diagnoses. High energy trauma that can lead to a scapula fracture should also include the following on the differential diagnosis: rib fracture, pneumothorax, hemothorax, glenohumeral dislocation, humerus fracture, and clavicle fracture. The shoulder girdle is complex, so high-energy injury mechanisms to one part can affect any other associated part.

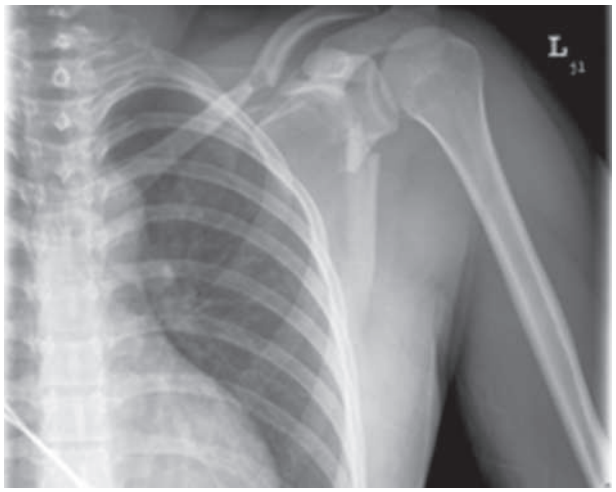

Fig. 45.11 Extra-Articular Fracture Involving the Neck of the Scapula. Note the associated midclavicular fracture.

Diagnostic testing

Radiology. The three-view trauma shoulder series will reveal most scapular fractures, as will careful examination of the scapula on the trauma chest radiograph. An os acromiale (unfused acromial process epiphysis) is present in 3% of the population, will not be tender to examination, and should not be confused with an acromion fracture.

A comparison film can be useful, because the abnormality is present bilaterally in 60% of cases. Although additional dedicated scapula views can be obtained in the ED, the presence and the extent of scapular injury is best determined by CT scan.[8] In the event that a trauma chest CT scan has been obtained to search for associated injuries, a three-dimensional reconstruction of the scapula should be requested to define the nature and extent of the injury.

Management. Presence of a scapular fracture should prompt a thorough search for associated thoracic, intracranial, orthopedic, and neurovascular injuries. Most fractures, including fractures with severe comminution heal rapidly with nonoperative therapy. Initial therapy consists of analgesia, immobilization in a sling for comfort to support the ipsilateral upper extremity, and passive range-of-motion exercises (see Fig. 45.10). Most patients require a sling for 2 to 4 weeks, physical therapy, and follow-up assessment for delayed displacement.

Nondisplaced fractures of the body, spine, and acromion process usually require no further therapy. Displaced acromial fractures that impinge on the GHJ require surgical management. Rarely, the acromion is fractured as part of a superior dislocation of the humeral head. In these instances, an accompanying tear of the rotator cuff which may require surgical repair is invariably present. If the coracoclavicular ligaments remain intact, fractures of the coracoid process respond well to conservative therapy. Severely displaced coracoid fractures with ruptured coracoclavicular ligaments usually require open reduction and internal fixation. Scapular neck and glenoid fossa fractures present the most difficult management issues. Although most of these injuries also do well with conservative therapy, open reduction and internal fixation may be necessary to improve long-term function.[9]

Proximal Humerus

Foundations. Fractures of the proximal humerus occur primarily in the older population, in whom structural changes (osteoporosis) weaken the proximal humerus, predisposing it to injury from low-energy falls. Although most of these injuries involve minimal displacement and are adequately managed with conservative therapy, significantly displaced fractures may require operative intervention. Displacements encountered with fractures of the humerus usually reflect the pull of the attached muscle groups.

Fractures of the proximal humerus separate along old epiphyseal lines, producing four distinct segments consisting of the articular surface (anatomic neck), greater tuberosity, lesser tuberosity, and humeral shaft (surgical neck). The Neer classification system is based on the relationship of these fracture fragments. In this system, a segment is considered displaced if it is angled more than 45 degrees or separated more than 1 cm from the neighboring segment. Because this classification system considers only displacement, the number of fracture lines is irrelevant. There are four major categories of fracture: (1) minimal displacement (Fig. 45.12), (2) two-part displacement (Fig. 45.13), (3) three-part displacement, and (4) four-part displacement. When present, anterior and posterior dislocations are included as part of the classification. Impaction and head-splitting fractures are classified separately.

The classic mechanism of injury involves a fall on an outstretched abducted arm. Concurrent pronation limits further abduction and levers the humerus against the acromial process; this produces a fracture or dislocation, depending on the tensile strengths of the bone and surrounding ligaments. Older patients are prone to fracture, whereas younger persons are apt to have dislocations. The combined injury (fracture and dislocation) may be seen in middle-aged patients. Proximal humerus fractures also may result from a direct blow to the lateral side of the arm or from an axial load transmitted through the elbow. High-energy mechanisms and polytrauma are more common in younger persons.

Fig. 45.12 Three-part minimally displaced fracture of the proximal humerus involving the greater and lesser tuberosities.

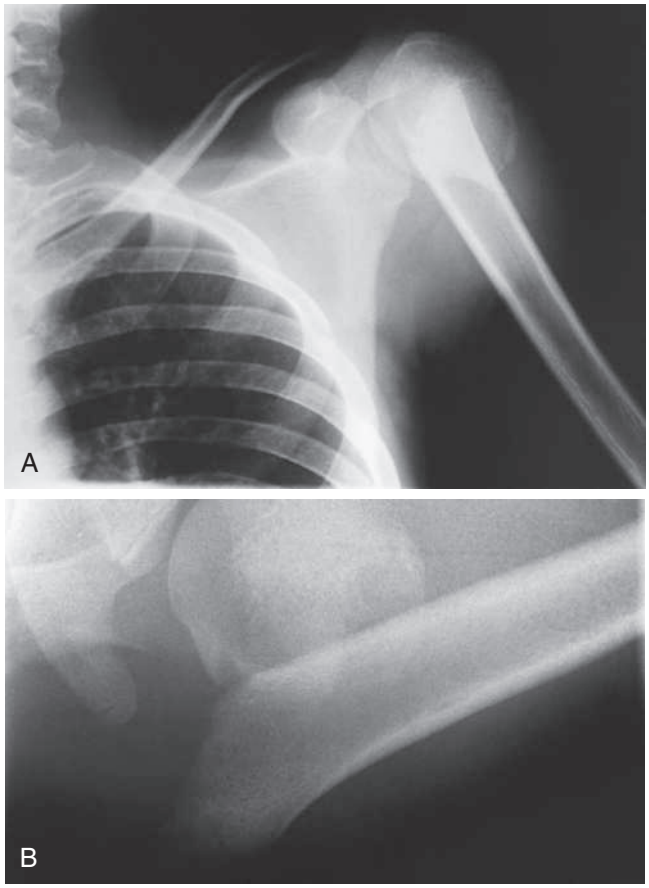

Fig. 45.13 Anteroposterior (A) and axillary (B) radiographic views of a two-part displaced fracture of the proximal humerus. The degree of displacement often is better visualized on the axillary view. (Courtesy David Nelson, MD.)

Clinical features. The affected arm is held close to the body, and movement is restricted by pain. Tenderness, hematoma, ecchymosis, deformity, or crepitus may be noted over the fracture site. A thorough neurovascular examination is essential to identify associated injuries of the axillary nerve, brachial plexus, or axillary artery (see Table 45.1). The most common complication of proximal humeral fractures is adhesive capsulitis. This complication can be prevented by the early initiation of pendular shoulder exercises, along with a thorough rehabilitation program. One of the most devastating complications is avascular necrosis (AVN), which is more common in multi-part fractures, and fracture-dislocations due to the disruption of the blood supply to the humeral head.[10] Repeated forceful attempts at reduction of fracture-dislocations may be associated with subsequent heterotopic bone formation (myositis ossificans). Neurovascular injuries (axillary nerve, brachial plexus, and axillary artery) may be encountered with displaced surgical neck fractures and fracture dislocations.

Differential diagnoses. The differential diagnosis of a proximal humerus fracture includes: glenohumeral dislocation, AC joint separation, rotator cuff tendon tear, or soft tissue injury including hematoma, contusion, and muscle strains.

Diagnostic testing. The three-view trauma series allows for assessment of the number of fracture fragments and degree of displacement or angulation. Cross-sectional imaging is usually not necessary in the ED; however, there may be certain situations where it is helpful, including making the diagnosis of an occult fracture, orthopedic surgery request for surgical planning, and further evaluation of neurovascular structures. If there is high concern for a vascular injury, a CT scan with contrast is the most appropriate study. If there is concern for a peripheral nerve injury, an MRI may be helpful, although a normal MRI does not rule out an associated nerve injury. In such instances, patients may require an outpatient electromyography (EMG) and orthopedic consultation.

Management. Minimally displaced fractures (see Fig. 45.12) constitute up to 80% to 85% of all cases. In these instances, limited displacement or angulation is present, and the fracture segments are held together by the capsule, periosteum, and surrounding muscles. Initial treatment consists of adequate analgesia and immobilization with a sling. A Cochrane review noted that rapid commencement of physiotherapy (within 1 week) resulted in less pain without compromising long-term outcomes.[11] Initial passive exercises (see Fig. 45.10) are gradually replaced by more active and resistive exercises. Most nondisplaced fractures heal over 4 to 6 weeks.

The management of displaced two-part, three-part, and four-part fractures remains controversial and an orthopedist should be consulted. A prospective randomized clinical trial failed to show a significant functional difference between operative and nonoperative treatment of displaced two-part, three-part and four-part fractures in elderly patients.[12,13] If operative treatment is selected, the procedures of choice for three-part and four-part fractures are reverse hemiarthroplasty or hemiathroplasty.[14,15]

Fracture-dislocation injuries are best managed in consultation with an orthopedic surgeon before attempts at reduction (except in cases of neurovascular compromise or unavailability of an orthopedic surgeon). Reductions of these injuries in the ED may be unsuccessful, and manipulation can cause separation of previously non-displaced segments. Closed reduction under fluoroscopic visualization and general anesthesia is preferable.

Pediatric Proximal Humeral Fracture

Foundations. Fractures of the proximal humeral physis and metaphysis are uncommon and account for a small proportion of pediatric fractures.[16] The injury can occur at any age while the physis remains open but is most common in adolescent boys. The most common mechanism of injury involves a fall onto the outstretched hand, and the fracture typically occurs through the zone of hypertrophy in the epiphyseal plate. Injuries can be classified according to their location (Salter system), stability, and degree of displacement.[16]

Clinical features. The patient typically holds the injured arm tightly against the body, using the opposite hand. The area over the proximal humerus is swollen and tender to palpation. Complications are rare and include malunion, growth plate disturbances, and injuries to the neurovascular bundle. Markedly displaced or angulated fractures can result in a residual loss of mobility.

Differential diagnoses. The differential diagnosis for pediatric proximal humeral fractures varies based on age and acuity of the injury. Differential diagnoses for acute traumatic injuries include osteochondral lesion in the GHJ (rare in the upper extremity), AC joint injury (more common in late teenage years as physis reaches maturity), and glenohumeral dislocation.

Diagnostic testing. Orthogonal radiographs help confirm the diagnosis. Comparison views may be helpful with minimally displaced fractures (Fig. 45.14). POCUS can also be used to identify these injuries.

Management. Fractures of the proximal humeral epiphysis can result in significant permanent injury and disability as the physis accounts for 80% of the longitudinal growth of the bone. Urgent orthopedic consultation should be obtained for all such injuries in the ED.

Dislocations

Sternoclavicular

Foundations. SCJ dislocations are infrequent and account for less than 1% of all dislocations.[17] Significant forces are required to disrupt the strong ligamentous stabilizers of this joint. The most common causes are MVCs and injuries sustained in high impact contact sports.

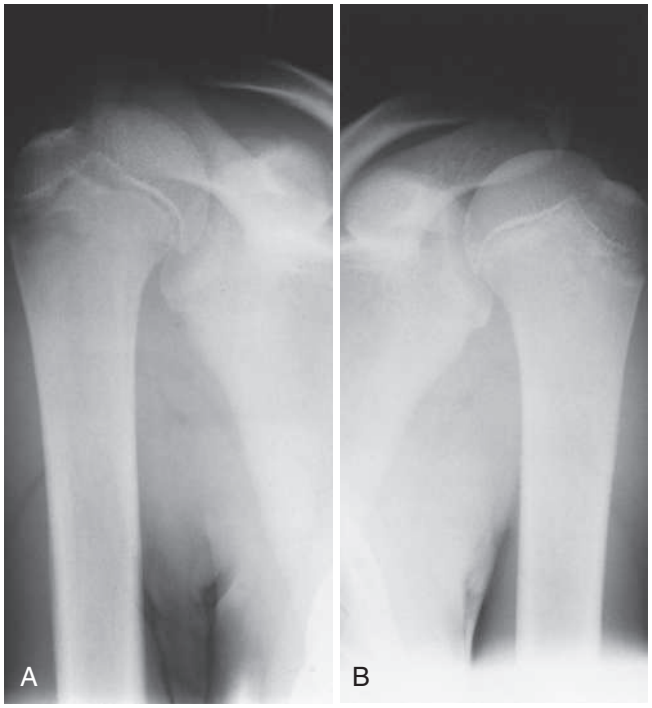

Fig. 45.14 (A) Salter I injury of the right proximal humeral epiphysis. (B), Normal left side is included for comparison.

The vast majority of dislocations are anterior. Posterior dislocations, although less common, can be associated with life-threatening injuries within the superior mediastinum.[18] The usual mechanism of injury for anterior and posterior dislocations is pictured in Fig. 45.15. Posterior dislocations can also result from a direct blow to the medial clavicle.

Injuries to the SCJ can be graded into three types.[17] A grade I injury is a mild sprain of the sternoclavicular and costoclavicular ligaments. A grade II injury is associated with subluxation of the joint (anterior or posterior) secondary to disruption of the sternoclavicular ligament and capsule. Complete rupture of the sternoclavicular and costoclavicular ligaments results in a grade III injury (true dislocation). In patients younger than 25 years old, these may represent Salter type I injuries if the medial clavicle epiphysis is unfused.[17]

Clinical features. Clinical suspicion based on mechanism and exam is the single most important factor in diagnosing these injuries. The injured extremity is flexed at the elbow and supported across the trunk by the opposite arm. Pain results from any movement of the upper extremity or lateral compression of the shoulders. The SCJ may be mildly swollen and tender to palpation. With an anterior dislocation, the displaced medial end of the clavicle may be palpable. Posterior dislocations are more painful and may be associated with complaints of hoarseness, dysphagia, dyspnea, and weakness or paresthesia in the ipsilateral upper extremity. The patient's neck is often flexed toward the injured side and the clavicular notch of the sternum may not be palpable. Hoarseness may be related to tracheal injury. Damage to the innominate vein may present as cyanosis and venous congestion of the neck, which should prompt vascular imaging and consultation. Complications of anterior injuries are primarily cosmetic. By contrast, 25% of posterior dislocations may be complicated by life-threatening injuries to intrathoracic and superior mediastinal structures.[18] These include compression or laceration of the great vessels, tracheoesophageal fistula, tracheal compression, pneumothorax, thoracic outlet syndrome, and brachial plexus injuries.

Differential diagnoses. The differential diagnosis for patients with traumatic SC joint pain include medial clavicle fracture, rib fracture, costochondral injury, sternum fracture, sternoclavicular dislocation, contusion, mediastinal injury, and pneumothorax.

Diagnostic testing. Although diagnosed clinically, sternoclavicular dislocation requires radiological confirmation. Findings on standard anteroposterior, oblique, and specialized (40-degree cephalic tilt) SCJ views are challenging to interpret. These dislocations and associated injuries are best visualized by a chest CT angiogram (Fig. 45.16). POCUS can be a useful bedside adjunctive test.[19]

Management. Treatment of grade I injuries includes sling immobilization for comfort and primary care follow-up. Immobilization generally is maintained until symptoms improve and full painless motion is restored. Grade II injuries should be immobilized with a sling and the patient referred for orthopedic follow-up care. Grade II injuries require a longer course of immobilization (4 to 6 weeks) and are more likely to be associated with persistent pain. Grade III injuries are generally managed by closed reduction and rarely with open reduction.

Anterior dislocations may be reduced in the ED with proper analgesia and on occasion may require general anesthesia. Patient positioning is optimized by a bolster between the scapulae (Fig. 45.17). Stable reductions should be maintained in a sling and referred for orthopedic follow-up care. Most reductions are unstable; and because the deformity is primarily cosmetic and not functional, the treatment of choice for recurrent anterior dislocations is benign neglect and pain control.

Posterior dislocations constitute true orthopedic emergencies and should be reduced expeditiously. Ideally, reduction of posterior dislocations should be attempted under general anesthesia due to the risk of injury to mediastinal structures and potential need for open reduction.[18] ED reduction may be required for patients with airway obstruction or vascular compromise. The patient is positioned as described previously (see Fig. 45.17). If traction alone does not reduce the dislocation, concurrent clavicular manipulation may be helpful. After sterile preparation of the skin and administration of local anesthesia, the clavicle shaft is grasped with a sterile towel clip and pulled out anterolaterally (Video 45.1).[18] Once reduced, these injuries generally are stable and can be immobilized with a sling. An alternate method of reduction involves traction to the adducted injured arm while both shoulders simultaneously are forced posteriorly with direct pressure. This technique levers the clavicle into place and requires far less force.

Acromioclavicular Joint

Foundations. Injuries of the ACJ occur primarily in young men as a result of MVCs, bicycle accidents, or participation in high impact contact sports. The most common mechanism of injury involves a fall or direct blow to the point of the shoulder with the arm adducted. The ACJ also can be injured after a fall onto the outstretched hand. The

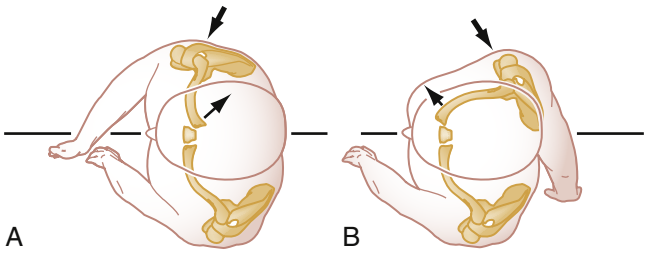

Fig. 45.15 Mechanisms That Produce Posterior and Anterior Displacements of the Sternoclavicular Joint. (A) When a compression force *(upper arrow)* is applied to the posterolateral aspect of the shoulder, the medial end of the clavicle is displaced posteriorly *(lower arrow)*. (B) When the lateral compression force *(upper arrow)* is directed from the anterior position, the medial end of the clavicle is dislocated anteriorly *(lower arrow)*. The same mechanism could apply with any type of lateral compression injury of the shoulder. (From Neer CS, Rockwood CA. Fractures and dislocations of the shoulder. In Rockwood CA, Green DP, eds. *Fractures in adults*. 4th ed. Philadelphia: JB Lippincott; 1984.)

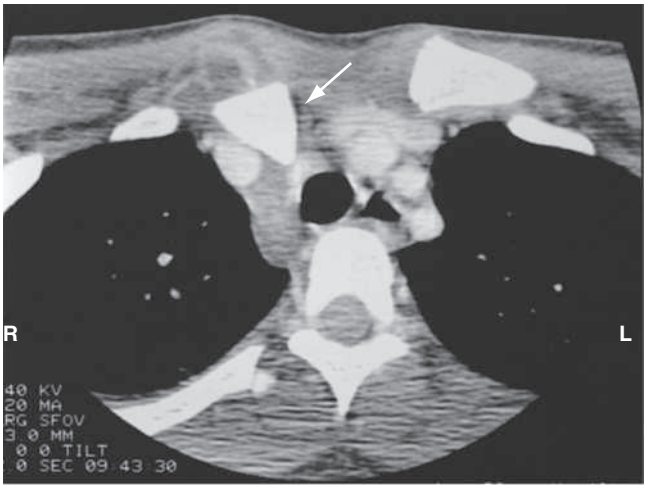

Fig. 45.16 This computed tomography (CT) scan shows posterior dislocation of the right sternoclavicular joint (SCJ; *arrow*) with compression of the superior mediastinum. (Courtesy Donald Sauser, MD.)

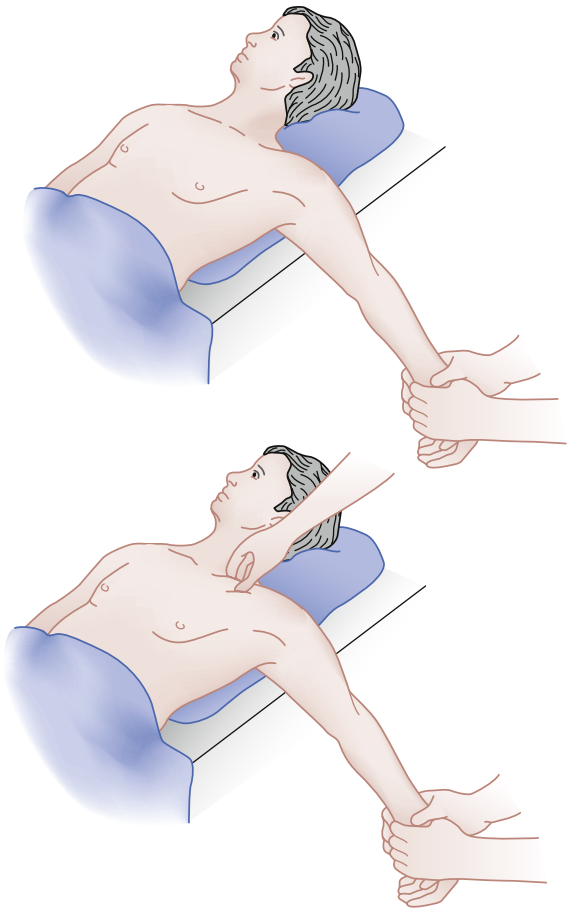

Fig. 45.17 Reduction of Dislocated Sternoclavicular Joints. A rolled sheet is placed posteriorly between the shoulder blades to elevate both shoulders approximately 5 cm above the table. Traction is applied to the arm in an extended (10- to 15-degree) and abducted (90-degree) position. If reduction does not occur, an assistant can add posterior pressure on the medial end of the clavicle for anterior dislocations (not pictured). (From Simon RR. *Emergency orthopedics: the extremities*. 7th ed. Norwalk, CT: McGraw-Hill; 2015.)

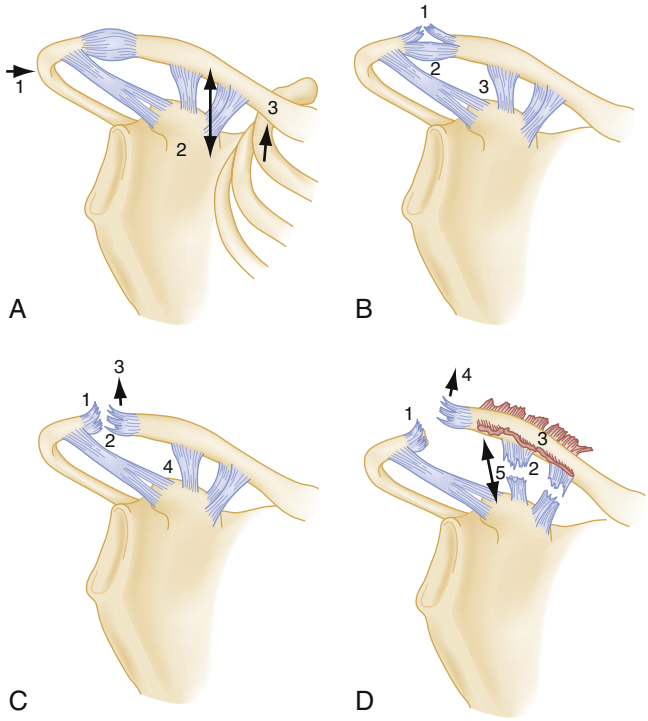

Fig. 45.18 Mechanism of Injury and Classification of Acromioclavicular Joint Injuries. *Arrows indicate direction of applied force and relevant movement.* (A) The direct force is applied to the point of the lateral shoulder (1); the scapula and attached clavicle are forced downward and medially; the clavicle approaches the first rib (2). If the force continues, the first rib abuts the clavicle, producing a counterforce (3). Depending on the magnitude of the force, a grade I, II, or III sprain may occur. (B) Grade I sprain. A few fibers of the acromioclavicular ligament stretch, and a few tear (1); the ACJ is stable (2); the coracoclavicular ligament is intact (3). (C) Grade II sprain (subluxation). The joint space widens but the coracoclavicular distance is maintained. The capsule and the acromioclavicular ligament rupture (1); the joint is lax and unstable (2); the end of the clavicle rides upward, with displacement usually less than half of the width of the end of the clavicle (3); the coracoclavicular ligament remains intact (4); the attachments to the trapezius and deltoid remain intact. (D) Grade III sprain (dislocation). The capsule and acromioclavicular ligaments rupture (1); the coracoclavicular ligament ruptures (2); the insertions of the trapezius and deltoid tear away (3); the clavicle rides upward (4); the interval between the clavicle and the coracoid process is greatly increased (5). *Not pictured:* In type IV and V injuries, the ligamentous and muscle disruptions are similar to the disruptions encountered in type III injuries, but the clavicle is displaced either posteriorly into the trapezius (type IV) or superiorly in an exaggerated fashion (coracoclavicular distance increased 100% to 300%; type V). In the rare type VI injury, the clavicle is displaced inferiorly. (From DePalma AF. *Surgery of the shoulder*. 3rd ed. Philadelphia: JB Lippincott; 1983.)

weak acromioclavicular ligaments rupture first. With increasing force, the coracoclavicular ligament ruptures, and the attachments of the deltoid and trapezius muscles are torn from the distal clavicle.

Classification is based on the degree of damage sustained by the acromioclavicular and coracoclavicular ligaments (Fig. 45.18) and the Rockwood 6-class grading system.[20]

Clinical features. Patients should be examined while they are upright, because the supine position can mask ACJ instability, and it is helpful to visualize both shoulders simultaneously to assess for symmetry. Type I and type II injuries are associated with mild tenderness and swelling over the ACJ margin, with minimal deformity and full range of motion (albeit painful). Patients with type III, IV, V, and VI injuries have severe pain and hold the arm tightly adducted to reduce traction stress across the joint. In type III injuries, the shoulder hangs downward and the clavicle rides high, producing a characteristic clinical deformity that can be reduced by an upward force under the elbow. In type IV injuries, the clavicle may be palpable posteriorly. In type V injuries, the clavicle is dramatically displaced superiorly and palpable subcutaneously above the acromion; however, unlike type III it is not reducible by elbow elevation. In type VI injuries, the clavicle displaces inferolaterally behind the biceps tendon and the shoulder assumes a flattened clinical appearance.

The most common concurrent injuries are associated fractures of the clavicle and coracoid process. The most common complications of ACJ injuries are residual symptomatic instability, cosmetic deformity, and joint tenderness due to secondary degenerative changes.[21]

Differential diagnoses. While a lateral blow to the shoulder can cause an AC joint dislocation, other important diagnostic considerations include distal clavicle, coracoid or acromion process fractures, rotator cuff injuries, and glenohumeral dislocation.

Diagnostic testing

Radiology. The recommended projections include routine anteroposterior and axillary lateral view to evaluate for vertical

migration of the clavicle and anteroposterior displacement, respectively. A Zanca view (an anteroposterior with 15-degree cephalic tilt view) can improve visualization by removing the scapula from behind the joint. Anteroposterior and Zanca views are ideally obtained with a view of both joints on a single-wide film. Standing radiographs help unmask a higher-grade injury. A difference of more than 25% between the injured and uninjured sides is diagnostic of a complete coracoclavicular disruption.[20] With type I injuries, the radiographic appearance is essentially normal. With type II injuries, radiographs show upward or posterior displacement of the clavicle less than half the height of the clavicle and less than 25% side to side difference of coracoclavicular distance.[20] With type III, IV, and V injuries, radiographic features include a widened joint, an increased coracoclavicular distance, and either superior or posterior displacement of the clavicle (Fig. 45.19) with the lower margin of the clavicle cephalad to the upper margin of the acromion. Advanced cross-sectional imaging is rarely indicated in the ED management of AC joint separations. Vascular injury is extremely unlikely with AC joint injuries; however, if there is suspicion, a CT scan with contrast can be obtained. Orthopedic surgeons may request a CT scan to help further characterize the anatomy and associated injury pattern for potential surgical patients. MRI may be helpful in the evaluation of soft tissues (e.g., rotator cuff, labrum, ligaments) but is rarely indicated in the ED.

Management. Type I and II injuries should be immobilized in a sling for comfort and to remove stress on injured ligaments. Patients with these injuries can be referred for follow-up with their primary care physician. When pain has subsided (1 to 2 weeks), gradual range-of-motion and strengthening exercises can begin, with a return to sporting activities when pain-free function has been achieved (usually 2 to 6 weeks).

The management of type III injuries is variable, although most favor initial nonoperative management.[22,23] Selected patients who are young, competitive athletes, or perform repetitive overhead activities may be candidates for surgical intervention. Treatment of type III injuries in the ED should consist of sling immobilization with sports medicine or orthopedic referral for follow-up in 1 to 2 weeks. Type IV and V injuries classically have been treated surgically; however, recent literature suggests that nonoperative treatment leads to similar functional outcomes.[21] Type VI injuries require early surgical treatment.

Glenohumeral Dislocations

Foundations. The GHJ is the most commonly dislocated major joint in the body. Dislocation follows a bimodal age distribution for men, age 20 to 30 and greater than 85 years old, however there is a unimodal age distribution for women in their 60s.[24] The GHJ can dislocate anteriorly, posteriorly, or inferiorly. Anterior dislocations account for 96% to 98% of all glenohumeral dislocations.[25] Posterior dislocations account for most of the remainder, whereas inferior (*luxatio erecta*) dislocation is rare.

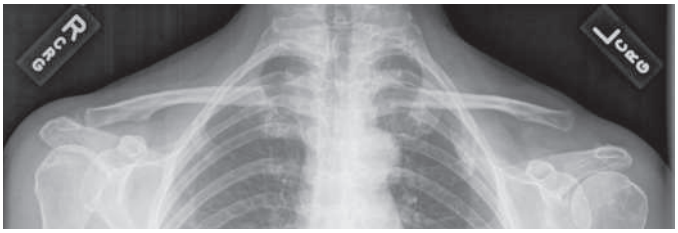

Fig. 45.19 Third-Degree Sprain of the Left Acromioclavicular Joint. The coracoclavicular distance is increased. Bilateral clavicle view (patient is standing) provides comparison to the unaffected side. (Courtesy Erik Foss, MD.)

Anterior Dislocations

Pathophysiology. Anterior dislocations can result from indirect or direct forces. In younger persons, the injury usually is sustained during athletic activities involving rapid movements with the arm elevated, abducted and externally rotated, or rarely by a direct posterolateral force. A characteristic pathologic feature is avulsion of the anteroinferior glenohumeral ligament with capsulolabral detachment (Bankart's lesion). In older patients, a fall onto the palm of an outstretched arm is the more common mechanism of injury.

Anterior dislocations can be classified according to their cause (traumatic or nontraumatic), frequency (primary or recurrent), and the anatomic position of the dislocated humeral head (Figs. 45.20 and 45.21). In most dislocations (99%) the humeral head will assume

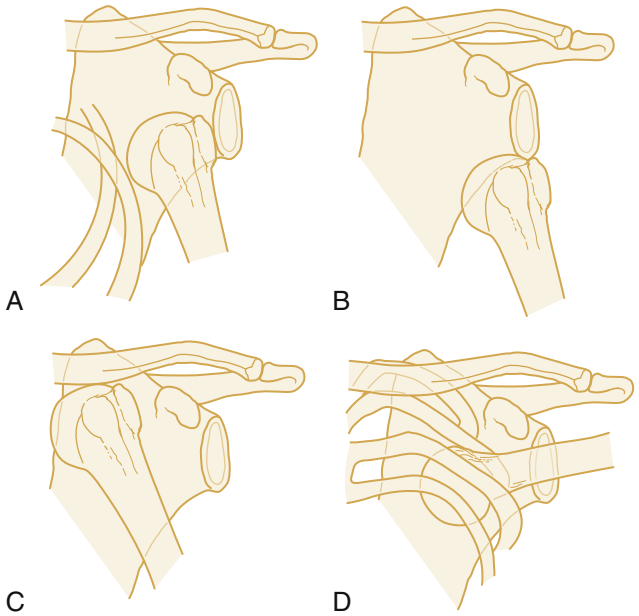

Fig. 45.20 Types of Anterior Dislocation. (A) Subcoracoid. (B) Subglenoid. (C) Subclavicular. (D) Intrathoracic. (From DePalma AF. *Surgery of the shoulder.* 3rd ed. Philadelphia: JB Lippincott; 1983.)

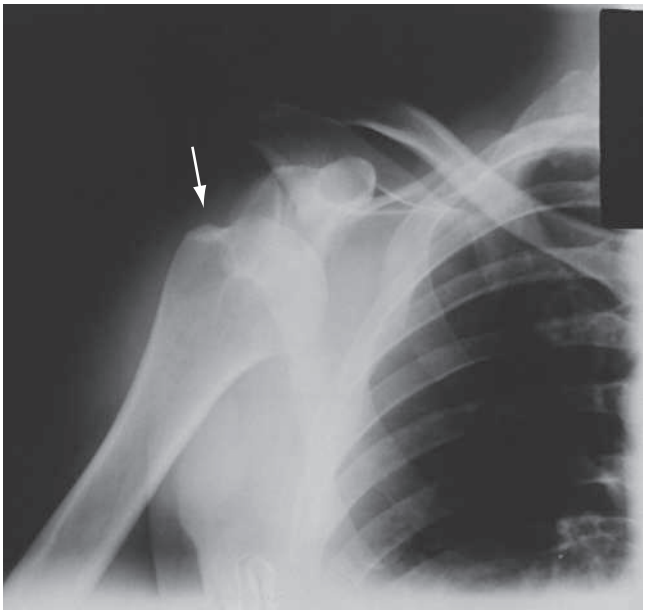

Fig. 45.21 Recurrent anterior subcoracoid dislocation with Hill-Sachs deformity of the humeral head *(arrow).*

a subcoracoid or subglenoid position. Of these, the subcoracoid is more common, and the head is displaced anteriorly and rests inferior to the coracoid process. Subclavicular and intrathoracic dislocations are extremely rare and involve the addition of strong lateral to medial forces.

Clinical features. The patient presents in severe pain often supporting the dislocated shoulder with the opposite extremity. The lateral edge of the acromion process is prominent, and the normally rounded shoulder assumes a "squared-off" appearance. The coracoid process is indistinct, and the anterior shoulder appears full.

Anterior dislocations can be associated with injuries of the brachial plexus, axillary nerve or artery. Axillary nerve injury occurs in less than 10% of patients.[24,26] Complications from the dislocation event include fractures, soft tissue trauma and neurovascular injuries. Most axillary nerve injuries are neurapraxic, management is expectant, and the prognosis for recovery of function is good. Rotator cuff tears are especially common in primary dislocations in patients older than 40 years old, increasing to 80% in patients over 60 years old. Supraspinatus tears resulting in failure to abduct the arm are commonly confused with an axillary nerve injury. Most of these patients require tendon and capsular repair to restore shoulder stability. Recurrence also is a common complication after anterior dislocation and there is an inverse relationship between age and stability.[27] Patients younger than 30 years old have recurrence rates of 79% to 100%. A large Hill-Sachs deformity, Bankart's lesion, or a glenoid rim fracture are associated with increased risk of recurrence. The traditional method of treatment (immobilization followed by physical therapy) is ineffective in preventing redislocation in young athletic patients. Bankart lesions are believed to be the primary predisposing factor for recurrence, and affected patients derive benefit from early arthroscopic repair of the lesion.[27] Recurrence rates decline with increasing age and in the presence of a greater tuberosity fracture.

Differential diagnoses. Patients presenting with shoulder pain and a full anterior shoulder on examination should be evaluated for glenohumeral dislocation, proximal humerus fracture, and proximal biceps tendon rupture. Less likely, but also worth considering, are muscular tears (pectoralis major, pectoralis minor, biceps brachii).

Diagnostic testing

Radiology. Radiographs including anterior-posterior, transscapular Y view, and axillary lateral will confirm the clinical diagnosis and identify the position of the humeral head. Radiographs are indicated in first-time dislocations but may be omitted in patients with a history of recurrent dislocations. POCUS may be useful as a diagnostic bedside test.[25] Some patients with a dislocation will have an associated fracture—most commonly, a compression fracture of the posterolateral aspect of the humeral head (Hill-Sachs deformity) caused by forceful impingement against the anterior rim of the glenoid fossa. Hill-Sachs fractures are not clinically significant unless they are large enough to cause recurrent shoulder instability or painful clicking or catching, in which case surgical repair may be necessary.

Management. Reduction of the dislocation should be accomplished expeditiously, because the incidence of neurovascular complications increases with time as does the reduction difficulty due to muscle spasm. For healthy patients with a history of recurrent dislocation, reduction may be attempted before imaging. A post-reduction film remains advisable to aid in the identification of glenoid rim fractures, as well as Hill-Sachs deformities, which when large can be associated with subsequent shoulder instability. POCUS can also be used to assess for successful relocation.

Procedural sedation is often used to facilitate reduction in the ED. Adequate analgesia often can also be provided through intra-articular injection of a local anesthetic agent. This technique is especially useful when intravenous procedural sedation is contraindicated or unable to be performed.[28] Longer acting local anesthetic agents (e.g. bupivacaine) may also offer continued post-reduction analgesia. Multiple studies have found that intra-articular lidocaine achieved similar reduction effectiveness (RR 0.92) when compared with procedural sedation with fewer complications. Depending on the duration of the dislocation, nature (primary vs. recurrent) and technique, reduction can also be attempted and accomplished successfully without the use of any analgesia or sedation, provided the examiner is prepared to stop the procedure if the patient experiences pain.

Reduction can be accomplished with various techniques, most of which involve traction, leverage, or scapular manipulation principles. The ideal method should be simple, quick, and effective; require little assistance; and cause no additional injury to the shoulder. It is important to be familiar with several techniques of reduction because none are uniformly successful. Several common techniques are described in Table 45.3. Clues to a successful reduction include feeling of a "clunk," relief of pain, normalization of anatomy, and improvement in range of motion. The neurovascular examination should be repeated and recorded after any reduction attempt. Most of these techniques are usually effective; however, approximately 5% to 10% of dislocations cannot be reduced in the ED and require reduction under anesthesia. After reduction, the affected extremity is immobilized with a sling and swathe bandage for comfort. Patients should be discharged with adequate analgesia and follow-up. Primary dislocations and complicated cases (associated fracture, rotator cuff tear, axillary nerve injury) should follow up with an orthopedist or sports medicine specialist in 1 to 2 weeks. Immobilization duration can be individualized according to age, dislocation type (initial vs. recurrent) and associated injury. General recommendation is sling immobilization until orthopedic follow-up in 1 to 2 weeks. Younger patients (under 30 years old and especially those with recurrent dislocations) can benefit from the capsular stiffness incurred by longer period of immobilization. Older patients (over 50 years old) are unlikely to have a recurrent dislocation and therefore benefit from early range of motion exercises to prevent adhesive capsulitis. The most important post-reduction therapy is a rehabilitation program aimed at restoring the static and dynamic stabilizers of the GHJ.

Posterior Dislocation

Pathophysiology. Posterior dislocations are uncommon, accounting for fewer than 5% of all glenohumeral dislocations.[24,26] The glenoid fossa acts as a partial buttress protecting against posterior dislocations. Posterior dislocations are easily missed on initial evaluation. Obtaining true orthogonal images (axillary lateral or scapular "Y" view) can prevent misdiagnosis. The axillary lateral if obtainable is preferable. If missed, posterior dislocations may remain unrecognized ("locked posterior dislocations") for weeks or months.

A posterior dislocation can result from several distinct mechanisms of injury. A posterior dislocation can occur after a fall onto the outstretched hand with the arm held in flexion, adduction, and internal rotation or after a direct blow to the anterior aspect of the shoulder.[26] Convulsive seizures (epileptic or after electrical shock) have been associated with unilateral or bilateral posterior dislocations. A seizure disorder should be suspected in cases of unexplained nocturnal posterior dislocations. Acute posterior dislocations are classified into three types—subacromial (most common), subglenoid, and subspinous—based on the final resting position of the humeral head.

Clinical features. Early diagnosis is essential to prevent long-term complications. The affected arm is held across the chest in adduction and internal rotation. The normal shoulder contour is replaced by a flat, squared-off appearance, and the coracoid process is prominent and easily palpated. Sometimes a dimple is apparent in the anterior

TABLE 45.3 Techniques to Reduce Anterior Shoulder Dislocations

Reduction Technique	Description
Stimson (hanging weight)[a]	Patient placed prone with the dislocated shoulder hanging over the edge of the examining table. Attach a 10- or 15-pound weight to the wrist or lower forearm providing traction in forward flexion. Reduction usually occurs over 20–30 min (see Fig. 45.22).
Traction/countertraction	Apply traction along the abducted arm while an assistant using a folded sheet wrapped across the chest applies countertraction. Although commonly used, this technique requires more force than others (see Fig. 45.23).
External rotation method	No traction involved. Patient seated or in supine, the involved arm is slowly and gently adducted to the side. The elbow is flexed to 90 degrees, and slow, gentle external rotation is applied to achieve reduction (see Fig. 45.24). Success rates with this method range from 80% to 97%.
Cunningham[a]	Patient sits without slouching in a hard-backed chair. Adduct the affected arm to the body and place elbow in full flexion resting against operator's shoulder. Operator then provides traction by placing their wrist on patient's forearm while asking the patient to shrug shoulders superiorly and posteriorly. The operator adds massage down through the trapezius, deltoid, and the biceps muscles. This technique is targeted to relax muscles causing a dynamic obstruction.
Milch technique[a]	Patient is placed supine and the head of the bed is elevated 20–30 degrees. The affected arm is held by the wrist and slowly abducted and externally rotated. The operator stops whenever resistance to motion is encountered and continues when the patient is relaxed. If the humerus has not reduced by the time 90 degrees of abduction and 90 degrees of external rotation have been reached, gentle longitudinal traction is applied along the humerus while the free hand is used to exert lateral and superior pressure on the humeral head to complete the maneuver. The effectiveness of this method has been attributed in part to more conical symmetry of the muscle forces acting across the glenohumeral joint (GHJ).
FARES[a]	A variation of the Milch technique called *FARES* (FAst, REliable, and Safe). FARES technique adds oscillation in a vertical direction while the affected arm is abducted. It is more effective, faster, and less painful than the traction/countertraction and Kocher methods.
Scapular manipulation[a]	Reduction is accomplished by repositioning the glenoid fossa rather than the humeral head. Manipulation can be combined with the other techniques, particularly Stimson or traction/countertraction. Apply traction (manual or hanging weights), and then manipulate the scapula by rotating the inferior tip medially and stabilizing the superior and medial edges with the opposite hand. This technique can also be used in a seated position in which a second operator applies traction in the forward horizontal position. Scapular manipulation can be difficult in obese patients, in whom it is difficult to palpate and grasp the inferior tip of the scapula (see Fig. 45.25).
Not recommended	Hippocratic method (traction with the foot in the axilla) and the Kocher maneuver (leverage, adduction, and internal rotation), are no longer recommended because of a high incidence of associated complications (axillary nerve injury, humeral shaft and neck fractures, capsular damage).

[a]This may also be attempted with minimal to no analgesia or sedation.

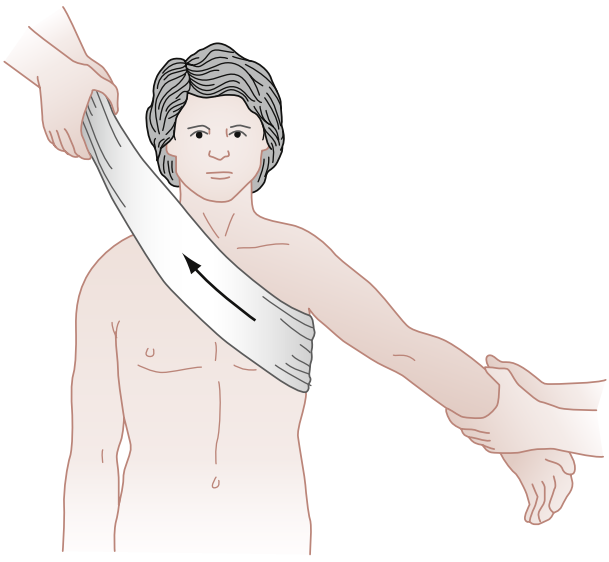

Fig. 45.23 Traction/countertraction method for reducing anterior shoulder dislocations.

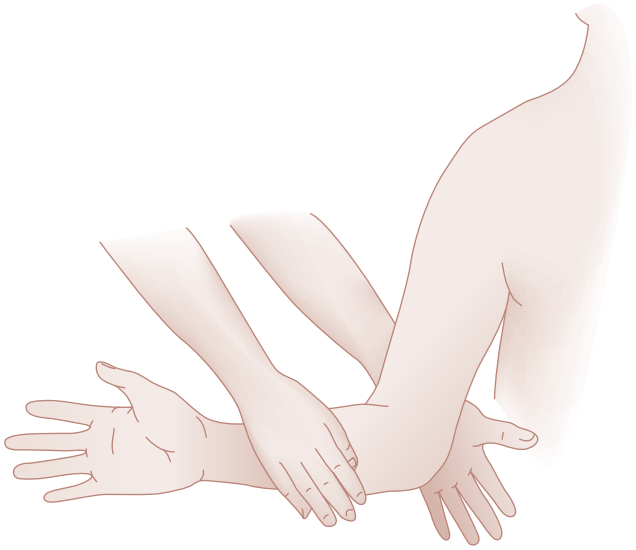

Fig. 45.24 External Rotation Technique for Reducing Anterior Shoulder Dislocations. The involved arm is slowly adducted to the patient's side, and the elbow is flexed 90 degrees. Gentle external rotation is applied to the forearm to achieve reduction. (From Simon RR, Koenigsknecht SJ. *Emergency orthopedics: the extremities*. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

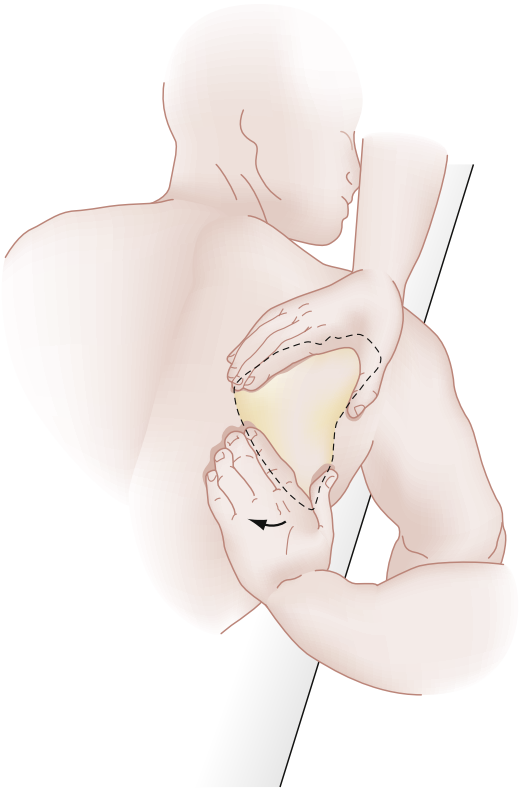

Fig. 45.25 Proper hand position and direction of rotation during shoulder relocation via the scapular manipulation technique. *Arrow indicates direction of applied force.* (From Kothari RU, Dronen SC. The scapular manipulation technique for the reduction of acute anterior shoulder dislocations. *J Emerg Med*. 1990;8:625.)

shoulder inferior to the acromion. The humeral head may be palpable posteriorly beneath the acromion process. Abduction is severely limited, external rotation is completely blocked, and restricted forearm supination may be present.

Posterior glenohumeral dislocations usually are associated with anteromedial impression fractures of the articular surface. A similar fracture of the posterolateral aspect of the humeral head is present with anterior dislocations (Hill-Sachs). Impression fractures involving more than 20% of the articular surface usually are unstable and require surgical repair post reduction.

Fractures of the glenoid rim, greater tuberosity, lesser tuberosity, and humeral head account for most associated injuries. The subscapularis muscle rarely may be avulsed from its insertion site on the lesser tuberosity. Neurovascular injuries are uncommon because the anterior location of the neurovascular bundle protects it from injury.

Differential diagnoses. Posterior glenohumeral subluxation is a much more common event than posterior glenohumeral dislocation and remains an important consideration in the evaluation of all patients. These patients are at risk of a posterior labral tear as a result of the trauma. Other important considerations include proximal humerus fracture, glenoid fracture, and rotator cuff strain or tear.

Diagnostic testing

Radiology. True or standard anteroposterior radiographs can appear deceptively normal with posterior dislocations. Radiographic features include loss of the half-moon elliptic overlap of the humeral head and glenoid fossa on a standard anteroposterior film. In addition, the distance between the anterior glenoid rim and the articular surface of the humeral head is increased (the *rim sign*). The humeral head is profiled in internal rotation and takes on a "lightbulb" or "drumstick" appearance (Fig. 45.26A). A true anteroposterior film shows abnormal overlap of the glenoid fossa with the humeral head (see Fig. 45.26B) and can be useful in visualizing an impaction fracture of the anteromedial humeral head (reverse Hill-Sachs deformity). This fracture may produce a curvilinear density on the frontal projection parallel to the articular cortex of the humeral head (the *trough sign*). An orthogonal view, such as a trans-scapular Y (see Fig. 45.26C), axillary lateral (see Fig. 45.26D), or apical oblique view, confirms the diagnosis. The axillary lateral view or apical oblique view also identifies associated fractures of the humeral head and posterior glenoid rim. If an adequate orthogonal view cannot be obtained, a shoulder CT scan should be considered. POCUS has also been used to diagnose posterior shoulder dislocations in the ED.

Management. Closed reduction may be attempted in the ED with procedural sedation. The technique incorporates internal rotation and lateral traction to dis-impact the humeral head from the glenoid rim. In the absence of humeral neck fracture or significantly engaged reverse Hill-Sachs lesion, the *Stimson technique* can also be used (see Table 45.3). If unsuccessful, reduction with the patient under general anesthesia is indicated. After reduction, the shoulder should be immobilized in a simple sling, or if available in an external rotation sling with slight abduction (with the use of a towel roll) until orthopedic follow-up in 1 to 2 weeks. Cases that were missed initially and manifest as chronic or "locked" posterior dislocations should be discussed with the orthopedist, because they often require semi-elective open reduction and internal fixation or arthroplasty.

Inferior Glenohumeral Dislocation (Luxatio Erecta)

Pathophysiology. *Luxatio erecta* is a rare type (<0.5%) of glenohumeral dislocation in which the superior aspect of the humeral head is forced

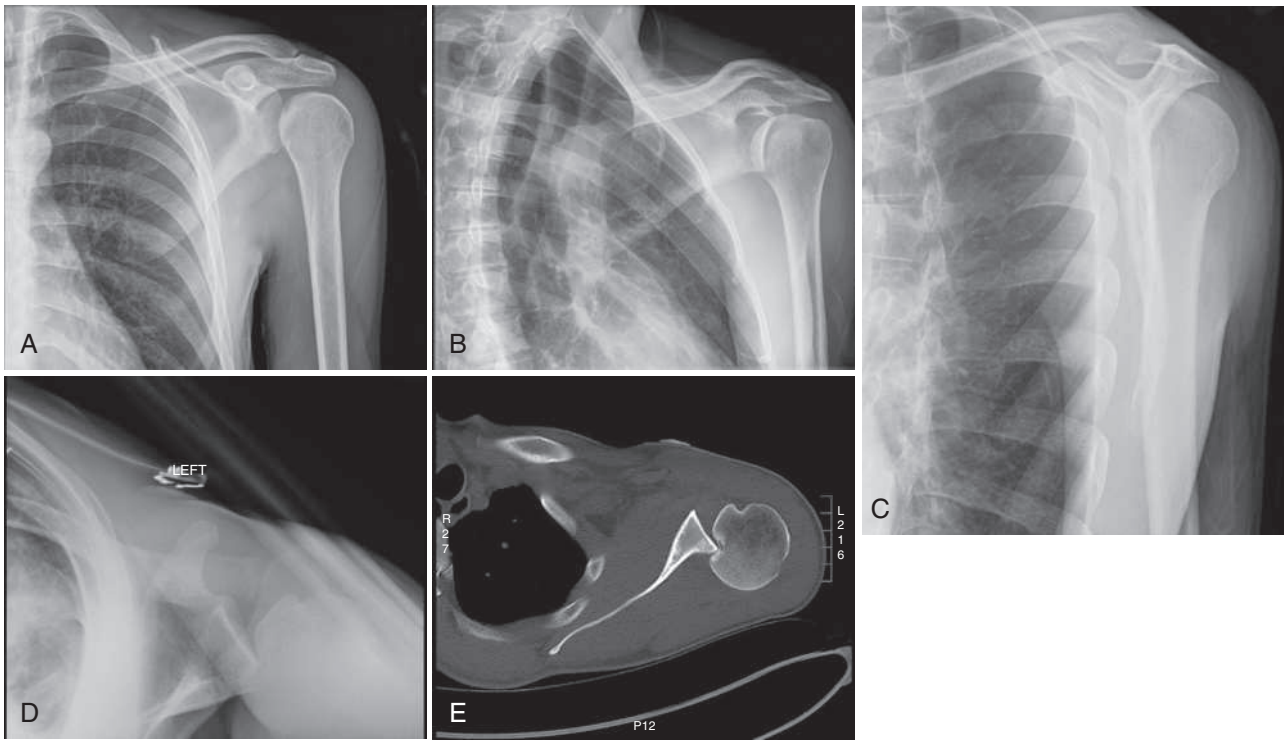

Fig. 45.26 Routine anteroposterior (A) radiograph of a posterior dislocation. Note the "lightbulb" or "drumstick" appearance of the humeral head while in internal rotation. True anteroposterior (Note the abnormal overlap of the glenoid rim and humeral head) (B) transscapular (C) and axillary (D) radiographic views of a posterior glenohumeral dislocation. Axial CT image showing locked posterior dislocation with reverse Hill-Sachs lesion (E).

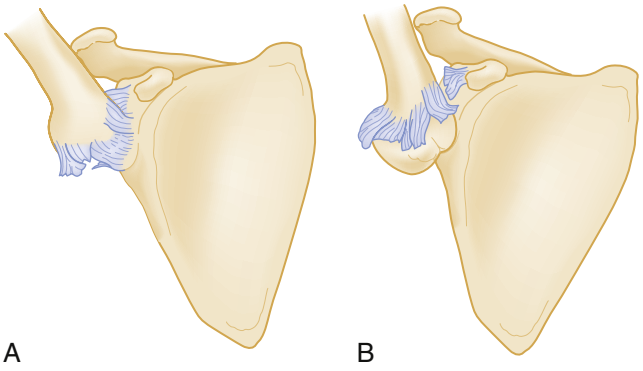

Fig. 45.27 Inferior Dislocation (Luxatio Erecta). (A) The mechanism by which this injury occurs in hyperabduction. (B) Leverage from impingement of the humeral shaft against the acromion ruptures the capsule and dislocates the head inferiorly. (From Simon RR, Koenigsknecht SJ. *Emergency orthopedics: the extremities*. 2nd ed. Norwalk, CT: Appleton & Lange; 1987.)

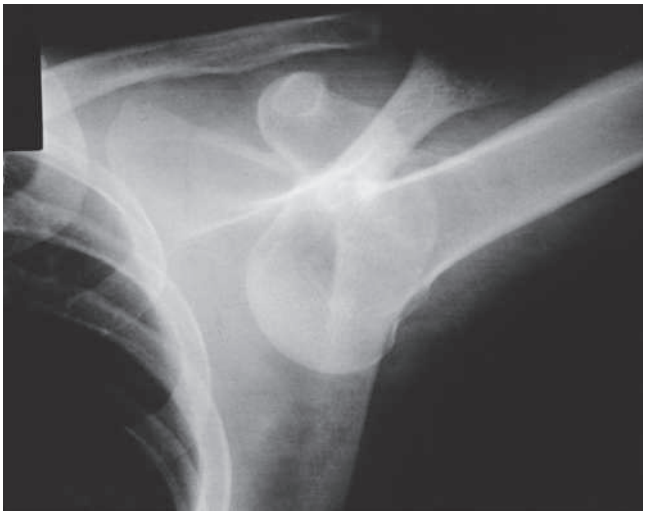

Fig. 45.28 Anteroposterior Radiographic View of an Inferior Glenohumeral Dislocation. The humeral shaft lies parallel to the spine of the scapula.

below the inferior rim of the glenoid fossa (Fig. 45.27). Application of a direct axial load to an abducted shoulder also can disrupt the weak inferior glenohumeral ligament and drive the humeral head downward.

Clinical features. Clinically, the patient has the arm locked overhead in 110 to 160 degrees of abduction. The elbow usually is flexed, and the forearm typically rests on top of the head. The shoulder is fixed in this position. The inferiorly displaced humeral head may be palpable along the lateral chest wall. A thorough neurovascular examination is essential to evaluate for associated injuries. Neurapraxic lesions of the brachial plexus are common, and thrombosis of the axillary artery has been reported. Other associated injuries include tears of the rotator cuff, damage to the glenoid labrum, and avulsion fractures of the greater tuberosity.[29]

Differential diagnoses. Luxatio erectae dislocations are easily mistaken, diagnosed, and treated as subglenoid anterior dislocations, because the radiographic features are remarkably similar.

Diagnostic testing

Radiology. Standard radiographs show the superior articular surface inferior to the glenoid fossa (Fig. 45.28). In addition, the

humeral shaft characteristically lies parallel to the spine of the scapula on the anteroposterior view. This radiographic feature is useful in distinguishing luxatio erecta from a subglenoid anterior dislocation; in the latter, the humeral shaft lies parallel to the chest wall. Associated fractures of the acromion, coracoid, clavicle, greater tuberosity, humeral head, and glenoid rim are common.

Management. Reduction usually can be accomplished by traction/countertraction maneuvers (Fig. 45.29) under procedural sedation. Regional anesthesia in the form of an ultrasound-guided interscalene block can also facilitate reduction. Multiple attempts may be necessary; occasionally, "buttonholing" of the capsule will prevent closed reduction, necessitating an orthopedic consultation for open reduction. An alternative approach is the two-step closed reduction maneuver in which the inferior dislocation is first converted into an anterior dislocation before being reduced.

Scapulothoracic Dissociation

Foundations. Scapulothoracic dissociation is a rare and severe injury characterized by complete disruption of the scapulothoracic articulation and may be thought of as a partial or complete closed internal forequarter amputation of the upper extremity. Mechanism of injury involves a sudden traction force to the body while the arm remains fixed or a high energy distracting force directed over the shoulder. Approximately half of the reported cases involve motorcycle accidents, with the injury occurring when the motorcyclist hangs onto the handlebars while the body is forced away.

Clinical features. Because most patients present with significant concomitant trauma, the dislocation may not be initially recognized. Massive local soft tissue swelling of the shoulder, clavicle distraction, and more than 1 cm of lateral displacement of the scapula on the anteroposterior chest radiograph is considered pathognomonic (Fig. 45.30). Clavicle distraction injuries include acromioclavicular separation, displaced fractures of the clavicle, and dislocations of the SCJ. Vascular lesions (subclavian, axillary, or brachial vessels) have been reported in 65% to 100% of patients and severe neurologic injuries in 95%. Acute limb ischemia is rare because of the extensive collateral network in the shoulder. Outcomes generally are poor, with death in 10% of cases and a flail anesthetic upper extremity in complete brachial plexus injuries often requiring above-elbow amputation.

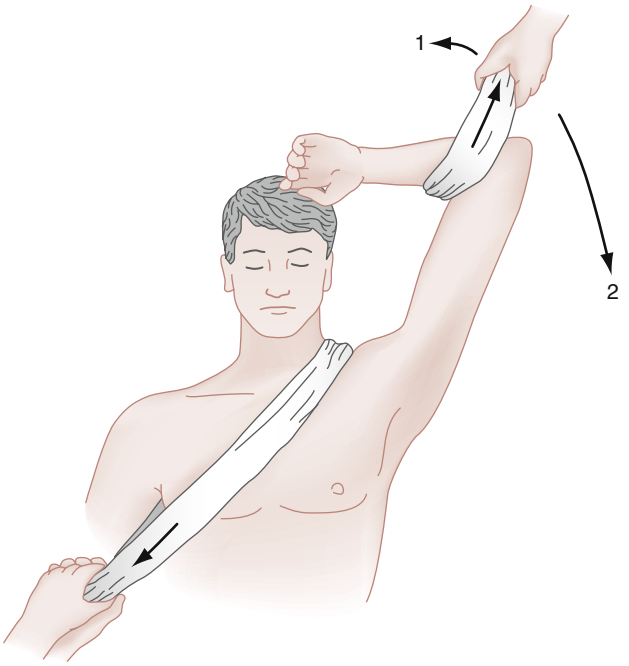

Fig. 45.29 Traction/Countertraction Method for Reduction of Luxatio Erecta Humeri. *Arrows indicate direction of applied force and relevant movement.* The initial maneuver (1) includes steady axial traction in line with the humeral shaft position, followed by gentle abduction. This reduces the glenohumeral dislocation. At this point (2), the arm is brought down to a position of adduction and internal rotation. (Redrawn from Davids JR, Talbott RD. Luxatio erecta humeri: a case report. *Clin Orthop Relat Res.* 1990;252:144.)

Differential diagnoses. Scapulothoracic disassociation is the result of a significant forceful movement and evaluation for concurrent neurovascular injuries is paramount to prevent secondary neurovascular complications. Alternative injuries that can result from a similar mechanism include brachial plexus injury, glenohumeral dislocation, scapular fracture, proximal humerus fracture, and AC joint dislocation.

Diagnostic testing. Vascular and neurologic injuries can be confirmed through emergent CT angiography and MRI.[30]

Management. Identification is a critical step in the management of this injury. Rarely occurring in isolation, these dislocations will typically require consultation with a trauma surgeon for ongoing management of multiple traumatic injuries. Additionally, in the case of a suspected vascular injury, early consultation with a vascular surgeon is necessary to prevent ischemic complications. There is no clear consensus regarding the timing of osseous stabilization or optimal management of nerve injuries. The complexity of the injury requires a decision tailored to the patient. It is recommended that early consultation with a trauma surgeon be initiated to help guide patient-specific decisions.

Soft Tissue Conditions

Impingement Syndrome

Foundations. Impingement syndrome of the subacromial space occurs across a wide spectrum of the population from the young adult overhead throwing athlete to the older adult performing repetitive daily activities. This exists as a pathophysiologic continuum from rotator cuff tendinopathy and subacromial bursitis to the endpoint of rotator cuff rupture. The subacromial space is the area between the coracoacromial arch and the greater tuberosity of the humerus. This space, which is only a few millimeters wide, contains the long head of the biceps, the rotator cuff, and the subacromial bursa. The bursa provides the gliding mechanism between the musculotendinous cuff and the coracoacromial arch. Impingement can occur during shoulder forward flexion, between 60 and 120 degrees of abduction and in the extremes of adduction. The critical wear from impingement is centered on the supraspinatus tendon, near its insertion on the greater tuberosity. Narrowing of the subacromial space (due to anatomic variants of anterior acromion) and occupations that require excessive overhead activity accelerate the entire process resulting in rotator cuff tendinitis. With time, the inflammatory reaction spreads to involve the adjacent bursa. This inflammation leads to edema, thickening, and fibrosis, further narrowing the subacromial space (secondary impingement) eventually followed by attritional changes within the rotator cuff. Because the rotator cuff is a primary humeral head depressor, loss of function worsens secondary impingement.

The impingement process also may involve the long head of the biceps. In such cases, bicipital tendinitis, degeneration, or rupture may also be present. Impingement in this context occurs at 120 to 180 degrees of abduction (Fig. 45.31).

Clinical features. The spectrum of illness is marked by a progression of symptoms. Initially patients report a dull ache around the deltoid area after strenuous activity. The inflammatory process within the bursa and tendons leads to the formation of minor adhesions. Disruption of these

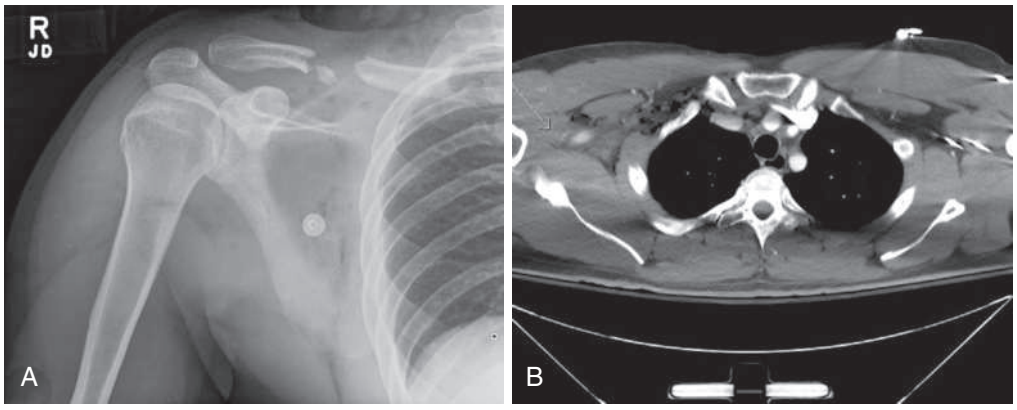

Fig. 45.30 Scapulothoracic dissociation with associated clavicle fracture (A) and computed tomography (CT) scan of associated axillary artery injury *(arrow)* (B).

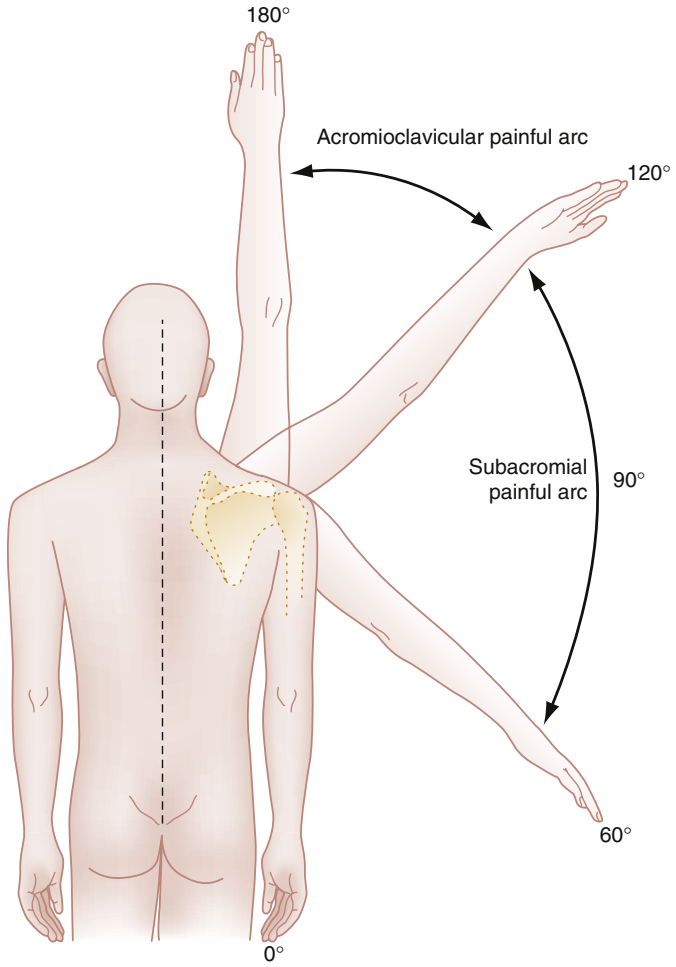

Fig. 45.31 Arcs of painful abduction: subacromial painful arc, 60 to 120 degrees; acromioclavicular painful arc, 120 to 180 degrees. (From DePalma AF. *Surgery of the shoulder*. 3rd ed. Philadelphia: JB Lippincott; 1983.)

adhesions is thought to account for the pain becoming more persistent and particularly severe at night. Significant tendon degeneration can lead to tears in the rotator cuff.

On examination, tenderness can be elicited over the supraspinatus and anterior acromion. A painful arc of abduction at 60 to 120 degrees (see Fig. 45.31) has a sensitivity and specificity of approximately 50% and 75%, respectively. The Hawkins-Kennedy impingement sign (arm placed into 90 degrees of forward flexion followed by internal rotation), has a sensitivity and specificity of 80% and 60%, respectively.

Differential diagnoses. People presenting with vague shoulder pain localizing to lateral shoulder that is worse with movement may have impingement syndrome; however, alternative diagnoses include: rotator cuff tendinopathy, RC tear, calcific tendinopathy, and glenohumeral osteoarthritis.

Diagnostic testing. POCUS can show thickening of the supraspinatus tendon and associated fluid in the subacromial bursa.[31]

Management. Initial treatment for impingement syndrome is conservative and consists of rest, simple analgesia using acetaminophen or analgesic doses of nonsteroidal antiinflammatory drugs (NSAIDs), and modification of activities that produce pain. Radiographs may help to evaluate for bony abnormality but are not necessary in the evaluation and management of impingement syndrome. Diagnostic ultrasound can confirm chronic changes in the supraspinatus as sequelae of this disease and may be performed in the hands of an experienced sonographer. Cross-sectional imaging is not indicated in the ED. Patients should be advised to seek primary care follow-up if not better within 1 to 2 weeks for consideration of physical therapy to maintain range of motion and strengthen the rotator cuff. Subacromial decompression for treatment refractory disease is controversial and may not provide additional benefit over physical therapy alone.[32]

Rotator Cuff Tears

Foundations. The rotator cuff acts as a dynamic stabilizer of the GHJ. Its primary function is to hold the humeral head in place throughout the full range of rotational motion (see Fig. 45.5). The infraspinatus and teres minor act as external rotators, whereas the subscapularis is an internal rotator. The supraspinatus assists initiation of shoulder abduction.

The tenuous blood supply of the rotator cuff, abusive tensile overload, and chronic wear of the supraspinatus under the coracoacromial arch predispose it to age-related degenerative changes and impingement. The advanced stage of this process is characterized by complete rupture.

Rotator cuff tears typically involve the dominant arm and occur in men over 40 years old. The occupational history is significant for strenuous overhead work activity.[33] Tears can be classified according to their chronicity, size, completeness, and pattern location. Acute tears (10%) usually are associated with a specific traumatic event. The most common mechanism of injury is forced abduction associated with significant resistance; this usually occurs when the patient attempts to break a fall with an outstretched hand.

Clinical features. With acute tears, patients report a sudden tearing sensation in the shoulder followed by severe pain that radiates into the lateral arm. Pain and muscle spasm limit shoulder motion in the acute setting. Physical findings depend on the completeness, size, and location of the tear. Point tenderness is usually present over the site of rupture (greater tuberosity). A discrepancy between active and passive range of motion is highly suggestive of a complete rotator cuff tear. Additionally, weakness or pain in the plane of motion of the affected rotator cuff tendon is suggestive of a tear. The acute pain resulting from hemorrhage and spasm subsides over a few days at which point a repeat exam will confirm the loss of function with significant tears.

Chronic tears account for approximately 90% of all lesions. Chronic tears are attritional and more insidious in their presentation. Early findings include the painful arc sign, as a result of secondary impingement of the supraspinatus in the subacromial space. The pain is often worse at night and interferes with sleep. Worsening pain is followed by the gradual onset of weakness in the arm. Flexion and abduction are affected with involvement of the supraspinatus. The patient attempts to initiate abduction with scapulothoracic movement. A tear in the subscapularis tendon causes pain or weakens internal rotation. A tear in the teres minor or infraspinatus compromises external rotation.

Differential diagnoses. Rotator cuff tears are rarely acute traumatic injuries. In the evaluation of a suspected chronic rotator cuff tear alternative considerations include impingement syndrome, rotator cuff tendinopathy, biceps tendinopathy, AC or GH joint osteoarthritis.

Diagnostic testing

Radiology. Plain radiographs likely will be normal in acute or chronic tears and are not generally indicated.[34] If obtained, they may show nonspecific degenerative changes within the GHJ and subacromial space. The hallmark of a complete tear is superior displacement of the humeral head best seen on an external rotation view. Outpatient ultrasound examination, MRI, or an MRI arthrogram can confirm the diagnosis. POCUS appears to be an excellent initial screening test for the detection of partial- and full-thickness rotator cuff tears (Fig. 45.32). When compared to MRI, POCUS by a trained clinician has similar diagnostic accuracy for full thickness tears.[35]

Management. Acute tears should be immobilized in a sling for comfort and the patient referred for orthopedic follow-up within 1 to 2 weeks. Early surgical repair (before 4 months) is preferred in young or active individuals.[36,37] The management of chronic tears includes pain control and a shoulder rehabilitation program. Orthopedic or sports medicine follow-up care may be needed as patients with persistent pain and weakness may require surgical management.

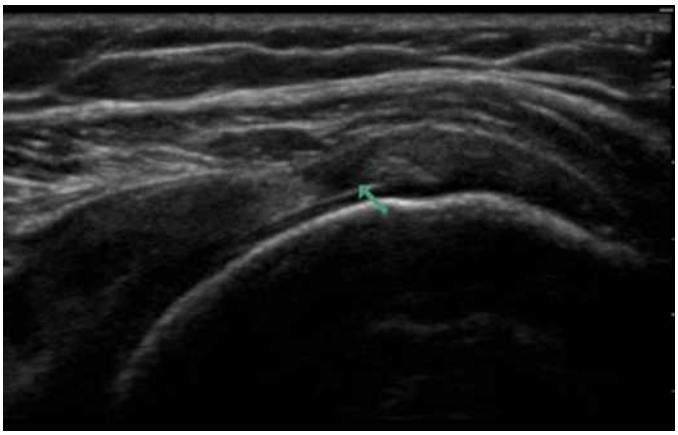

Fig. 45.32 Bedside ultrasound image of a rotator cuff a full-thickness rotator cuff tendon tear. The *arrow* points at the full thickness discontinuity of the tendon. Note the anechoic fluid that extends from the bursal to the articular surface. (Courtesy Ryan Petering, MD.)

Lesions of the Biceps Muscle

The biceps muscle is composed of two heads. The long head originates from the supraglenoid tubercle and glenoid labrum and ascends over the humeral head to enter the arm by way of the bicipital groove. The long head is covered by a synovial sheath and is held in place within the groove by the coracohumeral and transverse humeral ligaments.[1] The short head of the biceps originates from the coracoid process and inserts with the long head onto the radial tuberosity. The biceps muscle is responsible for flexion as well as supination at the elbow and serves as a stabilizer for the GHJ.

Bicipital Tendinitis

Pathophysiology. Anatomically, the long head of the biceps is subject to the same stresses as those incurred by the rotator cuff within the subacromial space. Irritation and microtrauma as a result of repetitive elevation or abduction of the shoulder produce an inflammatory reaction within the synovial sheath. Bicipital tendinitis is often associated with other impingement conditions.[38] Primary bicipital tendinitis (inflammation without other underlying pathology) is rare and affects younger individuals.

The typical patient is middle-aged and involved in an occupation or recreational activity that requires repetitive overhead movement. The pain localizes to the anterior part of the shoulder along the bicipital groove. There is usually no history of trauma. Abduction and external rotation in particular are painful. Pain is worse at night and may interfere with sleep.

Clinical features. On examination, point tenderness can be elicited over the biceps tendon as it passes through the bicipital groove. This is best shown with the arm in 10 degrees of internal rotation. Active range of motion is limited by pain, but the passive range remains intact. Supination against resistance *(Yergason test)* with the arm adducted and the elbow flexed to 90 degrees reproduces the pain in 50% of cases. Another provocative test is the biceps resistance test (*Speed's test*), in which forward flexion of the shoulder (elbow extended and forearm supinated) carried out against resistance produces pain in the bicipital groove. The specificity of these tests is limited in the presence of impingement and rotator cuff disease.

Differential diagnoses. The differential diagnosis of insidious onset anterior shoulder pain includes proximal biceps tendon tear, rotator cuff tear, rotator cuff tendinopathy, labrum tear, subluxing biceps tendon, and ACJ or GHJ osteoarthritis.

Diagnostic testing

Radiology. Radiographs are usually normal and not indicated unless fracture or dislocation is suspected. If obtained, they may show evidence of subacromial space impingement by associated acromioclavicular arthritis and osteophytic spurs. The preferred imaging modality is ultrasound or MRI. Ultrasound has been found to be excellent in diagnosing complete rupture, subluxation or dislocation, but is less sensitive for partial tears.

Management. Emergency treatment consists of rest (sling for comfort), ice, and oral analgesia. Gentle exercises are encouraged as symptoms subside. Although the bicipital sheath can be injected by landmarks with a corticosteroid preparation, the procedure is technically difficult, and inadvertent direct tendon injection can lead to tendon rupture. Referral to a sports medicine specialist in 1 to 2 weeks is appropriate if injection-based therapy is a consideration. Surgery may be necessary in patients who fail to respond to conservative therapy.

Ruptures of the Biceps Tendon

Foundations. Ruptures of the biceps tendon can be classified into proximal and distal types. Distal ruptures are rare (estimated to have an annual incidence of 2.55 per 100,000) and are not discussed here.[39]

Microtears and other age-related attritional changes within the long head predispose it to rupture. The rupture can be spontaneous or follow a traumatic event involving either forced extension or resisted supination and flexion.

Clinical features. The classic history of an acute rupture is that of a sudden snap or pop, followed by pain and ecchymosis along the arm. Recent fluoroquinolone or oral steroid use increases the risk of tendon rupture. With a complete rupture, distal retraction of the muscle results in a "Popeye" musculature appearance of the arm. A difference in muscle contour *(Ludington sign)* also may be seen when both arms are placed behind the head and the biceps muscles are contracted. Functionally, forearm supination is weakened, but elbow flexion stays strong because the coracobrachialis and short head of the biceps remain intact. Most bicep tendon ruptures are associated with rotator cuff disease.[40]

Differential diagnoses. Alternative differential considerations for anterior shoulder pain after an acute pop include: subluxing bicep tendon, rotator cuff tendon tear, glenohumeral dislocation, and labrum tear.

Diagnostic testing

Radiology. Radiographic findings usually are unremarkable, and the confirmatory test of choice is MRI. POCUS can be used to identify presence or absence of tendon in bicipital groove, and fluid collection within the sheath.

Management. The injured arm should be immobilized in a sling with the elbow in 90 degrees of flexion. The patient should be referred to an orthopedist or sports medicine specialist for further evaluation in one week. Surgical repair is a consideration in young, active persons. Conservative therapy (range-of-motion and strengthening exercise) is also an option as the intact short head of the bicep provides adequate function and strength. In older patients, this is preferred because the cosmetic deformity is minimal and functional loss minimal.

Calcific Tendinitis

Foundations. Shoulder calcific tendinitis affects up to 10% of the population and frequently is encountered in the ED. The condition affects people aged 40 to 60 years old and is painful in 65% of patients. Calcific deposits occur primarily in the supraspinatus tendon near its attachment to the greater tuberosity. Women are more often affected than men and 10% to 20% of the patients have bilateral deposits.

Clinical features. The clinical presentation can be divided into silent, subacute, and acute phases based on the physical characteristics of the calcific deposits and the nature of the inflammatory response. The *painful arc syndrome* (see Fig. 45.31) is a hallmark of the subacute phase of calcific tendinitis. Enlargement and softening of the deposit lead to narrowing of the subacromial space, resulting in impingement under the acromial arch.

A severe inflammatory reaction within and around the deposit produces the acute phase of calcific tendinitis. Often there is a precipitating history of atraumatic repetitive motion (e.g., swinging a tennis racket). The patient is in severe pain and holds the arm close to the chest. Active and passive range of motion is severely limited. Examination findings will be similar to those with shoulder impingement syndrome. Severe pain is related to increased intra-tendinous pressure, and spontaneous rupture of the deposit into the subacromial bursa may be associated with dramatic relief of symptoms.

Differential diagnoses. The clinical presentation of symptomatic calcific tendinopathy can be similar to that of rotator cuff tendinopathy, rotator cuff tendon tear, impingement syndrome, and osteoarthritis of the AC or GH joints.

Diagnostic testing

Radiology. Radiographs show calcific deposits in the involved tendon (Fig. 45.33). POCUS can identify and effectively localize calcific deposits (Fig. 45.34).

Management. The acute phase should be treated with a sling for comfort, NSAIDs, and avoidance of offending activities. Refer patients to primary care or sports medicine clinic in 1 to 2 weeks, because they may benefit from subacromial bursa steroid injections, or needle lavage procedures. The subacromial injection of anesthetic with corticosteroids for calcific tendinitis may give targeted relief (steroids take 1 to 3 days to take effect). With an experienced outpatient provider, patients may also be candidates for needle lavage (careful targeted puncturing of the calcific deposits to decrease intra-tendinous pressure) under ultrasound or fluoroscopy guidance. Minimally invasive surgical intervention may be helpful for refractory symptoms.[41] Early shoulder range-of-motion exercises are encouraged in all patients to minimize the risk of adhesive capsulitis.

Adhesive Capsulitis

Foundations. Adhesive capsulitis ("frozen shoulder") is a specific diagnostic entity characterized by an idiopathic inflammatory reaction within the capsule and synovium of the GHJ. Subsequent adhesion formation within the capsule leads to restricted active and passive range of motion. Adhesive capsulitis should be differentiated from other, more common causes of the painful stiff shoulder (e.g., calcific tendinitis, rotator cuff syndrome, osteoarthritis, or trauma), which also may be associated with decreased range of motion. Any condition associated with prolonged disuse of the arm can result in capsular contraction, including immobilization for painful intrinsic shoulder

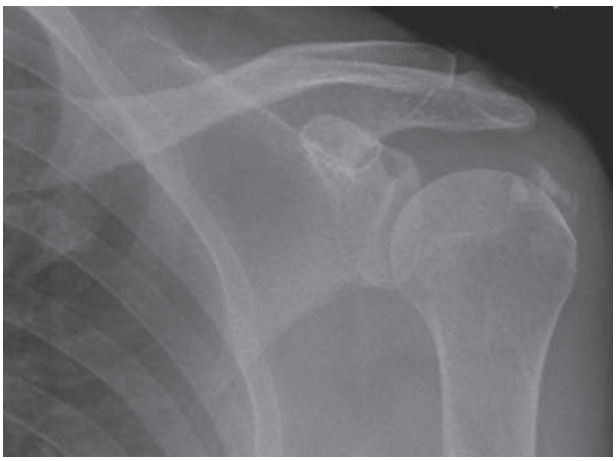

Fig. 45.33 Radiograph with Rotator Cuff Calcific Tendinitis. Note abnormal calcification near greater tuberosity.

Fig. 45.34 Ultrasound image of rotator cuff calcific deposit *(arrow)* within subscapularis tendon. (Courtesy Ryan Petering, MD.)

conditions or use of a sling in healthy uninjured shoulders such as after a mastectomy or a distal upper extremity injury (e.g., Colles fracture).

Clinical features. Risk factors for developing adhesive capsulitis include female sex, age between 40 and 60 years old, thyroid disease, and diabetes mellitus.[42–44] The nondominant arm usually is affected and the patient has trouble with the activities of daily living. The pain is typically most severe at night and localized over the deltoid area. As the condition progresses, there is uniform limitation of all glenohumeral movement. On passive testing of external rotation, a sense of mechanical restriction of joint motion can be appreciated. Shoulder radiographs usually are normal in appearance if no associated pathologic condition is present.

Differential diagnoses. Asymmetric limitations in passive and active range of motion are hallmarks of adhesive capsulitis. Other causes of limited passive and active range of motion include chronic dislocations, in particular external rotation limitation is apparent in both adhesive capsulitis and chronic posterior glenohumeral dislocation. Other considerations include GH joint osteoarthritis and rotator cuff pathology.

Diagnostic testing. The diagnosis of adhesive capsulitis is typically made based on a clinical exam and history alone. Radiographs are helpful to evaluate for alternative diagnoses such as osteoarthritis or a missed dislocation. There are characteristic findings on MRI of adhesive capsulitis; however, this imaging modality is rarely needed to make the diagnosis and is not indicated in the ED setting.

Management. The best form of therapy is preventive in nature. Prolonged shoulder immobilization is to be avoided, and early motion encouraged (see Fig. 45.10). Treatment of adhesive capsulitis in the ED consists of NSAIDs and referral to a sports medicine provider or orthopedic surgeon within one to two weeks. Initial therapy is conservative and consists of a gentle assisted exercise program along with an intra-articular steroid injection.[45,46] Surgical treatment, including manipulation under anesthesia and arthroscopic capsular release, is reserved for patients who fail to improve with nonoperative treatment.

Injection Therapy

The local injection of corticosteroid preparations has long been used in many painful conditions that affect the shoulder, including rotator cuff tendinitis, subacromial bursitis, calcific tendonitis and adhesive capsulitis. Ultrasound guidance for subacromial injection has improved accuracy. Although advocated for relieving the inflammatory reaction, corticosteroid injections in general do not alter the underlying disease process, and there is no evidence that they are superior to short courses of antiinflammatory doses of NSAIDs. Systemic complications are rare after local injection therapy, although patients with diabetes mellitus may experience elevated glucose levels. Site-specific complications include articular cartilage damage, tendon weakening or rupture, and subcutaneous atrophy resulting in localized skin pigment changes. Direct tendon injection is particular hazardous and is associated with increased risk of tendon rupture. Corticosteroid injection treatments generally can be deferred to outpatient providers (primary care, sports medicine, or orthopedic specialists).

CHAPTER 45: QUESTIONS AND ANSWERS

1. A 27-year-old male unrestrained driver is involved in a high speed motor vehicle collision (MVC) with direct impact of the steering wheel into his anterior chest wall. Which shoulder girdle injury represents a true orthopedic emergency?
- **a.** Anterior glenohumeral dislocation
- **b.** Anterior sternoclavicular dislocation
- **c.** Posterior glenohumeral dislocation
- **d.** Posterior sternoclavicular dislocation

Answer: d. Posterior sternoclavicular dislocations can be associated with life-threatening injuries within the superior mediastinum and intrathoracic cavity; therefore, they are considered true orthopedic emergencies and should be reduced expeditiously. Reported complications associated with posterior sternoclavicular dislocations include compression or lacerations of the great vessels, tracheal compression, pneumothorax, thoracic outlet syndrome, tracheoesophageal fistula, and injury to the brachial plexus.

2. A 30-year-old patient presents complaining of right shoulder pain and limited range of motion. On physical examination, you note that the shoulder has a "squared off" appearance and is held in abduction and external rotation. The patient is unable to adduct the arm or internally rotate without severe pain. What is the best way to manage this patient without the aid of other emergency department (ED) personnel?
- **a.** Hippocratic method
- **b.** Kocher maneuver
- **c.** Milch technique
- **d.** Traction/countertraction method

Answer: c. The ideal method for reduction of an anterior shoulder dislocation should be simple, quick, and effective; require little assistance; and cause no additional injury to the shoulder. It is wise to be familiar with several techniques of reduction because none is uniformly successful. The Milch technique (see Table 45.3) allows for reduction by a single practitioner, and it can be attempted without procedural sedation. Older techniques, such as the Hippocratic method (traction with the foot in the axilla) and the Kocher maneuver (leverage, adduction, and internal rotation), are no longer recommended because of a high incidence of associated complications (axillary nerve injury, humeral shaft and neck fractures, and capsular damage). Traction/countertraction requires two people to reduce the shoulder (see Table 45.3).

3. A 19-year-old skateboarder presents to the emergency department (ED) complaining of left shoulder pain with his left arm in adduction and supporting the elbow with his right hand. An obvious clavicular defect is palpable on exam. Urgent orthopedic consultation is recommended for which type of clavicle fracture?
- **a.** Minimally displaced midclavicular fracture
- **b.** Type I lateral clavicle fracture
- **c.** Type II lateral clavicle fracture
- **d.** Type III lateral clavicle fracture

Answer: c. Type I lateral clavicle fractures are stable and minimally displaced because the coracoclavicular ligaments are intact. Type II fractures are associated with a torn coracoclavicular ligament and have a tendency to displace because the proximal fragment lacks any stabilizing forces. Type III injuries involve the articular surface. More urgent orthopedic consultation (before 72 hours) is recommended for type II lateral clavicle fractures, because these fractures have up to a 30% incidence of nonunion and may benefit from surgical repair.

4. A 75-year-old right-handed woman presents to the emergency department (ED) after sustaining a ground level fall onto an outstretched right arm. She is holding her right arm in adduction and supporting the weight of the arm with her left hand. On examination she does not have an obvious palpable defect but there is significant pain in her shoulder with any attempt to move her arm. She has intact lateral deltoid sensation and full symmetric radial pulses. The x-ray demonstrates a proximal humerus fracture with minimal displacement. Which of the following is the most appropriate next step in care?
- **a.** Emergent orthopedic consultation for operative repair
- **b.** Pain control, immobilization, and discharge with outpatient follow-up with orthopedics
- **c.** Orthopedics consultation for outpatient surgical repair after resolution of swelling
- **d.** Emergent vascular surgery consult due to high risk of associated vascular injury

Answer: b. Proximal humerus fractures with minimal displacement respond well to conservative care. Patients may begin physical therapy as soon as one week after the fracture. Surgical repair is rarely indicated for minimally displaced fractures, hence answers (a) and (c) are incorrect. She has good radial pulses and these fractures are not commonly associated with secondary vascular injury.

5. A 30-year-old recreational basketball player presents after an awkward fall onto an outstretched left arm during a pickup basketball game with severe left shoulder pain. He is supporting his left elbow with his right hand and refuses to move his arm due to pain. There is a dimple inferior to the acromion and diffuse pain with palpation throughout his shoulder. There is no evidence of neurovascular injury. True and standard AP radiographs do not show any fracture or obvious dislocation. The technician was unable to obtain an axillary lateral due to significant pain with abduction. Which of the following is the next best step?
- **a.** Obtain modified axillary lateral or trans-scapular Y view radiograph
- **b.** Upper extremity CT with intravenous contrast
- **c.** Discharge with outpatient follow-up with primary care
- **d.** Refer to orthopedics for likely complete supraspinatus tear

Answer: a. Posterior dislocations glenohumeral dislocations are uncommon but cannot be excluded with a true orthogonal view. Options to consider in this patient include a modified axillary lateral, apical oblique, or transscapular Y view. A missed posterior dislocation can result in a locked posterior dislocation requiring orthopedic intervention under general anesthesia. If there is a high clinical suspicion, a non-contrast shoulder CT scan can reveal the diagnosis; however, the most appropriate next step would be to obtain orthogonal views. Contrast is only necessary if there is suspicion for an associated vascular injury which is uncommon with posterior GH dislocations. Although an acute rotator cuff tear can present similarly, this patient has had incomplete radiographic imaging and therefore a diagnosis of rotator cuff tear represents premature closure.

46

Pelvic Injuries

Michael C. Bond and Michael K. Abraham

KEY CONCEPTS

- The most serious pelvic ring injuries caused by high-energy impact are (1) anteroposterior compression fractures ("open-book" fracture), (2) vertical shear fractures, and (3) fractures involving significant displacement. These injuries are associated with major blood loss and transfusion requirements.
- Pelvic fractures are a marker for serious injury to other organ systems. The vast majority of patients who die after sustaining a pelvic fracture have multiple trauma.
- Careful examination of the perineum and buttocks, as well as digital rectal and vaginal examinations, are necessary to diagnose open fractures and expanding hematomas.
- Computed tomography (CT) is the imaging test of choice to diagnose pelvic fracture and concurrent intra-abdominal injuries for patients stable enough to undergo imaging. CT aids in establishing surgical priorities and planning of definitive orthopedic care.
- There is an increasing incidence of low-energy (e.g., fall from standing) pelvic fractures in older patients which often are managed medically due to multiple co-morbidities and poor bone quality that would make an anatomic reduction difficult to obtain.
- Fragility pelvic fractures in older patients often involve the anterior column of the acetabulum, are more comminuted, and result in severe impaction of the femur head.
- In the hemodynamically unstable patient who cannot undergo CT imaging, the anteroposterior radiograph usually reveals serious pelvic fractures that cause major pelvic bleeding, which is sufficient information to undertake pelvic stabilization.
- The combination of posterior arch fracture plus hypotension is associated with a mortality rate of approximately 50%.
- Early fluid resuscitation with blood products in a 1:1:1 ratio (packed red blood cells: platelets: fresh frozen plasma) is recommended for unstable patients suspected of having active pelvic bleeding.
- Trauma hospitals should have institutional guidelines and mechanisms to facilitate early decisions regarding treatment for pelvic hemorrhage. Treatment options include angiography and embolization, pelvic packing, invasive fixation, or a combination of these.
- Unstable patients with a positive focused assessment with sonography in trauma (FAST) and a pelvic fracture should be treated with laparotomy with pelvic stabilization and possible pelvic packing, followed by angiography.
- Unstable patients with a negative FAST and a pelvic fracture should be treated with pelvic stabilization (such as a pelvic binder) and angiography, and then a repeat FAST and laparotomy if they remain unstable.
- "Open-book" pelvis fractures should be internally compressed with a pelvic binder or sheet to reduce the size of the pelvis, unless the fracture forces have already internally rotated the hemi-pelvis. In this case, further internal compression may cause an increase in the pelvic diameter.
- Patients with pelvic fractures are at high risk for subsequent deep venous thrombosis (DVT), despite the use of mechanical and chemical thromboprophylaxis.

FOUNDATIONS

Background and Importance

Patients with traumatic **pelvic** ring injury are challenging for the emergency care provider. Pelvic ring **fracture**s present significant risk for exsanguinating pelvic **hemorrhage** caused by the extreme magnitude of force required to disrupt the pelvic ring. This frequently causes tearing of fragile pelvic veins and severe injuries to other organs. Prompt stabilization of pelvic fractures, rapid identification of other major injuries and sites of blood loss, and coordination of definitive angiographic and surgical treatments are the necessary steps to help avoid the development of hemorrhagic shock.

The majority of high-energy pelvic ring injuries are caused by motor vehicle collisions (MVCs), motorcycle crashes, pedestrians being struck by motor vehicles, and falls from a height. With the aging population, an increase in low-energy **fragility** fractures has also been noted. A nationwide inpatient sample from the United States showed a 24% increase in fragility pelvic fractures from 1993 to 2010.[1] A Finnish study showed a quadruple increase in the incidence of pelvic fractures in the elderly, typically from low energy trauma (such as a fall from standing) from 1970 to 2013.[2] Overall, the percentage of pelvic and **acetabular** fractures has been significantly increasing at U.S. level 1 trauma centers (1995 to 1999 32.7% of fractures; 2008 to 2012 39.9% of fractures).[3]

Mortality of patients with pelvic fracture ranges between 5% and 30% in studies of large cohorts of trauma patients. The presence of a pelvic fracture has been consistently shown to be an independent risk factor for death. In a study using multivariable analysis, however, pelvic factures were not associated with an increased 30-day mortality when it was adjusted for age, Injury Severity Score (ISS), American Society of Anesthesiologists (ASA) physical status classification score, Glasgow Coma Score (GCS), and shock.[4] Overall mortality rates appear to be improving. An investigation analyzing 22 years of pelvic registry data showed that hospital mortality decreased by one-third (from 9.3% to 3.8%) despite increasing median ISS scores.[5] Male patients showed a significantly higher mortality than female patients, as well as a higher median ISS, while the mortality rates of patients aged greater than 80 years did not significantly differ from those aged greater than 60 or 70 years.[5] Obesity has also been shown to be an independent risk factor of morbidity and mortality, and the incidence of pelvic fractures is higher in the obese when compared to those with a normal body habitus.[6]

Mortality rates for older patients with hip fractures, hip contusions and pelvic fractures were comparable during the hospital stay and at follow-up 4 and 12 months later. Retrospective studies of older patients with low-energy pelvic fractures demonstrate a mean one-year mortality of 16%.[7] Patients with pelvic fractures who present with shock on arrival to the hospital have mortality rates of up to 50%. Increased age, the presence of shock at the time of arrival, presence of multisystem injuries, and the need for transfusion increase the risk of death.

Despite advances in motor vehicle safety design, MVCs continue to be a major cause of pelvic fracture, with lateral impact collisions remaining the most prevalent mechanism. The widespread use of front impact airbags has had little protective effect on these lateral collisions. However, side-impact airbags reduce the risk of death in lateral impact MVC by 30% to 40%. Current research suggests that side impact airbags reduce the risk of head injuries by 30%, but they have minimal protective effect on thoracic or pelvic injuries. Newer technology, such as knee bolster airbags, has been claimed to reduce the risk of knee-thigh-hip injuries; however, there is not enough evidence to date to demonstrate their overall efficacy.

Anatomy, Physiology, and Pathophysiology

Bony and Ligamentous Anatomy

The right and left innominate bones and the sacrum together form the pelvic ring. The innominate bones consist of the pubis, ischium, and ilium (Fig. 46.1). The bony pelvis provides protection for its visceral contents, serves as attachment points for muscles, and transmits weight from the trunk to the lower limbs. The main weight-bearing forces are transmitted through the posterior wall of the pelvis, called the *posterior arch,* which is composed of thick bone and ligaments. The rich network of major arteries, veins, and nerves that course in front of the posterior arch can be injured concomitantly with forces responsible for bony injuries.

Knowledge of the ligamentous attachments of the pelvic ring is crucial to understanding stability derangements in pelvic injuries. Pelvic stability is maintained by soft tissue components including ligaments, muscles, and fascia that make up the pelvic floor. Anteriorly, the symphysis pubis provides the major mechanical stability. Posteriorly, a composite of strong ligaments—the sacrospinous, sacrotuberous, iliolumbar, and anterior and posterior sacroiliac ligaments—maintain the integrity of the posterior arch (Fig. 46.2). These ligaments are the primary stabilizing force of the posterior pelvis. Disruption of these ligaments is the primary cause of a mechanically unstable pelvic fracture.

Vascular Anatomy

Most of the blood supply to the pelvis comes from the left and right internal iliac arteries. The internal iliac arteries course at the level of the sacroiliac joints. The various arteries that derive from the internal iliac arteries initially run in close proximity to the posterior pelvic arch and eventually anastomose extensively with one another, forming a rich collateral network (Fig. 46.3). The superior gluteal artery is the largest branch and is commonly injured in fractures of the posterior pelvic arch. The obturator and internal pudendal branches are often injured in fractures involving the pubic rami.

Arranged in a plexus that adheres closely to the pelvic walls, the venous system has many collateral branches but does not have valves, which allows bidirectional flow. Because these veins are thin-walled, they do not have the ability to constrict in response to damage. This anatomic arrangement of the arteries and veins accounts for the hemorrhage often associated with pelvic fractures.

Neurologic Anatomy

The cauda equina travels through the sacral spinal canal and exits through the sacral neural foramina to form the lumbar and sacral plexus. Injury to the posterior bony pelvis and sacrum can result in neurologic deficits in the lower extremities and autonomic dysfunction involving the bowel, bladder, and genitalia.

Pathophysiology and Key Patterns of Pelvic Fracture

Numerous classification schemes for pelvic fractures have been created. The Tile classification stresses the biomechanical stability of the pelvic ring (Box 46.1). The Young-Burgess classification emphasizes the mechanisms of injury (Box 46.2). From a practical viewpoint, it is highly useful to consider both of these elements in the assessment of a pelvic ring fracture. Both classification systems delineate numerous subtypes of injuries. For the emergency clinician, however, a good understanding of the principles of pelvic stability and the mechanism of injury is more important than a detailed knowledge of injury subtypes. The broad distinction between mechanically stable and unstable fractures of the pelvic ring is clinically useful in assessing patients, as those with unstable injuries have a higher mortality rate and greater transfusion requirements.

The Rommens Classification System was developed to classify fragility fractures, which are low-energy injuries often seen in the elderly. The World Health Organization (WHO) defines a fragility fracture as a fracture caused by an injury that would be insufficient to fracture normal bone; it is the result of reduced compressive or torsional strength of bone.[1] Based on analysis of plain radiographs and computed tomography (CT) scans, four types of fragility fractures of the pelvis (FFP) have been described (see Fig 46.5 and Box 46.3).[1] Type I and II fractures

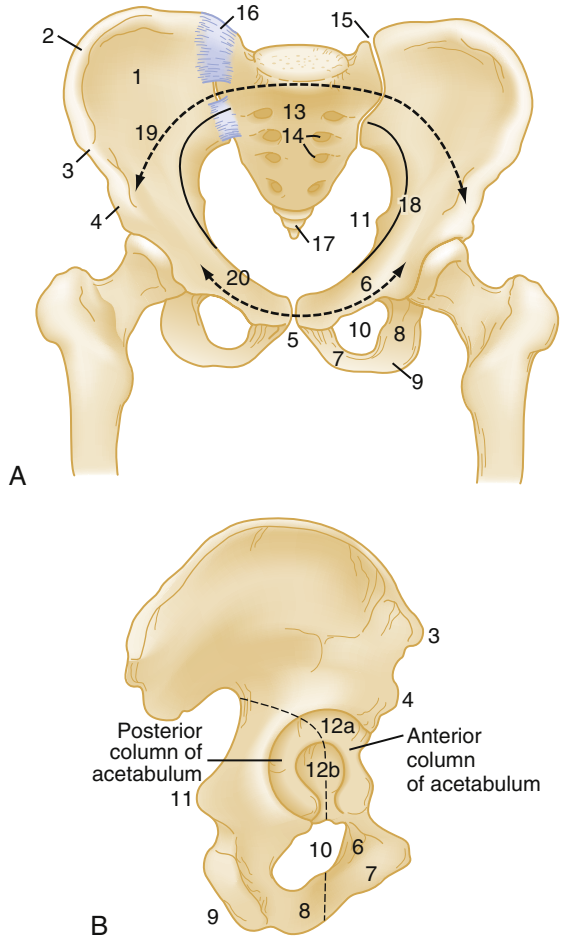

Fig. 46.1 Bony Pelvic Anatomy. (A) Anterior view of pelvis. (B) Lateral view of right innominate bone. *1,* Iliac fossa; *2,* iliac crest; *3,* anterior superior iliac spine; *4,* anterior inferior iliac spine; *5,* symphysis pubis; *6,* superior ramus of pubis; *7,* inferior ramus of pubis; *8,* ramus of ischium; *9,* ischial tuberosity; *10,* obturator foramen; *11,* ischial spine; *12,* acetabulum (*12a,* articular surface; *12b,* fossa); *13,* sacrum; *14,* anterior sacral foramina; *15,* sacroiliac joint; *16,* anterior sacroiliac ligament; *17,* coccyx; *18,* arcuate line; *19,* posterior or femorosacral arch, through which main weight-bearing forces are transmitted; *20,* anterior arch.

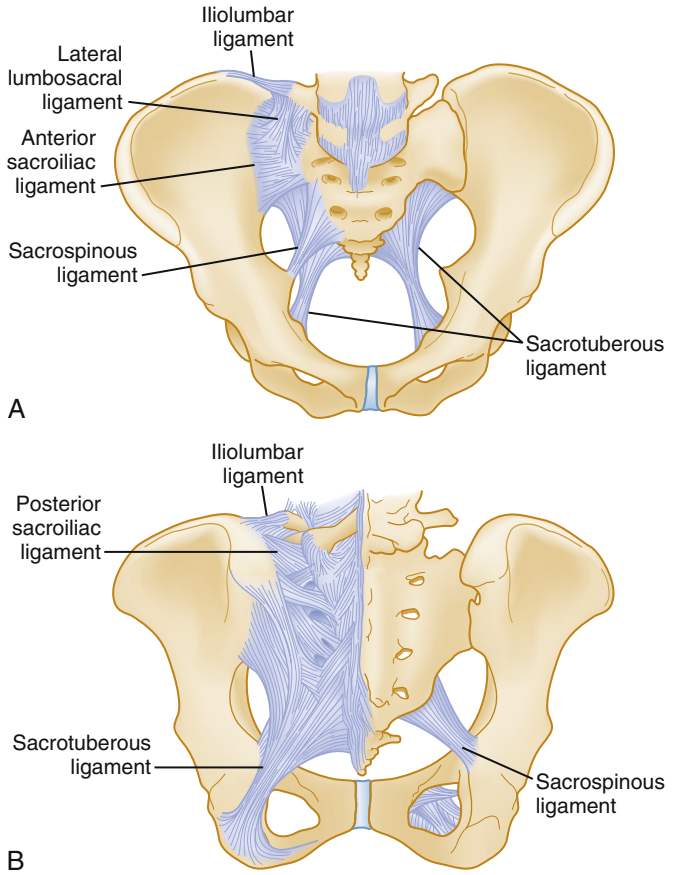

Fig. 46.2 (A) Anteroposterior view of the pelvis indicates that the sacrospinous ligament is a triangular strong ligament lying anterior to the sacrotuberous ligament, which is a strong broad band extending from the lateral portion of the dorsum of the sacrum to the ischial tuberosity. (B) The major posterior stabilizing structures of the pelvic ring, that is, the posterior tension band of the pelvis, include the iliolumbar ligament, posterior sacroiliac ligaments, sacrospinous ligaments, and sacrotuberous ligaments.

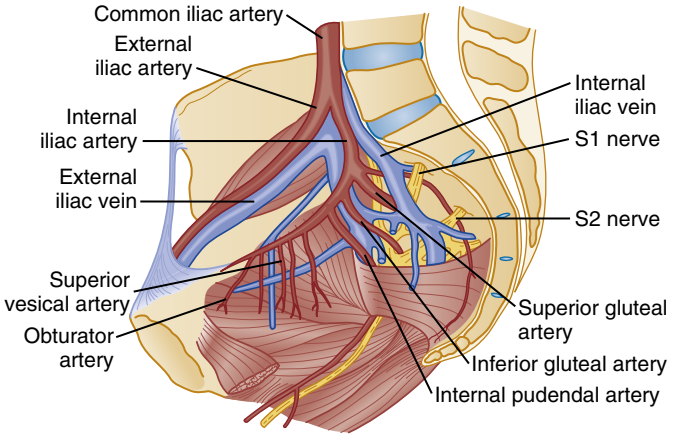

Fig. 46.3 The Internal Iliac Plexus of Arteries and Veins. (From Tile M. *Fractures of the Pelvis and Acetabulum*. 3rd ed. Philadelphia: Lippincott, Williams & Wilkins; 2003.)

are generally stable and treated nonoperatively, while type III and IV fractures require surgical fixation.

Overall inter-observer agreement has been shown to be fair in all three classification systems, and for Tile class B or C fractures, there was substantial agreement between experienced surgeons.[8]

BOX 46.1 Tile's Classification of Pelvic Fractures

Type A: Stable, posterior arch intact; includes avulsion fractures, isolated iliac wing fracture, pubic rami fractures, minimally displaced ring fracture, and transverse fractures of the sacrum or coccyx.

Type B: Partially stable, incomplete disruption of the posterior arch; includes anteroposterior injuries ("open-book" fracture) and lateral compression injuries; may be unilateral or bilateral; these injuries are rotationally unstable but vertically stable.

Type C: Unstable, complete disruption of the posterior arch; includes iliac, sacroiliac, and vertical sacral injuries that result from vertical shearing forces; may be unilateral or bilateral. These injuries are both rotationally and vertically unstable.

BOX 46.2 Young-Burgess Classification of Pelvic Fractures

Anteroposterior Compression

I. Symphysis diastasis <2.5 cm
II. Symphysis diastasis >2.5 cm, sacrospinous and anterior sacroiliac ligament disruption, results in rotational instability
III. Symphysis diastasis >2.5 cm, with complete disruption of the anterior and posterior sacroiliac ligament, results in complete rotational and vertical instability

Lateral Compression

I. Sacral crush injury on ipsilateral side
II. Sacral crush injury with disruption of posterior sacroiliac ligaments; iliac wing fracture may be present (crescent fracture); rotationally unstable
III. Severe internal rotation of ipsilateral hemipelvis with external rotation of contralateral side ("windswept" pelvis), rotationally unstable

Vertical Shear

Vertical displacement of symphysis and sacroiliac joints resulting in complete rotational and vertical instability

Combined Mechanisms

Any combination of the aforementioned mechanisms

BOX 46.3 Fragility Fracture of the Pelvis

Type I—Anterior pelvic ring fracture only (~17.5% incidence)
- Type IA—Unilateral fracture
- Type IB—Bilateral fractures

Type II—Nondisplaced posterior pelvic ring fracture (>50% incidence)
- Type IIA—Nondisplaced and isolated posterior fractures
- Type IIB—Sacral crush injuries with anterior disruption
- Type IIC—Nondisplaced sacral, sacroiliac, or iliac fractures with anterior disruption

Type III—Displaced but unilateral posterior pelvic ring fracture with an anterior pelvic ring fracture (11% incidence)
- Type IIIA—Displaced unilateral ilium fracture
- Type IIIB—Displaced unilateral sacroiliac fracture-dislocation
- Type IIIC—Displaced sacral fracture

Type IV—Displaced bilateral posterior fractures (~19% incidence)
- Type IVA—Bilateral iliac fractures or sacroiliac disruptions.
- Type IVB—Fracture is a spinopelvic dissociation associated with bilateral vertical fractures through the sacral ala with a horizontal component
- Type IVC—Fracture is a combination of different posterior instabilities

Stable Injuries (Tile Type A)

Fractures of individual bones without involvement of the pelvic ring represent one-third of all pelvic fractures. Most stable pelvic fractures heal well with rest and analgesia (Fig. 46.4).

Nondisplaced or minimally displaced fractures of the pelvic ring. The normal pelvis is not completely rigid, due to the slight mobility at the sacroiliac joints and symphysis pubis and the inherent elasticity of the bone. It is possible to sustain a single break in the pelvic ring; however, identification of a single break in the ring should prompt a thorough search for a second disruption.

The most common pelvic ring fracture is an isolated fracture of the superior or inferior pubic ramus. These fractures are stable and are generally categorized as an FFP type I (Fig 46.5) fracture. They are common in the elderly after a mechanical fall and should be given consideration in the evaluation of an acutely painful hip. Fracture of the body of the ischium is a rare injury that can result from a fall into the sitting position. Like all similarly classified fractures, fractures around the obturator foramen are managed conservatively with bed rest, analgesia, and early mobilization.

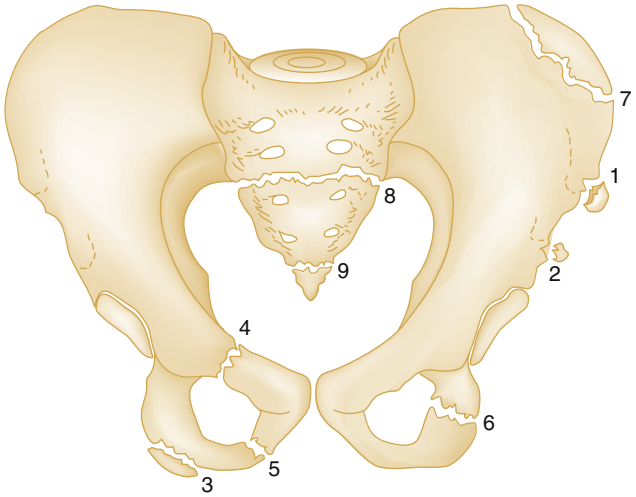

Fig. 46.4 Fractures of Individual Pelvic Bones. *1,* Avulsion of anterosuperior iliac spine; *2,* avulsion of anteroinferior iliac spine; *3,* avulsion of ischial tuberosity; *4,* fracture of superior pubic ramus; *5,* fracture of inferior pubic ramus; *6,* fracture of ischial ramus; *7,* fracture of iliac wing; *8,* transverse fracture of sacrum; *9,* fracture of coccyx. (From Tile M. *Fractures of the Pelvis and Acetabulum*. 3rd ed. Philadelphia: Lippincott, Williams & Wilkins; 2003.)

Fracture of the superior and inferior pubic rami on the same side is a commonly encountered injury after a fall or MVC. These are generally stable fractures and are treated conservatively. However, the presence of significant displacement at the fracture site indicates a second disruption elsewhere in the pelvic ring. Alternatively, fractures of both rami on the same side can be associated with an unrecognized impaction fracture of the posterior pelvis.

If the patient with a ramus fracture reports posterior pelvic pain, even if plain radiographs do not reveal a posterior injury, further investigations could reveal posterior fractures, such as occult bony or ligamentous injury of the acetabulum or sacroiliac joint. Up to 95% of elderly patients with isolated ramus fractures on plain films will have a sacral fracture detected by magnetic resonance imaging (MRI). This finding does not generally alter treatment, however, and an MRI is not indicated for most elderly patients with ramus fractures. Among the mechanically stable pelvic fractures, the lateral compression type I fracture described by Young and Burgess (Fig. 46.6), characterized by a pubic ramus fracture with ipsilateral sacral compression, bears special consideration. Although mechanically stable, this fracture has a mortality rate of nearly 10% and a high incidence of associated injuries.

A *straddle fracture* is a four-pillar injury involving fractures of both pubic rami on both sides of the symphysis pubis, creating a "butterfly segment" (Fig. 46.7), and is produced by a direct blow with a straddle mechanism. Although these fractures can occur without posterior arch disruption, four-pillar injuries are commonly associated with lateral compression or vertical shear forces, which can cause concomitant injuries to the posterior pelvic arch. CT of the pelvis is indicated in four-pillar injuries to detect and classify the posterior arch injury and to plan orthopedic treatment. The genitourinary tract is often injured with this type of pelvic fracture and should be evaluated meticulously (see Fig. 46.7).

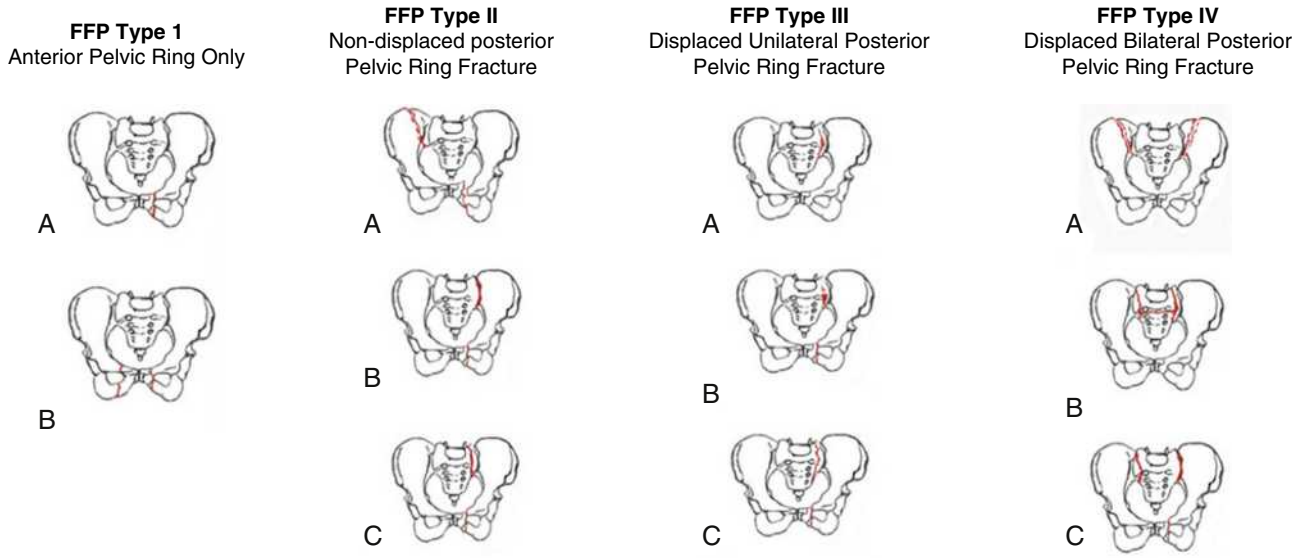

Fig. 46.5 Illustrations showing the four types of fragility fractures of the pelvis (FFP). The letters A, B, and C correspond with the subcategories of each fracture type as defined in the Box 46.3. (Modified with permission from Rommens PM, Wagner D, Hofmann A. Fragility fractures of the pelvis. *JBJS Rev.* 2017;5[3]:01874474-201703000-00004.)

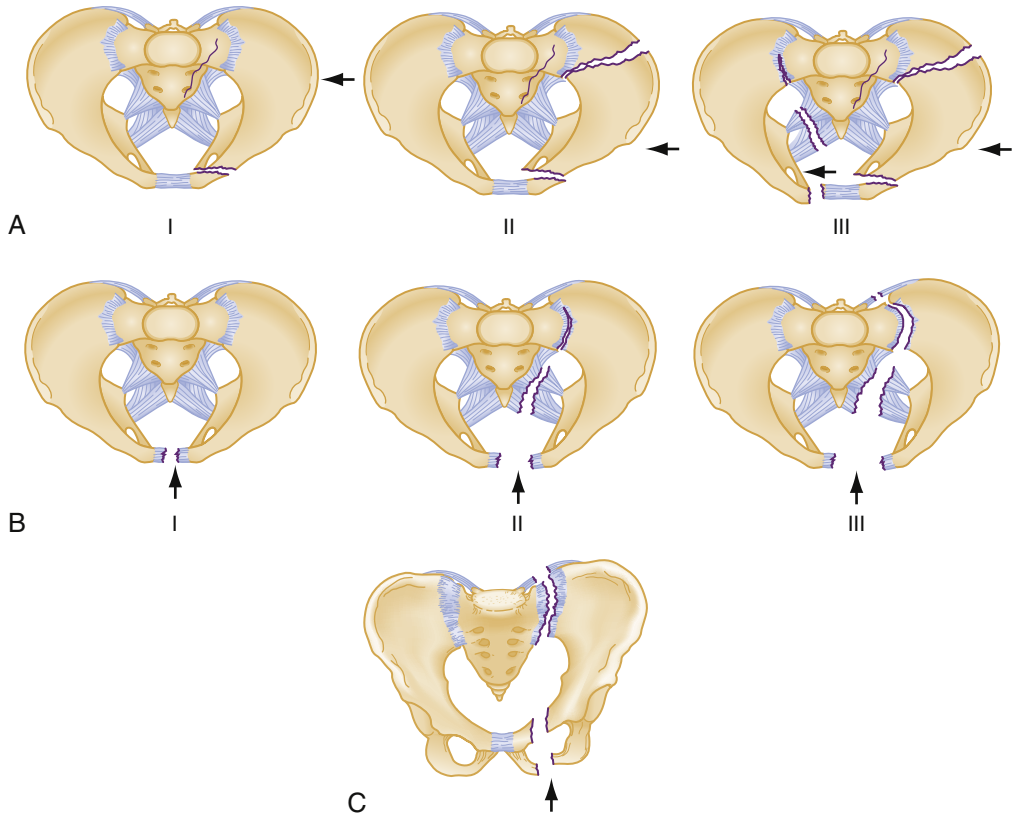

Fig. 46.6 Young-Burgess Classification. (A) Lateral compression. *Type I,* A posteriorly directed force causing a sacral crushing injury and horizontal pubic ramus fractures ipsilaterally. *Type II,* A more anteriorly directed force causing horizontal pubic ramus fractures with an anterior sacral crushing injury and either disruption of the posterior sacroiliac joints or fractures through the iliac wing. *Type III,* an anteriorly directed force that is continued, causing external rotation of the contralateral side; the sacroiliac joint is opened posteriorly, and the sacrotuberous and sacrospinous ligaments are disrupted. (B) Anteroposterior compression. *Type I,* Symphysis disrupted but with intact posterior ligamentous structures. *Type II,* Continuation of a type I fracture with disruption of the sacrospinous and potentially the sacrotuberous ligaments and an anterior sacroiliac joint opening. *Type III,* Continuation force disrupts the sacroiliac ligaments. (C) Vertical shear. Vertical fractures in the rami and disruption of all posterior ligaments. This injury is equivalent to an anteroposterior type III or a completely unstable and rotationally unstable fracture. *Arrow indicates the direction of force.* (Redrawn from Young JWR, Burgess AR. *Radiologic Management of Pelvic Ring Fractures.* Baltimore: Urban & Schwarzenberg; 1987. Browner BD. *Skeletal Trauma: Basic Science, Management, and Reconstruction.* 3rd ed. St Louis: Saunders/Elsevier; 2003.)

An isolated fracture of the iliac wing was first described by Duverney in 1751 and now bears his name. It is caused by direct trauma to the iliac crest, usually by lateral compression forces. Although there is usually minimal displacement because of the arrangement of the muscle attachments of the abdominal wall, orthopedic consultation in the emergency department (ED) is recommended. Extension of the fracture into the acetabulum alters treatment and prognosis. Severely displaced fractures of the iliac wing require open reduction and internal fixation (ORIF). A high incidence of major associated non-pelvic injuries has been reported among patients with isolated iliac wing fracture.

Transverse fractures of the sacrum. Transverse fractures of the sacrum do not compromise the pelvic ring. Transverse fractures at or below the S4 level are unlikely to be accompanied by neurologic injury. An upper sacral transverse fracture is the result of a flexion injury, such as being struck on the lower back by a heavy load while bending over, or by direct forces to the sacrum, as in a fall from a significant height. The patient often reports pain in the buttocks, perirectal area, and posterior thighs. There may be local pain, swelling, and bruising overlying the sacrum. Gentle bimanual rectal examination might elicit severe pain and abnormal motion and allow detection of a palpable hematoma. Radiographically, the fracture may be difficult to visualize on anteroposterior and lateral projections, in which case a pelvic outlet view may be diagnostic. Simple transverse fractures at or below S4 are treated conservatively. Above S4, neurologic injuries are common, necessitating careful clinical evaluation and surgery intervention when neurologic compromise is present.

Avulsion fractures. These usually occur during athletic activities and are the result of a sudden, forceful muscular contraction or excessive muscle stretch. They are seen more commonly in older children and teenagers before the corresponding physis matures and closes; adults can have the same symptoms from ligamentous injury at these sites, which may not be evident on a plain film or CT scan. The sites of ligamentous attachments on the pelvis are highlighted in Fig. 46.8.

The ischial tuberosity can be avulsed during strenuous contraction of the hamstrings. The result is pain on palpation of the involved tuberosity, which is increased by flexion of the hip with the knee in extension (hamstrings stretched), but not with the knee flexed (hamstrings relaxed). Ischial tuberosity avulsion can also cause chronic discomfort without a history of acute injury.

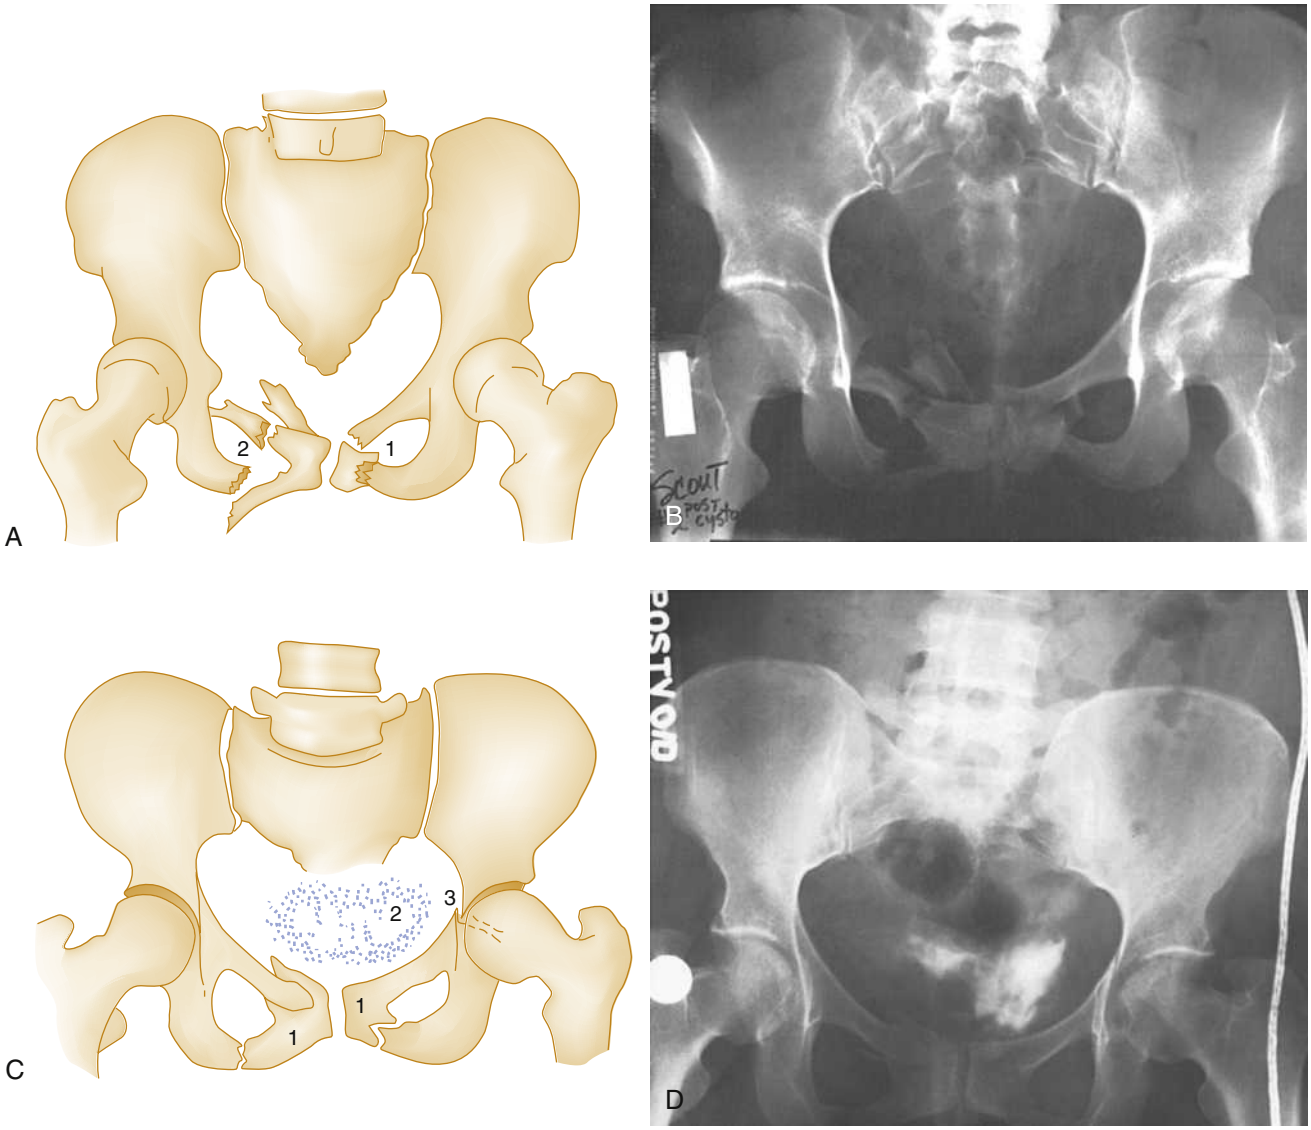

Fig. 46.7 Four-Pillar (Straddle) Fracture. (A and B) Partial inlet view of pelvis shows straddle fracture. *1* and *2,* Marked comminution of left pubic bone and comminuted right superior and inferior rami. This partial inlet projection shows displacement of fragments into the pelvis, which is not evident on the anteroposterior view of the same patient in C and D. A true inlet projection and computed tomography (CT) scan (not available) would provide further information about the posterior arch, which is injured frequently in straddle fractures and should be imaged (see text). (C and D) Post-void cystogram of the same patient with anteroposterior pelvis. *1,* Fractures of pubic rami are seen again but do not appear to be as displaced compared with A and B, because this projection is an anteroposterior view. Even minor degrees of angulation of the x-ray beam can change the appearance of pelvic fracture displacement. *2,* Extravascular contrast indicates bladder rupture. *3,* Left acetabular fracture is seen in this projection but not in B because of the difference in projection. The acetabular fracture disrupts the ilioischial line (see also Fig. 46.13) and is a posterior column fracture.

A portion of the iliac crest epiphysis can be avulsed by contraction of the abdominal muscles. Similarly, the anterior superior iliac spine can be avulsed by forcible contraction of the sartorius muscle. Forceful contraction of the rectus femoris (as in kicking a ball) can result in the less common injury of anterior inferior iliac spine avulsion; however, this radiographic finding should be distinguished from a normal variant, the *os acetabuli*, which is a secondary center of ossification at the superolateral margin of the acetabulum. Physical examination findings are similar in these injuries and reveal local pain, swelling, and limitation in the motion of the hip.

Conservative treatment, including analgesia and bed rest in a position that avoids tension on the affected muscles, is generally all that is required for avulsion injuries; surgical treatment is rarely necessary. Orthopedic consultation within a week is advised for follow-up care.

Stress fractures. Stress fractures can occur with vigorous athletic or military training or during the last trimester of pregnancy. The diagnosis of stress fractures is based on the clinical history and can be confirmed by radionuclide bone scan, although MRI has been shown to be a superior method for detecting these injuries.[9]

Pathologic and insufficiency fractures. Pathologic fracture related to neoplasm, Paget disease, or dietary osteomalacia should be included in the differential diagnosis of any pelvic fracture. Radiation therapy increases the risk of pelvic fracture.

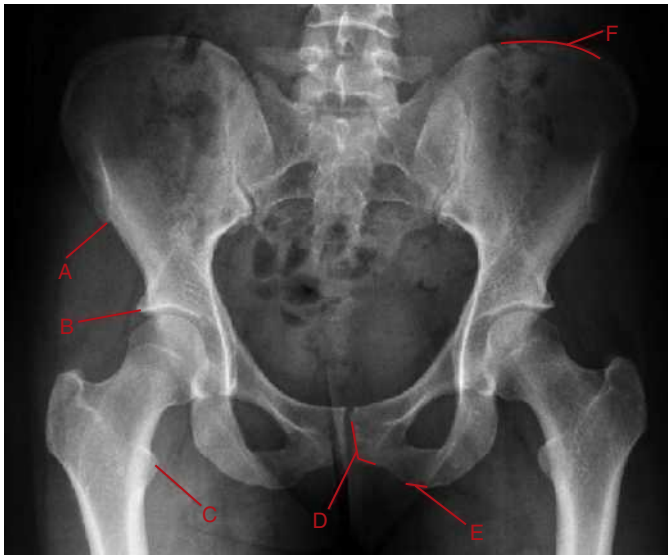

Fig. 46.8 Site of Tendon Insertion for Muscles Originating From the Pelvis. *A,* Sartorius (origin on the anterior superior iliac spine). *B,* Rectus femoris (origin on the anterior inferior iliac spine). *C,* Iliopsoas (inserts on lesser trochanter). *D,* Adductors and gracilis (origin on body of pubis or inferior pubic rami). *E,* Hamstrings (origin on the ischial tuberosity). *F,* Abdominal muscles (origin on the iliac crest).

Partially Stable and Unstable Injuries (Tile Types B and C)

Partially stable and unstable injuries are caused by high-energy impact. The forces applied to the pelvis determine the types of injuries that occur. Generally, forces can be applied to the pelvic ring in anteroposterior, lateral, or vertical directions, resulting in characteristic injury patterns; combinations of forces result in more complex injuries. The terms *unstable fracture* (referring to mechanical stability) and *unstable patient* (referring to hemodynamic status) should not be used interchangeably, although a cause-and-effect relationship often exists.

Anteroposterior compression. Severe anteroposterior compression forces cause disruption at or near the symphysis pubis. The symphysis is normally ≤0.5 cm in an adult but can increase 2 to 3 mm during or after pregnancy. Symphysis widening less than 2.5 cm is considered a stable injury; however, with continued force in the anteroposterior direction, the hemipelvis externally rotates, tearing the sacrospinous, sacrotuberous, and anterior sacroiliac ligaments. The sacroiliac joint opens and hinges on the intact posterior sacroiliac ligaments. The resulting injury is aptly described as an "open-book" fracture. The pelvis is rotationally unstable in the horizontal plane, but the intact posterior sacroiliac ligaments maintain vertical stability.

When diastasis of the pubic symphysis is greater than 2.5 cm on an anteroposterior radiograph, a resultant posterior injury is seen as widening of the sacroiliac joint and occasionally as a sacral or iliac fracture (see Fig. 46.6). If the injurious forces continue, they can separate the hemipelvis, and the sacroiliac joint is seen as widely separated on a plain anteroposterior radiograph (Fig. 46.9) and on CT. The anteroposterior radiograph can be misleading in suggesting a pure open-book fracture in cases with symphysis disruptions greater than 2.5 cm. Since these cases are commonly associated with vertical shear fractures, clinical and CT assessment for vertical instability is essential to classify the fracture properly and plan treatment accordingly. These same forces can also injure the neurologic and vascular structures at the posterior arch. The overall volume of the pelvis increases in the open-book injury, facilitating the expansion of a retroperitoneal hematoma. Several studies have demonstrated that patients with severe grades of anteroposterior compression injuries have the highest crystalloid and

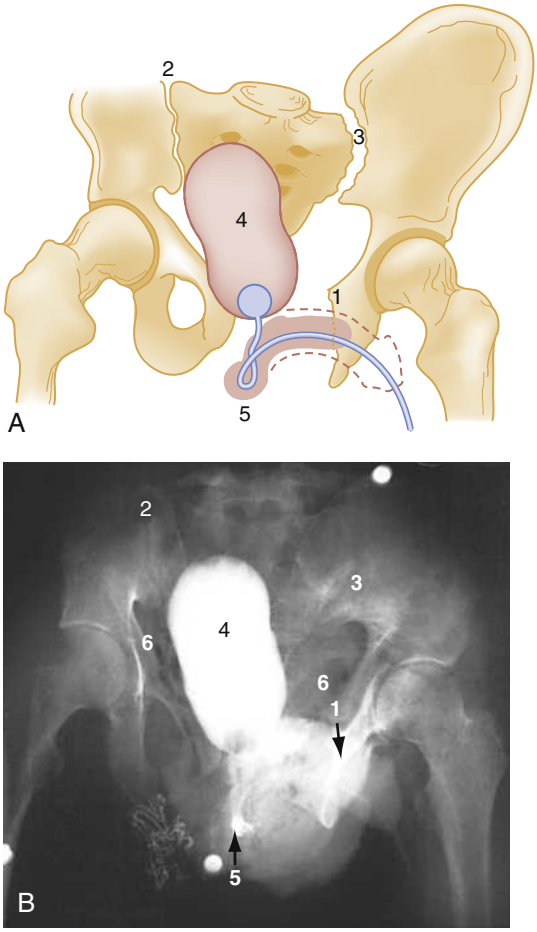

Fig. 46.9 Interpretive drawing (A) and radiograph (B). Severe unilateral "open-book" fracture from anteroposterior compression forces, which is also open (compound). *1,* Separated pubic symphysis with asymmetry of hemipelvis; *2,* normal sacroiliac joint; *3,* separated sacroiliac joint; *4,* cystogram with displacement and abnormally elongated shape of bladder caused by retroperitoneal hematoma associated with separated left sacroiliac joint, which has pushed the bladder to the right; *5,* extravasated contrast into perineum from urethral rupture; *6,* soft tissue air indicating an open fracture.

blood requirements. In addition, these injuries can be associated with non-pelvic injuries that contribute to significant blood loss.

Lateral compression. Lateral compression of the pelvic ring results in varying degrees of internal rotation of the affected hemipelvis. Initially, this causes buckling of the sacrum and horizontal pubic rami fractures. Rami fractures can occur on the ipsilateral or contralateral side, the latter being referred to as a "bucket-handle" fracture (Fig. 46.10).

As the magnitude of force increases, the symphysis can be disrupted, causing overlapping of the pubic bones. On plain radiographs, evidence of injury to the sacrum might be subtle; therefore, overlapping pubic bones with any significant displacement should prompt a search for a posterior injury.

Similar to the anteroposterior injury, as disruption of the posterior ligaments increases, so does rotational instability. In the most severe lateral compression trauma, the ipsilateral pelvis rotates internally to such a degree that the contralateral pelvis might externally rotate. This is referred to as a "windswept" pelvis. Lateral compressive injuries result in varying degrees of horizontal rotational instability; however, the vertical stability of the pelvis is maintained (see Fig. 46.10).

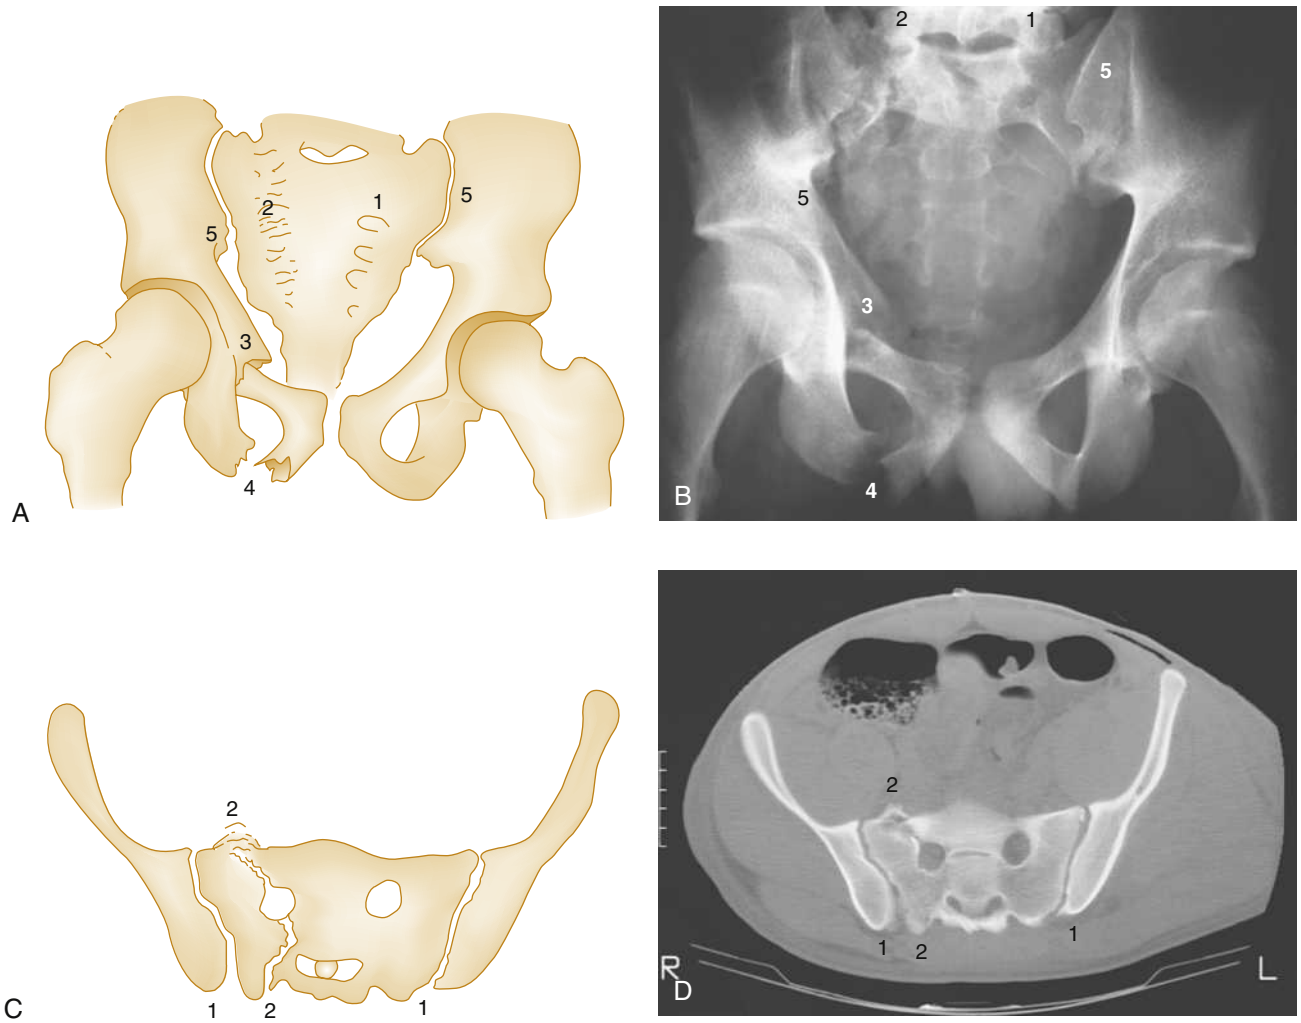

Fig. 46.10 Lateral Compression Fracture. (A and B) Anteroposterior view of the pelvis. *1,* Normal sacral foraminal lines on the left; *2,* sacral foraminal lines on the right are indistinct and do not mirror the normal side, indicating the subtle second break in the pelvic ring; *3* and *4,* fractures of the superior and inferior pubic rami are overriding and displaced, indicating the lateral compression forces (there must be a second break in the pelvic ring); *4,* the "bucket-handle" fracture; *5,* normal sacroiliac joints. (C and D) Computed tomography (CT) scan of the same pelvis. *1,* Normal sacroiliac joints; *2,* compression fracture of the sacrum through the foramen corresponding to the loss of definition of the foraminal lines in A and B.

Because internal rotation causes the pelvic volume to decrease, lateral compressive injuries are generally associated with lesser degrees of blood loss than are anteroposterior injuries.

Vertical shear. Vertical shear injuries are the most unstable injuries affecting the pelvic ring and are associated with violent axial loading of the hemipelvis (such as a fall from a height or "submarining" under a dashboard) that causes fractures in vertical planes. Anteriorly, the symphysis and rami could be disrupted. Posteriorly, gross displacement and instability in the rotational and vertical planes may be present through the sacrum, the sacroiliac joint, or the ilium such that the hemipelvis is displaced posteriorly and cephalad (Fig. 46.11).

Avulsion of the ischial spine, the lower lateral lip of the sacrum, and the transverse process of the fifth lumbar vertebra (sites of ligamentous insertion) (see Fig. 46.11 and Box 46.4) are important clues to the presence of vertical shear fractures. The vertical shearing forces transmitted through the bony pelvis are also transmitted through the rich vascular network and nerve plexus directly adjacent to the bone. This accounts for the major hemorrhage and neurologic injuries associated with vertical shear fractures.

Vertical sacral fractures. A crucial distinction in considering sacral fractures is that transverse fractures do not involve the pelvic ring, but vertical fractures do. Vertical sacral fractures are caused by high-energy injuries and were classified by Denis into three groups according to whether the fracture line extends (1) laterally to the sacral foramina, (2) through the foramina, or (3) medially to the foramina, involving the central spinal canal (Fig. 46.12). The radiographic diagnosis of this fracture hinges on examination of the symmetric cortical lines that are normally present at the superior margins of the sacral foramina on the anteroposterior view. Disruption, distortion, or asymmetry of these lines is an important marker of sacral fractures.

These injuries carry a high risk of neurologic complications: 6% when lateral to the foramina, 28% when through the foramina, and 58% when medial to the foramina. Neurologic dysfunction correlates with the nerve roots involved, but can also manifest as bowel, bladder, or sexual dysfunction. Urgent surgical correction (within 24 hours) is performed for fractures associated with neurologic dysfunction, with the goals of bony fixation of the sacrum and decompression of the affected nerve roots.

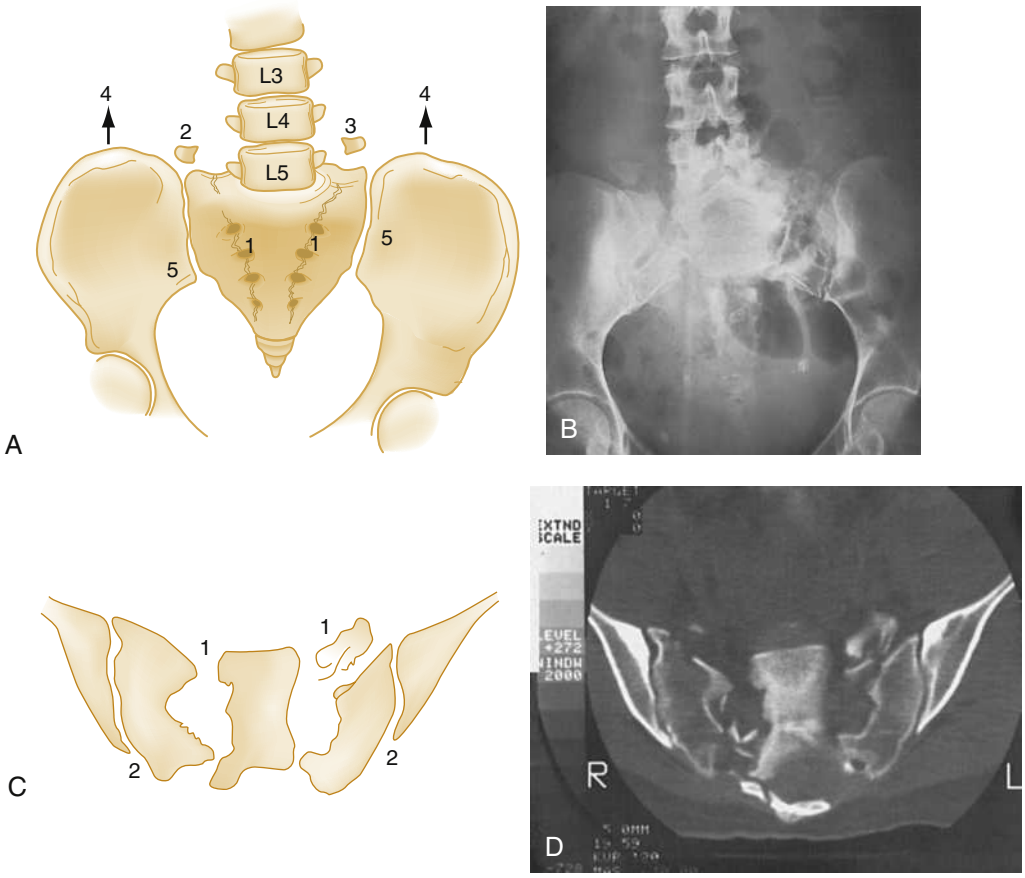

Fig. 46.11 (A and B) Vertical shear fractures bilaterally. At first glance the pelvis appears normal because of the smooth, uninterrupted arcuate line, but careful interpretation reveals the extremely critical nature of the injuries. *1,* Fractures through the sacrum—note loss of definition and symmetry of sacral foramina, indicating vertical fractures through both sides of the sacrum (see computed tomography [CT] scan in D). *2,* Transverse process fragment from right L5 (iliolumbar ligament attachment) is pathognomonic for a vertical shear fracture through the right sacrum. *3,* Transverse process fragment from left L5, pathognomonic for a vertical shear fracture through the left sacrum. *4,* Both hemipelves are dislocated cephalad because of the double-ring fractures through each side of the sacrum. This dislocation explains why the L5 transverse processes appear so close to the iliac crests. (The body of L5 is obscured because of rotational dislocation of the central free sacral fragment posteriorly and because of technique.) *5,* Normal sacroiliac joints. (C and D) CT scan of same pelvis. *1,* Bilateral comminuted fractures of sacrum with lateral displacement of both hemipelves; *2,* normal sacroiliac joints.

BOX 46.4 Radiographic Clues to Posterior Arch Fractures

- Avulsion of L5 transverse process[a]
- Avulsion of ischial spine[a]
- Avulsion of lower lateral lip of the sacrum (sacrotuberous ligament)*
- Displacement at the site of a pubic ramus fracture
- Asymmetry or lack of definition of bone cortex at superior aspect of the sacral foramina

[a] Indicates mechanical instability.

Open Pelvic Fractures

An open pelvic fracture is present when there is direct communication between the fracture site and a dermal, rectal, or vaginal wound. These are potentially lethal injuries, especially if not recognized early. Hemorrhage accounts for early mortality, and infection, sepsis, acute respiratory distress syndrome, and multisystem organ failure are causes of delayed death. The majority of older case series reported mortality rates greater than 50%; rates reported from more recent studies are generally less than 30%. A 2015 study of more than 30,000 patients reported in-hospital mortality of 2.7%, but this rate doubled for patients ages 55 to 70 years old and quadrupled for patients older than 70 years old.[10] Other predictors of mortality included injury severity, altered mental status, prolonged mechanical ventilation, or need for blood product administration.[10]

The skin over the posterior pelvis and gluteal area and perineum should be meticulously inspected for wounds. Some fractures are open only by virtue of a bone spicule penetrating the vagina or rectum, which can be identified by careful digital rectal examination (DRE) and vaginal examination. Hemorrhage from a large open laceration should be treated with direct manual pressure or pressure dressing. Traditionally, pelvic fractures communicating with the rectum have mandated a diverting colostomy; however, a systematic review of the literature on this topic found no difference in infection rates between patients treated with or without a colostomy.

Penetrating Pelvic Trauma

Because of the complex anatomy of the viscera, blood vessels, and nerves within the pelvis, penetrating trauma to this area presents another diagnostic challenge. Overall mortality in this group of patients is about 10%, but the mortality rate of patients who present in shock is

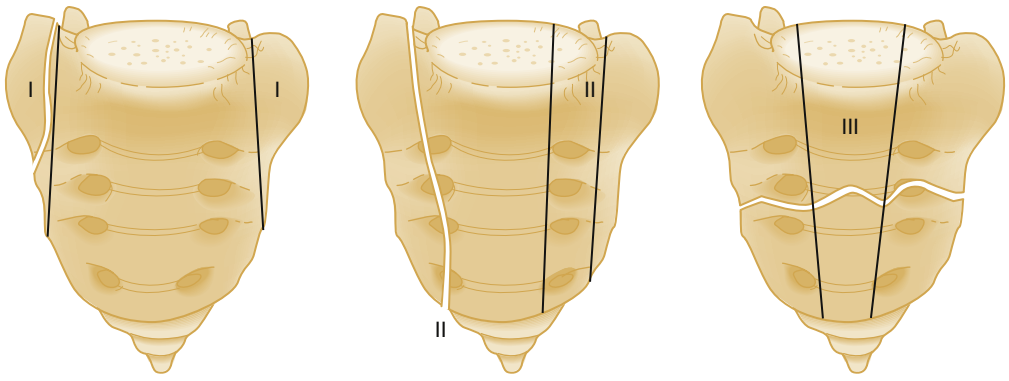

Fig. 46.12 The Denis Classification of Vertical Sacral Fracture. *Zone I* is lateral to the sacral foramina (known as the *sacral ala*). *Zone II* is transforaminal. *Zone III* is the central sacrum medial to the foramina.

BOX 46.5 Goldman Classification System for Pelvic Fracture Urethral Injury

I — Posterior urethra intact but stretched
II — Partial or complete pure posterior injury with tear of membranous urethra above the urogenital diaphragm
III — Partial or complete combined anterior/posterior urethral injury with disruption of the urogenital diaphragm
IV — Bladder neck injury with extension into the urethra
IVA — Injury of the base of the bladder with peri-urethral extravasation simulating a true type IV urethral injury
V — Partial or complete pure anterior urethral injury

TABLE 46.1 Neurologic Deficits of Pelvic Fractures as Expected by Nerve Root Level

Nerve Root	Expected Deficit
L5	Weakness—anterior tibial compartment Sensory deficit—dorsum of foot and lateral calf
S1 and S2	Weakness—hip extension, knee flexion, and plantar flexion Sensory deficit—posterior aspect of the leg, sole and lateral foot, genitalia
S2–S5	Sensory deficit to perineum, sexual dysfunction, bowel and bladder dysfunction

as high as 50%. Vascular injuries can involve the aorta; common iliac artery; external, internal, and common iliac veins; or a combination of vessels. Genitourinary structures and hollow viscera could be injured; fecal contamination from colorectal injury is a serious complication. The finding of blood on DRE is an important clue that a rectal injury has occurred. Emergent surgical consultation is recommended for all cases of penetrating pelvic trauma.

Associated Pelvic Injuries

Urologic Injury

The overall incidence of bladder or urethral disruption associated with any pelvic fracture is approximately 5% to 25%,[11] with increased risk among those with severe pelvic injuries. Because the urethra is far less exposed in women than in men, injury to the urethra in women with pelvic fracture is uncommon. MVCs are four times more likely to cause a pelvic fracture urethral injury (PFUI) than the second most common cause, falling from a height.[11] There are several classification systems for pelvic fracture urethral injuries. The Goldman Classification system is shown in Box 46.5.

Patients with fractures of the anterior arch of the pelvis were at greatest risk for bladder injury. Diastasis of the symphysis more than 1 cm and fracture around the obturator ring with displacement more than 1 cm are associated with a tenfold and threefold increased risk of bladder rupture, respectively.

The presence of gross hematuria indicates injury of the lower urinary tract. Other signs that suggest a urethral injury are scrotal or perineal hematomas, with a high riding prostrate on DRE. Bladder rupture is diagnosed in about 25% of patients with gross hematuria and pelvic fracture. Patients with blood at the urethral meatus in the context of pelvic fracture have up to a 90% incidence of urethral injury and indicate the need for a retrograde urethrogram followed by a cystogram (see Chapter 39). Gross hematuria is investigated with a combination of urethrography, intravenous pyelography, cystography, and CT. The sequence and types of examinations are individualized for each patient according to the capability of the heath care facility. Fracture of the inferomedial pubic ramus and widened symphyseal diastasis have both been shown to be predictive of a urethral injury. Retrograde urethrocystography done before CT of the pelvis might impair the ability of CT to detect extravasation of contrast, which would indicate active pelvic bleeding. Therefore, if CT is to be performed, it ideally is performed before retrograde urethrocystography.

Sexual dysfunction is a recognized complication of pelvic trauma, occurring in 44% of females and 50% of males. Even in the absence of a urethral injury, sexual dysfunction in men can occur secondary to neurovascular disruption associated with the pelvic fracture.

Neurologic Injury

The risk of neurologic injury correlates with instability of the pelvic injury, with a reported incidence of neurologic dysfunction of 2%, 4%, and 14% in Tile type A, B, and C fractures, respectively. Up to 10% of patients with acetabular fractures experience neurologic dysfunction. Neurologic injury occurs commonly in patients with vertical sacral fractures or transverse fractures above the S4 level. Up to 30% of patients with vertical fractures that involve the foramina have associated neurologic deficits. In patients with fractures medial to the foramina involving the spinal canal, almost two-thirds have neurologic deficits.

Pelvic injury can cause various plexopathies and radiculopathies, depending on the nerve root level of the injury (Table 46.1). In patients with sacral fractures, cauda equina syndrome may be fully or partially present. Hyperesthesia and subsequent anesthesia occur in a

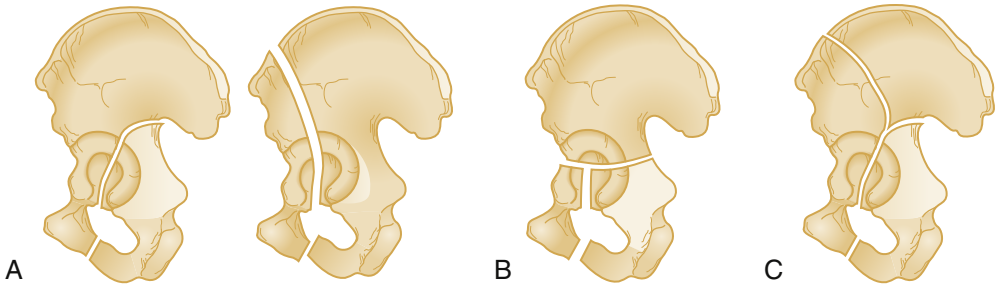

Fig. 46.13 Universal Classification of Acetabular Fractures. (A) Type A: Fractures of one column or one wall, for example, posterior column *(left)* and anterior *(right)* column. (B) Transverse (T-type) fractures involving both columns but, by definition, leaving a fragment of articular cartilage attached to the proximal ilium and thus to the axial skeleton. (C) Type C: Two-column fracture of the acetabulum. No portion of the articular surface remains attached to the axial skeleton because fracture of both columns of the ilium is proximal to the joint. (From Tile M. *Fractures of the Pelvis and Acetabulum*. 3rd ed. Philadelphia: Lippincott, Williams & Wilkins; 2003.)

saddle-shaped distribution in the groin, as well as weakness of ankle plantar flexion, hamstrings, and gluteus muscles and decreased or absent ankle jerk. If the lower sacral roots are affected, the patient might experience neurogenic bladder with overflow incontinence, motor and sensory deficits in the lower extremities, anal sphincter dysfunction, or sexual dysfunction. Patients with neurologic deficits from sacral fractures require urgent orthopedic or neurosurgical consultation.

Gynecologic Injury

Blood at the introitus may indicate a urethral injury, open pelvic fracture, or local laceration without communication with the bony pelvis. Delayed urologic or sexual dysfunction and complications with pregnancy are common after pelvic injury. Gynecologic consultation in the ED is recommended for any female who sustains an injury to the reproductive tract in association with a pelvic fracture and for all pregnant women who sustain a pelvic fracture of any kind.

Associated Non-Pelvic Injuries

The magnitude of force required to disrupt the pelvis commonly results in severe injuries to other organ systems. Among those patients who die as a result of these injuries, it is rare that the fracture is an isolated injury. Associated injuries in trauma patients with pelvic fracture can contribute more to the mortality risk than the pelvic injury itself.

Although patterns of non-pelvic injuries associated with certain patterns of pelvic fracture have been described, these findings have not been reproduced consistently in the literature. Severe injuries to the head, spine, thorax, aorta, and abdomen can occur in patients with both stable and unstable pelvic fractures and are associated with all major mechanisms of pelvic injury. Because of the forces involved, the diagnosis of a pelvic fracture should prompt a careful evaluation for other system injuries.

Acetabular Fractures

Pain and inability to bear weight are the hallmark complaints associated with acetabular fractures. On clinical examination, pain in the hip area with percussion of the heel of the foot or with medial pressure applied to the greater trochanter may indicate a potential acetabular fracture.

Acetabular fractures are broadly classified into three types (Fig. 46.13 and Box 46.6).

Type A fractures are subdivided into anterior and posterior column injuries. Posterior wall fractures are the most common acetabular injuries and are generally caused by a forceful impact to a flexed knee (such as a dashboard injury) where the force is transmitted up through the femur through the posterior acetabulum. As a result, concurrent fracture or **dislocation** of the patella are common. An associated posterior dislocation of the hip is frequently associated with posterior rim fracture of the acetabulum, which may result in an unstable hip joint, leading to recurrent dislocation. Posterior hip dislocation is commonly associated with secondary sciatic nerve injury. The anterior column of the acetabulum is commonly injured when a superior ramus fracture extends into the low anterior column.

BOX 46.6 Classification of Acetabular Fractures

Type A: Fractures of one column of the acetabulum (anterior or posterior column).
Type B: Transverse (T-type) fractures through both anterior and posterior columns; a portion of the acetabulum remains attached to the proximal ilium.
Type C: Transverse (T-type) fractures through both anterior and posterior columns; no portion of the acetabulum remains attached to the axial skeleton.

Type B fractures involve both anterior and posterior columns, but a portion of the acetabulum remains attached to the ilium. When the columns are split, the injury is referred to as a *transverse (T-type) fracture*. The T-type fracture is associated with the worst prognosis, due to the difficulty of obtaining an open anatomic reduction.

Type C fractures are two-column fractures of the acetabulum, with none of the articular surface remaining attached to the axial skeleton. These fractures are readily apparent on plain radiographs as a result of disruption of the ilium.

Assessment of an anteroposterior pelvic radiograph should focus on disruption of the ilioischial and iliopectineal lines, as well as the anterior and posterior lips of the acetabulum (Fig. 46.14). Ramus fractures should be evaluated for possible extension into the acetabulum. When plain radiographic films are used, oblique views of the acetabulum (Judet views) can aid in visualizing the anterior and posterior columns. CT is the imaging test of choice for visualizing acetabular fractures and, when deemed necessary, planning surgical repair. Fractures of the acetabulum often result from high energy mechanisms; thus, patients with isolated acetabular fractures might have significant hemorrhage necessitating blood transfusion. Patients with acetabular fractures require orthopedic consultation in the ED.

Acetabular fractures in older patients have different fracture patterns. In this population, the fracture often involves the anterior column, is more comminuted, and has a more severe articular impaction.[12] Most of these fractures are the result of low-energy trauma (fall

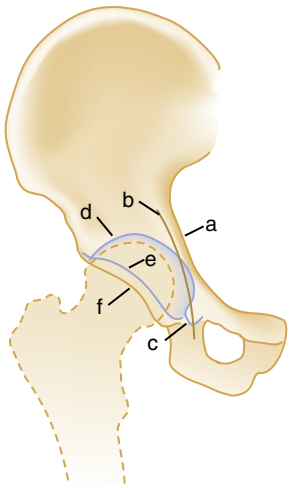

Fig. 46.14 Schematic Drawing of Radiographic Anatomy of Acetabulum in Anteroposterior Pelvis Projection. *a,* Arcuate (iliopubic) line; *b,* ilioischial line; *c,* radiographic U, or teardrop, caused by superimposition of parasagittal surface of ilium onto anteroinferior portion of acetabulum; *d,* acetabular roof; *e,* anterior lip of acetabulum; *f,* posterior lip of acetabulum. (Redrawn from Rogers LF, Novy SB, Harris NF. Occult central fractures of the acetabulum. *Am J Roentgenol.* 1975;124:98.)

from standing position) when the patient lands on the posterolateral hip in the region of the greater trochanter. The force vector drives the femoral head into the anterior column of the acetabulum. Management of older patients is further complicated by comorbid medical conditions and poor bone quality, osteoporosis, which limits the ability to obtain and stabilize an anatomic reduction.[12] Medical management is often the best treatment option. In one study, 56% of older patients who had low-energy fractures involving the anterior wall were treated nonoperatively.[13] In those patients that do undergo ORIF, approximately 25% of patients will ultimately need a total hip arthroplasty.[12] Factors that are associated with the need for total hip arthroplasty within 2 years of ORIF for acetabular fractures are shown in Box 46.7.[14]

Coccyx Fractures

Fractures of the coccyx are caused by a fall into the sitting position or being kicked in that area of the body. The bone can also be fractured during the birthing process. Physical examination reveals local tenderness to palpation in the gluteal crease cephalad to the anus. DRE may elicit pain and allow detection of abnormal motion of the coccyx. Normally, the tip of the coccyx moves 30 degrees anteriorly and 1 cm laterally. If displacement is detected during rectal examination, attempts at reduction are not recommended.

Radiographic confirmation of a coccygeal fracture is generally not necessary. Displaced fractures often are seen on the lateral view, but the diagnosis is evident on physical examination. Nondisplaced fractures can be difficult to identify radiographically. Rarely does the knowledge gleaned from radiographic studies alter the therapy to a degree that warrants radiation exposure to the pelvis, especially in women.

Treatment of coccygeal fracture consists of limited activity (as gaged by pain), stool softeners, non-opioid analgesia, and hot baths. As activity is increased, maneuvers that minimize discomfort include the use of an inflatable rubber donut cushion while sitting, alternately sitting on the side of each buttock, slouching to displace body weight more proximally, and sitting on a hard chair rather than a soft one, as sinking into a soft chair distributes weight onto the coccyx. Because of ongoing muscle forces on the bony fragment, healing is slow, and patients should be told that discomfort will persist for 4 to 8 weeks. If severe disability persists beyond that time frame, an orthopedic consultation is indicated for consideration of local steroid injection or possible coccygectomy.

BOX 46.7 Factors Predicting Need for Total Hip Arthroplasty Within 2 Years of Open Reduction Internal Fixation of Acetabular Fracture

- Age over 40 years
- Anterior dislocation
- Femoral head cartilage lesion
- Involvement of the posterior wall
- Marginal impaction
- Initial displacement of greater than 20 mm
- Nonanatomic reduction
- Postoperative incongruence of the acetabular roof
- Utilization of the extended iliofemoral approach

CLINICAL FEATURES

History

Understanding the mechanism of injury is an important means of determining a patient's risk of having a pelvic fracture and, if present, its pattern and severity. Low-energy injuries (such as ground-level falls) typically cause stable injuries to the pelvis; patients who have sustained high-energy injuries (MVCs and falls from heights) are at risk for unstable fractures of the pelvis, as well as associated injuries to other organ systems.

Determining the direction of forces applied to the pelvis can also give important clues to the types of injury sustained. Anteroposterior forces (such as head-on MVCs) can cause open-book injuries to the pelvis. Lateral forces from side-impact collisions can disrupt the posterior ligaments; however, the pelvic floor generally remains intact. Vertical shear injuries (such as falls from height) can disrupt the posterior ligaments and pelvic floor, causing instability of the pelvis.

Age is an important consideration in patients with pelvic fracture. When compared with their younger counterparts, elder patients have lower density bone, which fracture more easily, have an increased likelihood of hemorrhage, higher morbidity and mortality, greater number of comorbidities, and worse outcomes after acute resuscitation from hypotension. Pelvic fragility fractures in the elderly are nearly as severe as hip fractures in terms of loss of autonomy, mortality rates, and healthcare costs.[15]

Physical Examination

On inspection, rotation of the iliac crests indicates a serious pelvic fracture. Leg-length discrepancy suggests a hip injury or cephalad migration of an unstable hemipelvis. Thorough inspection of the skin and skin folds is necessary to identify open fractures. Perineal or genital ecchymosis or hematoma might be observed, and if many hours have elapsed since the injury, ecchymosis in the periumbilical region (Cullen sign), in the flank areas (Grey Turner sign), or over the inguinal ligament (Fox sign) may be present from retroperitoneal hemorrhage. Palpation along the pelvic ring, seeking the presence of point tenderness, is imperative; palpation starts at the symphysis anteriorly and proceeds to both pubic rami, the iliac spines and crests, and finally to the sacrum and sacroiliac joints posteriorly. The presence of tenderness in any of these locations is an important indicator of pelvic ring injury in alert patients without distracting injury.

Manipulation of the pelvis during physical examination is important to determine stability, but pressure should initially be applied gently and progressively increased, as long as the patient does not report pain. "Spring boarding" (i.e., vigorous downward pressure on the anterior superior iliac spines) to assess the rotational stability of the pelvic ring should be strictly avoided, because this maneuver has the potential to disrupt any tenuous blood clotting that may have occurred around a fracture site and can therefore worsen hemorrhage. Inward stability should be checked by bilateral compression of the iliac wings before outward stability to minimize the risk of opening the pelvis and causing more internal bleeding.

One recent study demonstrated the utility of the straight leg raise in the examination of patients with suspected pelvic fractures.[16] In their cohort of participants with a GCS of 15, all patients with a pelvic fracture, regardless of severity, were unable to SLR without pain (100% negative predictive value). The presence of pain was 100% sensitive in identifying patients with a pelvic fracture.[16]

The penis should be examined for blood at the meatus. DRE, once a fixture in assessment of pelvic trauma, is not sufficiently sensitive or specific to guide diagnosis of urethral or bladder injury (see Chapter 39). The DRE allows evaluation of sensation and sphincter tone for spinal cord injury, and the presence of frank blood, indicating possible mucosal disruption. A vaginal speculum examination should be performed to assess for an open fracture in women identified with fracture on imaging. If operative intervention is planned, this examination, which can be uncomfortable and distressing, is deferred to the operating room under anesthesia. Because it is possible to create an open fracture iatrogenically through the vaginal or rectal wall, the DRE and vaginal examination must be performed carefully, especially in unconscious patients who cannot localize pain. The examiner should be mindful when performing these examinations that bony spicules can lacerate the examining finger. Extravasated urine might be detected in the scrotum or the subcutaneous tissues of the penis, vulva, or abdominal wall. The presence and quality of pulses in the lower limb should be assessed, as should sensation, strength, and deep tendon reflexes.

DEEP VENOUS THROMBOSIS

Patients with pelvic fractures are at high risk for development of deep venous thrombosis (DVT) and pulmonary embolisms. The incidence of DVT and pulmonary embolism is almost 30% even with the patient on mechanical or chemical thromboprophylaxis.[17] The risk is higher in patients with complex acetabular fractures, associated injuries, when the time to surgery is longer that 2 weeks, and age greater than 60 years.[17] High index of suspicion for DVT is needed in these patients even if they are anticoagulants.

DIFFERENTIAL DIAGNOSIS

Pain can be referred from a multitude of areas. A detailed history and physical examination will often elicit the cause of a patient's pain. The causes of pelvic pain after trauma are outlined in Table 46.2. Thorough examinations of the back, abdomen, and lower extremities are necessary to exclude referred pain and associated injuries.

Coccydynia also can occur without fracture and is caused by trauma during parturition, faulty posture, and midline disk herniation (caused by nonsegmental referral of pain from irritation of the dura). Other causes include lumbar facet arthropathy, compression of the sacral roots, neuralgia from sacral plexopathy or sacrococcygeal neuropathy, infections, and local tumors.

TABLE 46.2 Differential Diagnoses of Pelvic Pain

Nontraumatic Causes	Traumatic Causes
• Appendicitis	• Acetabular fracture
• Colon cancer	• Back pain
• Constipation	• Femur fracture
• Cystitis	• Herniated disk
• Diverticulitis	• Hip fracture
• Ectopic pregnancy	• Muscle strain/sprain
• Endometriosis	• Pelvic fracture
• Fibroids	• Tendon/ligamentous strain
• Inflammatory bowel disease	• Vertebral fracture
• Intestinal obstruction	
• Miscarriage	
• Nephrolithiasis	
• Pelvic inflammatory disease	
• Prostatitis	
• Ruptured ovarian cyst	
• Testicular/ovarian torsion	

DIAGNOSTIC TESTING

Radiology

Plain Radiography

Routine radiographs of the pelvis are not necessary after blunt trauma if the patient is asymptomatic, awake, and alert and has normal findings on physical examination of the pelvis, including lack of tenderness to lateral and anteroposterior compression, direct pressure applied to the symphysis pubis, and a negative straight leg raise. However, routine anteroposterior plain radiography is indicated for patients with severe mechanisms of injury, such as MVC, pedestrian struck by motor vehicle, or fall greater than 10 feet, who are symptomatic or whose examination is compromised by either a decreased level of consciousness or distracting injuries.

On the anteroposterior radiograph, the symphysis pubis is normally no more than 0.5 cm wide, and a small (1- or 2-mm) vertical offset of the left and right pubic rami is normal. Overlapping at the symphysis pubis is abnormal and is the result of a crushing injury. Normally, the sacroiliac joint is approximately 2 to 4 mm wide.

On the anteroposterior view, the degree of pelvic rotation caused by technique and positioning can be judged by the presence of asymmetry in the size and shape of the left and right obturator foramina and iliac wings. Diastasis of the sacroiliac joint also causes an asymmetric appearance of the obturator foramina and the iliac wings. If there is displacement into external rotation, the affected iliac wing appears broader and the anterior iliac spine appears more prominent. Avulsion fractures of the fifth lumbar transverse process by the iliolumbar ligament often accompanies a sacroiliac joint disruption or a vertical sacral fracture and is a valuable clue to posterior arch injuries (see Fig. 46.11 and Box 46.4).

Several studies have shown that plain pelvic radiography has insufficient sensitivity and specificity to definitively identify or exclude pelvic fractures, and plain radiography is not generally necessary when abdominopelvic CT evaluation is obtained.[18] In particular, sacral fractures and sacroiliac joint disruptions are not well visualized on the anteroposterior view. However, the addition of inlet and outlet views of the pelvis increases the sensitivity and specificity of plain radiographs in detecting significant pelvic fracture (Fig. 46.15). Sacroiliac joint disruption should be considered in all patients with presumed stable

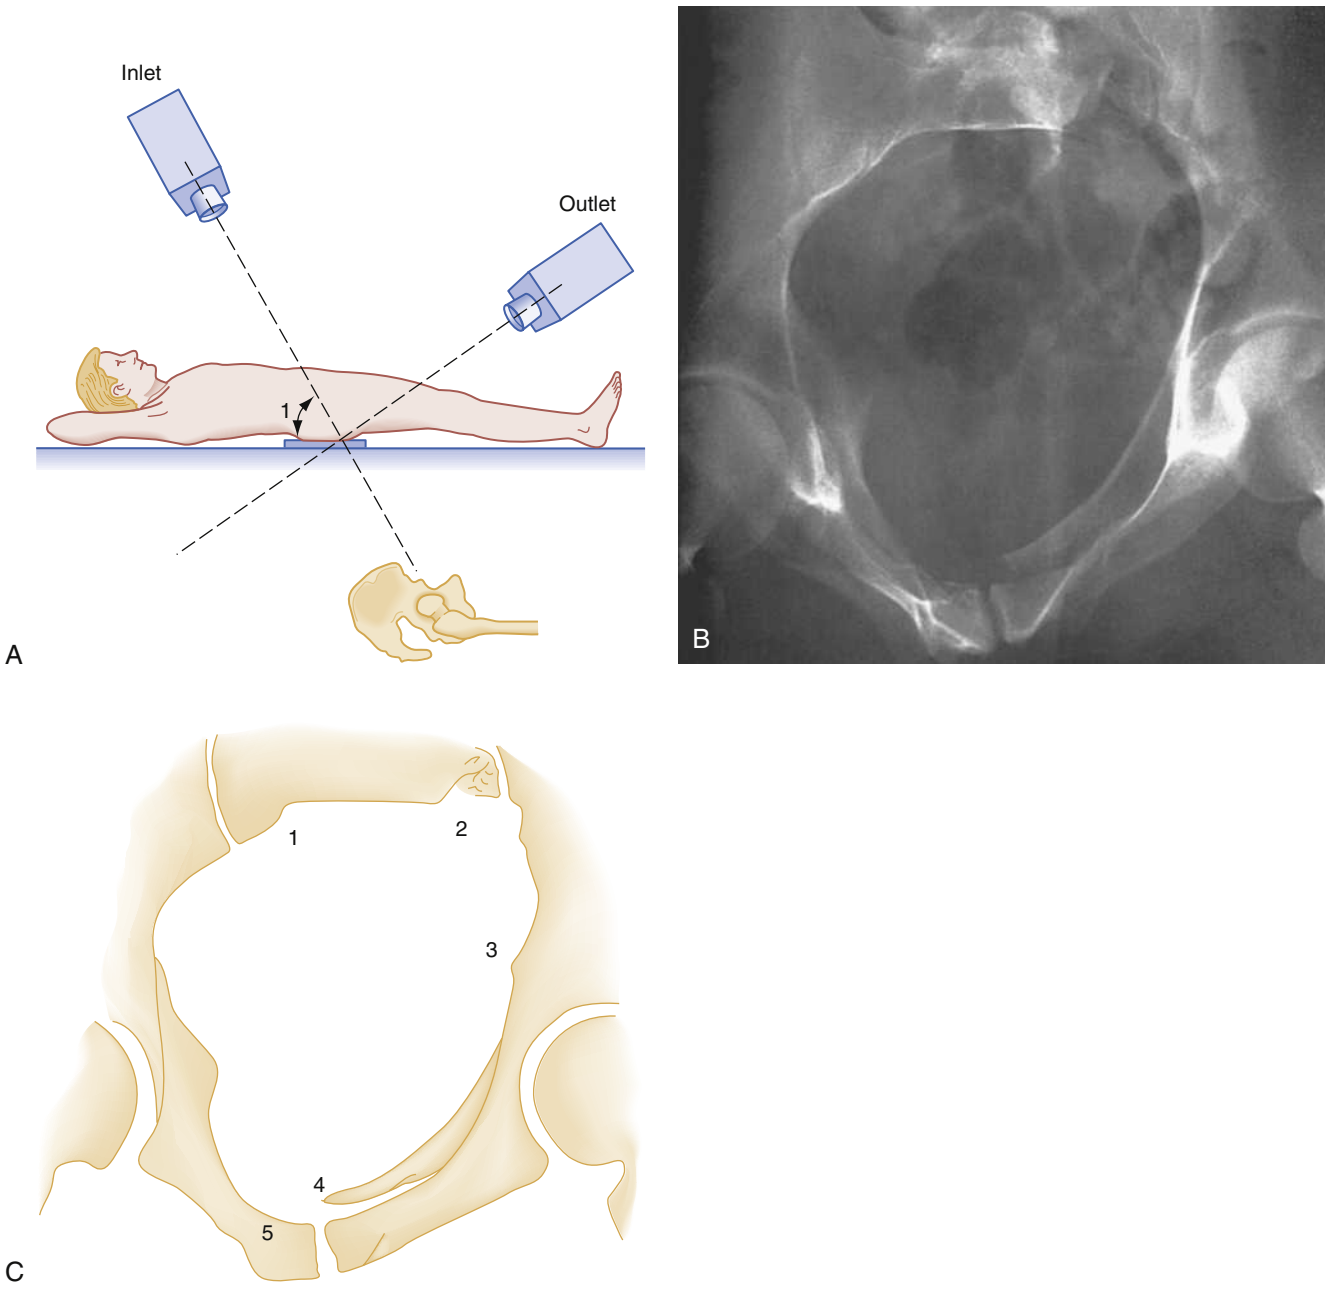

Fig. 46.15 (A) The inlet and outlet views. The inlet view is angled 60 degrees to the plate from head to feet; the outlet view is angled 30 degrees in the opposite direction. Both views can be obtained with a portable machine if necessary. Injuries to the sacrum and sacroiliac joint are commonly difficult to visualize with the anteroposterior view only. The combination of all three views allows the identification of virtually all significant injuries to the bony pelvis. (B) Inlet of pelvis is well demonstrated in this radiograph of a unilateral vertical shear fracture with cephalad and posterior displacement of the left hemipelvis. (C) Schematic of unilateral vertical shear fracture. *1,* Normal sacral ala on the right side; *2,* left sacral ala is indistinct because of a vertical fracture, and the cephalad and posterior displacement of this hemipelvis is shown by this inlet projection; *3,* ischial spine on the left is partially obscured by bowel gas, but it is located more cephalad compared with the right spine because of cephalad displacement of the left hemipelvis; *4,* fractured left superior pubic ramus with displacement cephalad; *5,* the inlet view is taken looking through the superior and inferior pubic rami, which are superimposed so that the obturator foramina are not seen.

anterior pelvic ring injuries with complaints of posterior pelvic pain for whom CT scanning is not anticipated.

When patients are too unstable to undergo CT investigation, or when significant hemorrhagic shock is present in the context of clinically suspected pelvic fracture, the anteroposterior pelvic radiograph is useful to screen for the pelvic injuries that are most often associated with major blood loss requiring urgent intervention. Findings that predict the need for a blood transfusion are highlighted in Box 46.8. Any of these signs could be associated with posterior pelvic injury. Therefore, plain radiography can be a vital test for patients who are unstable, those who are suspected to have unstable pelvic fracture on clinical examination, or those for whom CT cannot be immediately performed. These

BOX 46.8 Factors Predicting the Need for a Blood Transfusion in Patients With a Pelvic Fracture

- Displaced obturator ring fractures
- Displacement ≥0.5 cm of any fracture site in the pelvic ring in combination with a displaced symphysis pubis
- Obvious vertical displacement of the posterior pelvis
- Open-book fractures
- Shock index ≥0.9[36]

Tile C fractures as associated with the highest transfusion requirements.

studies may alert the clinician of the need for surgery, angiography, or other definitive management of pelvic hemorrhage.

Computed Tomography

CT is the imaging test of choice for evaluating the injured pelvis. If plain radiographs are negative and there is suspicion of an occult fracture, the sensitivity of clinical CT reports for detection of any type of fracture of the proximal femur, pelvis, or sacrum is 88%.[19] CT provides detailed visualization of the posterior arch and rotational deformities that indicate the relative stability of the pelvic ring. The acetabulum, which can be difficult to assess with plain radiographs, is well demarcated with CT. Furthermore, abdominopelvic CT provides detailed information about concomitant injury to abdominal organs, which aids in the planning of laparotomy, external fixation of the pelvis, angiography, and definitive orthopedic management. Controversy exists regarding whether all high-risk patients should undergo a "pan-scan," which is comprised of CT scanning of the head, neck, chest, abdomen, and pelvis, or whether a selective approach is better, using clinical indications to guide CT utilization. Proponents of pan-scanning argue that selective scanning of high-energy trauma patients leads to a high miss rate for important diagnoses that alter treatment plans. Although selective CT scanning misses some injuries, fewer than 5% of those missed injuries require a change in the treatment plan. CT imaging should be based on the evaluation of the patient, accounting for mechanism of injury, hemodynamic status, and suspicion of injury on physical examination. Some patients will require a pan-scan but obtaining this series of imaging on all patients meeting certain global criteria results in unnecessary radiation exposure, resource use, and expense. In general, CT scanning protocols are based on institutional preferences, guided by the literature. Imaging of the multiple-trauma patient is discussed in Chapter 32.

Unless a patient requires an immediate lifesaving surgical intervention, it is recommended that CT be used to evaluate patients with high-energy mechanisms of injury if pelvic fracture is suspected or has been confirmed by plain radiography; in order to better delineate the injury.

Evaluation of Hemorrhage

Hemorrhage is the most devastating complication of pelvic fracture. In the original series of high-energy pelvic injuries used to formulate their classification system, Burgess and colleagues found that an average of 14.8 units of blood were transfused in the anteroposterior compression group, 9.2 units in the vertical shear group, and 3.6 units in the lateral compression group. The correlation between transfusion requirements and type of pelvic fracture has been confirmed in other studies that demonstrate that unstable fracture patterns (including Tile class C and Young and Burgess lateral compression) increase the need for transfusion, interventional radiologic embolization, and risk of mortality.[20]

Major pelvic hemorrhage results from lacerations of the rich vascular network supplying the pelvis in the retroperitoneal space. Pelvic hemorrhage is commonly venous in origin; therefore, an intact peritoneum may help contain or tamponade a retroperitoneal hematoma. However, it is possible for bleeding to extend beyond the retroperitoneum and dissect into the anterior abdominal wall or through the peritoneum into the abdominal cavity. Bleeding can also occur from the marrow at the fracture sites. Finally, coagulopathies can lead to persistent retroperitoneal bleeding and should be considered when the patient does not respond to fluid and blood replacement.

BOX 46.9 Pelvic Fracture–Related Hemorrhage: Goals in the Emergency Department

1. Resuscitation: Recognize the patient who is in hemorrhagic shock and initiate blood transfusion early in the resuscitation.
2. Recognition: Realize that patients with posterior arch injuries are at higher risk for pelvic hemorrhage.
3. Evaluation: Identify associated non-pelvic injuries (especially head, chest, and intra-abdominal) that contribute immensely to an increase in mortality in patients with pelvic fracture.
4. Stabilization: Wrapping the pelvis in a sheet and towel clamps is the easiest way to immobilize the pelvis in the emergency department. Stabilization by external fixation or pelvic C-clamp should be performed by orthopedic surgeons.
5. Control of pelvic bleeding: Angiography is highly effective in treating pelvic arterial hemorrhage. Pelvic packing during laparotomy is another way of controlling bleeding. Institutional practices determine if one or both techniques are used.
6. Prevention: Avoid hypothermia and maintain body temperature above 36°C as this is associated with increased hemorrhage and decreased success if embolization is required.

The combination of pelvic and intra-abdominal bleeding is associated with life-threatening outcomes. Major pelvic injury is associated with intra-abdominal injuries in up to one-third of cases, particularly involving the liver and spleen. In the patient with pelvic fracture who is in shock, it is critical to establish early in the clinical course whether hemorrhage is occurring within the abdominal cavity and thus necessitating laparotomy. Diagnostic strategies for evaluation of hemorrhage resulting from pelvic fracture include diagnostic peritoneal lavage (DPL), bedside ultrasonography, and CT. Regardless of which is chosen, unnecessary laparotomy should be avoided at all costs, because a negative abdominal exploration is associated with a higher mortality rate for hemodynamically unstable patients with pelvic fractures.

Factors that have been associated with increased hemorrhage risk and need for hemorrhage control interventions are patients with Tile classification type B and C fracture patterns, hypothermia, and elevated serum lactate levels.[21] Box 46.8 lists factors that predict the need for a blood transfusion, and Box 46.9 summarizes goals for the ED treatment of pelvic fracture-related hemorrhage.

Diagnostic Peritoneal Lavage

DPL, once widely accepted as an accurate means of establishing the presence of intra-abdominal hemorrhage, has been largely supplanted by bedside ultrasound and CT imaging. When DPL is used, a supraumbilical peritoneal aspirate that is negative for blood indicates that the peritoneal cavity is not a major source of bleeding or a significant contributor to hemorrhagic shock. In the absence of another identified source of blood loss, a negative peritoneal aspirate in a patient with a major pelvic fracture and hypotension indicates pelvic hemorrhage.

Gross aspiration of blood suggests major intra-abdominal hemorrhage. Pelvic stabilization is indicated, with urgent laparotomy for hemodynamically unstable patients.

Ultrasound

Focused assessment with sonography in trauma (FAST) is the standard approach used to identify free intraperitoneal fluid in the trauma patient. An important caveat is that FAST is not helpful for evaluating the retroperitoneal space, where pelvic hemorrhage commonly occurs. However, FAST has essentially replaced DPL to identify whether intraperitoneal bleeding is the cause of the hypotension, leaving the pelvis as the probable source, when FAST is negative. Although a positive FAST study is widely used to decide whether to perform laparotomy in a hemodynamically unstable patient, its reliability in patients with major pelvic injury has been questioned. Historically, sensitivity has been reported at about 80% and specificity 95% for the detection of hemoperitoneum in patients with pelvic fracture. However, a recent case series of 81 patients in refractory shock showed that the FAST examination had a sensitivity of 96% and specificity of 96%.[22] The false-negative and -positive rates for FAST were 2% and 7%, respectively. The use of FAST in the evaluation of blunt abdominal trauma is discussed in Chapter 38.

Computed Tomography

CT is the diagnostic test of choice for detecting pelvic and intra-abdominal injuries. It reveals bleeding in the peritoneal and the retroperitoneal spaces. In many cases, CT of the pelvis with intravenous contrast can distinguish a stable hematoma from ongoing bleeding from pelvic arteries. The presence or absence of extravasated intravenous contrast material, indicated by a blush on CT, is useful in predicting which patients will require therapeutic angiography. However, absence of extravasation does not exclude the possibility of ongoing pelvic bleeding. Pelvic computed tomography angiography (CTA) can more accurately localize active pelvic bleeding and also distinguish bleeding from arterial and venous sources.[23] This distinction can have great impact on the decision to perform therapeutic angiography for active arterial bleeding.

MANAGEMENT

Resuscitation

Blunt trauma patients who have the combination of pelvic ring fractures and hemorrhagic shock have a mortality rate of approaching 50% and may require massive quantities of blood products. It is estimated that nearly 80% of deaths can be attributed to early uncontrolled hemorrhage and delays in hemostatis.[24] For patients in shock, resuscitation is described in Chapters 3 and 32.

For patients with pelvic fractures, achieving a normal pulse and blood pressure with fluid resuscitation alone in the ED may be an unrealistic goal. Such attempts may contribute to ongoing bleeding and may delay definitive treatment that can halt the hemorrhagic process.

Intravenous access in the lower limbs should be avoided in patients with severe pelvic fractures, because infused fluids and blood products might be lost through venous bleeding into the retroperitoneal space.

Box 46.9 details methods for controlling hemorrhage during the ED management of patients with pelvic fractures.

Control of Hemorrhage

In addition to blood transfusion, two important therapeutic modalities for control of hemorrhage are mechanical stabilization of the pelvis and angiographic embolization. There has been some debate as to which of these modalities should take precedence, and this has been predicated on institutional availability. As a general rule, angiography with therapeutic embolization of bleeding arteries is more effective than and takes precedence over invasive external fixation.

Stabilizing the Pelvis

Noninvasive techniques. The most readily available means to stabilize the pelvis quickly in the ED is a sheet and towel clamps. Wrapping the pelvis tightly with a sheet and securing it with towel clamps can reduce an open-book pelvic injury (Fig. 46.16) and the potential for volume and blood loss in the pelvis. We recommend early pelvic binder use, as this bedside maneuver is associated with improved survival and lower mean blood transfusion volume and mortality rates.[25]

Other commercial circumferential compression devices have been developed to facilitate noninvasive stabilization of the pelvis. Cadaveric studies suggest that these devices are effective at reducing an open-book pelvis. Patients with exsanguinating pelvic hemorrhage treated with a noninvasive splinting device appear to fare as well as those for whom formal external fixation was performed emergently.

Patients with open-book pelvic injuries are most likely to derive benefit from tight wrapping of the pelvis. This maneuver might not be desirable when lateral compression forces have already internally rotated the hemipelvis, where indiscriminate forceful wrapping could worsen the degree of displacement. Therefore, judgment is required to discern whether one is wrapping the pelvis to *reduce* the volume of an externally rotated pelvis or *splinting* a pelvis to minimize movement, especially when the patient is repositioned.

Formal external fixation. External fixation of the pelvis is performed by orthopedic surgeons to prevent movement at fracture sites and to control bleeding. Application of an external fixator does not appear to decrease morbidity or mortality rates but may improve clinical outcome by limiting hemorrhage and restoring mechanical integrity. Application of a fixator is a time-consuming process; it should not be attempted if it will delay more definitive treatment of pelvic bleeding by angiography or the treatment of other sources of severe blood loss. The timing of the application of the external fixator requires coordination among the emergency medicine physician, trauma surgeon, orthopedic surgeon, and interventional radiologist. Early surgical consultation is needed for efficient planning and prioritization of surgical management.

Many stable anteroposterior and lateral compression fractures can be treated definitively with an external fixator. When the pelvis is vertically displaced, traction combined with external fixation is necessary to reduce the pelvis, pending definitive open surgical repair. Most fixators can be constructed to allow convenient surgical access to the abdomen and pelvis. The specific mode of invasive fixation is specific to the institution and the orthopedic or trauma consultant.

Angiography and Embolization

Arteriography and venography have been evaluated for their utility in managing hemorrhage associated with pelvic fractures. Although pelvic bleeding is commonly venous in origin, venography is not useful in management. Extensive anastomoses and valveless bidirectional collateral flow make venous embolization impractical. In contrast, arteriography is superior at both diagnosing and managing arterial bleeding.

Angiography is indicated when hypovolemia persists in a patient with a major pelvic fracture despite attempts at controlling hemorrhage by other means. It is difficult to determine whether bleeding is venous or arterial in origin until angiography is performed. An inadequate response to initial resuscitation (defined as failure to maintain a systolic blood pressure above 90 mm Hg after the administration of 2 or more units of packed red cells) and the presence of contrast extravasation on admission CT are indicative of active arterial bleeding. Although the presence of contrast extravasation on CT is an indication for angiography, the absence of contrast blush on CT is not sufficient to rule out serious pelvic bleeding. Sacroiliac joint disruption, persistent systolic blood pressure below 100 mm Hg, hypothermia, elevated lactate levels,

Fig. 46.16 (A) Circumferential pelvic anti-shock sheeting is applied in this example patient. The patient's clothing should be removed before application. The sheet is positioned beneath the patient's pelvis smoothly. The ends of the sheet are crossed in an overlapping manner anteriorly (B) and are pulled taut (C). D, Clamps secure the smooth and snug sheet.

and female gender have been shown to be predictors of the need for embolization at the time of angiography.[21]

The timing of angiography is individualized for each patient, depending on priorities for the treatment of concomitant injuries. Early access to angiography has been associated with reduced mortality, and delays in angiography greater than 60 to 90 minutes, or time to embolization greater than 3 hours, are associated with worse outcomes.[24,26,27] Posterior arch disruptions are associated with the most severe hemorrhage; angiography should be considered at an early stage for patients with this injury. Whether patients undergo angiography from the ED or immediately preceding laparotomy, it is important to be mindful of the logistical delay that occurs in mobilizing the angiography team, so this intervention should be anticipated as early as possible. Transfer to the angiography suite requires orchestrating the necessary personnel and equipment to care for a critically injured patient. The use of mobile angiography equipment in the ED to control pelvic hemorrhage has been reported. This option removes logistical delays while ensuring a greater degree of safety in monitoring patients during the procedure.

The contrast material for arteriography is injected through the femoral artery on the less-injured side or via the upper extremity. The examination starts above the level of the aortic bifurcation and proceeds to selective branches of the internal iliac (hypogastric) artery. Transcatheter embolization with thrombogenic coils, foam, or spherules is used to stop hemorrhage from the branches of the internal iliac artery.

Embolization is highly effective for controlling arterial bleeding, with fewer than 10% of patients requiring repeat procedures because of ongoing bleeding. The complications that can result from embolization include gluteal muscle necrosis, surgical wound breakdown, infections, acute renal failure, impotence, and bladder necrosis.[28] Transcatheter arterial embolization has been associated with a 13.6% complication rate; this rate increases if bilateral internal iliac artery embolization is needed to control bleeding.[28] Other complications that have been reported are femoral pseudoaneurysms, rhabdomyolysis, and post-angiography acute ischemia of the lower extremity.[28]

Initial factors on presentation that predict a successful transarterial embolization in patients with pelvic fractures are prevention of hypothermia with maintenance of body temperature greater than 36°C, maintenance of the respiratory rate at approximately 22 breaths/min, sustained systolic blood pressure approximately 90 mm Hg, maintenance of heart rate of approximately 100 beats/min, associated injuries limited to two organ systems, ISS less than 20, and minor head trauma with a GCS greater than 13.[29]

Hemodynamically Unstable Patients With Pelvic and Intra-Abdominal Hemorrhage

Patients who hemorrhage from both the pelvis and the abdomen have mortality rates above 40% and deserve special consideration. These patients may be too unstable to undergo CT imaging. Prioritizing the need for laparotomy versus angiography in these patients becomes challenging when the need for laparotomy is based on the detection of intra-abdominal fluid by FAST (or DPL). Unnecessary laparotomy performed in patients who are hemodynamically unstable with pelvic fracture further increases their already high mortality rate. In these cases, it is crucial that the general or trauma surgeon, orthopedic surgeon, and interventional radiologist coordinate their efforts to optimize the timing of necessary procedures.

If DPL is performed, gross aspiration of blood is a strong indicator for prompt laparotomy. A positive FAST examination indicates hemoperitoneum, and it is generally accepted that laparotomy should be pursued before angiography in such cases. Given the significant rate of false-negative FAST examinations in patients with pelvic trauma, a single negative FAST examination should not be considered definitive enough to exclude significant intraperitoneal hemorrhage. However, patients with hemorrhagic shock and a negative FAST examination

with adequate windows are more likely to be bleeding from the pelvis injury. When concurrent pelvic bleeding is highly suspected (as with patients with severe open-book pelvic injuries), it is advisable that angiography promptly follow the laparotomy. The use of hybrid operative suites and aortic balloon occlusion may improve outcomes in this subset of patients.[24]

At the time of laparotomy, the orthopedic surgeon will determine if it is appropriate to place an external fixator. Packing the pelvis at the time of laparotomy is a means of achieving hemostasis with pelvic hemorrhage.[30] This procedure has been a mainstay of treating pelvic hemorrhages in selected European centers; it has become much more widely accepted as studies have documented improved mortality rates with its use. Part of the rationale for packing rather than angiography is the fact that pelvic bleeding is more commonly venous in origin, for which arteriography and embolization have no benefit. In contrast, packing might provide tamponade of bleeding from the posterior venous plexus. It is recommended that the pelvis be stabilized before packing to provide solid structural support. Intraperitoneal, retroperitoneal, and extraperitoneal techniques of packing have been described; the retroperitoneal and extraperitoneal approaches have been used rapidly in the ED setting. A systematic review of pelvic packing concluded that, for patients with hemodynamic instability caused by pelvic hemorrhage, packing can be used as a temporizing measure for control of bleeding until more definitive treatments can be initiated.

Resuscitative endovascular balloon occlusion of the aorta (REBOA) is another option for control of bleeding from pelvic fractures.[31] Similar to cross clamping the aorta, this endovascular balloon can be placed in the infrarenal position using the Seldinger technique to occlude the aorta and prevent blood from entering the pelvis. This technique is amendable to out-of-hospital or bedside placement in the ED with ultrasound guidance of the final position of the balloon.[32] Several studies have shown improved mortality in patients with hemorrhagic shock from non-compressible torso and pelvic injuries.[33-35] REBOA is associated with a risk of vascular injury and limb ischemia, so it is restricted to patients in extremis, similar to what is seen with cross clamping of the aorta.[31,35] With appropriate training, REBOA can be a safe bridge to obtain hemodynamic stability until more definitive hemorrhage control can be obtained in the operating room or angiography suite.

DISPOSITION

Disposition of the patient depends on whether or not the fracture is considered stable, and whether there are other injuries or significant comorbidities. Most patients who have stable fractures (such as pubic ram or minor iliac wing fractures) can be discharged to home with adequate analgesics and with crutches or canes, as needed, to aid in weight bearing. Patients with stable coccyx and sacral fractures might benefit from a donut pillow that distributes their weight onto their buttocks and away from the fracture site when seated.

Patients with unstable fractures, hemodynamic compromise, or significant associated injuries require admission to the surgical intensive care unit or hospital equivalent for definitive care. ED management consists of temporarily stabilizing the fracture, addressing any life-threatening injuries, and arranging admission or transfer to a hospital or service that can provide definitive care.

CHAPTER 46: QUESTIONS AND ANSWERS

1. While examining a patient with blunt abdominal trauma, you note blood at the urethral meatus. What is the most appropriate next step in the patient's management?
   a. Order a cystography
   b. Order a retrograde urethrogram
   c. Order a urinalysis
   d. Order an anterograde urethrogram
   e. Order an intravenous pyelography

Answer: b. Blood at the urethral meatus necessitates a retrograde urethrogram followed by a cystogram. Gross hematuria is investigated by a combination of urethrography, intravenous pyelography, cystography, and computed tomography (CT).

2. An avulsion fracture caused by the hamstring muscles most likely involves which of the following structures?
   a. Anterior inferior iliac spine
   b. Anterior superior iliac spine
   c. Iliac crest
   d. Ischial tuberosity
   e. Sacrum

Answer: d. Forceful contraction of the hamstrings can result in an injury of ischial tuberosity. The anterior inferior iliac spine may be avulsed during strenuous contraction of the rectus femoris muscle. A portion of the iliac crest epiphysis may be avulsed by contraction of the abdominal muscles. The anterior superior iliac spine may be avulsed by forcible contraction of the sartorius muscle.

3. A 25-year-old patient involved in a motor vehicle collision (MVC) presents with a suspected unstable pelvic fracture. The vital signs are blood pressure, 90/50 mm Hg; heart rate, 120 beats/min; and respiratory rate, 22 breaths/min. What is the most appropriate next step in this patient's management?
   a. Call trauma service for immediate laparotomy
   b. Call orthopedics for fixation
   c. Chest and pelvis radiographs
   d. Computed tomography (CT) scan of the abdomen and pelvis
   e. Perform serial abdominal and focused assessment with sonography in trauma (FAST) examinations

Answer: c. When patients are too unstable to undergo CT investigation, the anterior/posterior portable radiograph is useful in screening for pelvic injuries that are most associated with major blood loss. Findings with this technique that have been reported to predict the need for transfusion include "open-book" fracture, displacement of 0.5 cm or more at any fracture site in the pelvic ring, and displaced symphysis pubis or obturator ring fracture. Chest radiographs should be performed to rule out associated injuries that might be the cause of the patient's hypotension and tachycardia (e.g., hemothorax, tension pneumothorax, widened mediastinum).

4. Which of the following treatments can provide definitive control of hemorrhage from severe pelvic fracture?
   a. Blood transfusion
   b. Commercial circumferential pelvic compression devices
   c. External fixation
   d. Transfusion of concentrated clotting factors
   e. Wrapping pelvis with sheet

Answer: c. External fixation is an invasive strategy aimed at cessation of pelvic hemorrhage. Options A, B, and E are important for the emergency clinician to quickly stabilize a mechanically unstable pelvic fracture and hopefully minimize bleeding, but these options, per se, are not definitive treatments. Transfusion of blood products is important in overall resuscitation of the patient but does not stop bleeding from pelvic fractures.

5. Which of the following radiographic findings necessitates further evaluation of the pelvic ring?
   a. Asymmetry of the pelvis caused by rotation
   b. Duverney fracture
   c. Sacroiliac joint 4 mm wide on pelvic radiograph
   d. Symphysis pubis 7 mm wide
   e. Transverse fracture of the sacrum

Answer: d. On the anteroposterior radiograph, the symphysis pubis is normally no more than 5 mm wide, and a small (1 or 2 mm) vertical offset of the left and right pubic rami may be normal. Normally, the sacroiliac joint is approximately 2 to 4 mm wide. On the anteroposterior view, the physician may judge the degree of pelvic rotation caused by technique and positioning by the presence of asymmetry.

47

Femur and Hip Injuries

Michael K. Abraham and Michael C. Bond

KEY CONCEPTS

- A hip dislocation is an orthopedic emergency. The likelihood of avascular necrosis (AVN) is related to both the initial degree of trauma and the amount of time the femoral head remains out of joint. Reduction of the hip within 6 h after dislocation significantly decreases the incidence of AVN.
- When a painful hip makes ambulation difficult and plain radiographs do not reveal a fracture, computed tomography (CT) or magnetic resonance imaging (MRI) should be performed. MRI is the gold standard for diagnosis—although this does not need to be completed in the emergency department (ED).
- In patients with intertrochanteric fractures, hemodynamic instability can result from dehydration and blood loss. Up to 70% of patients with these injuries are under-resuscitated.
- It is important to identify acetabular fractures before closed reduction is attempted, because intra-articular bone fragments can interfere with effective reduction.
- In elderly patients, the use of femoral nerve blocks should be considered, due to the potential adverse effects of parenteral opioids.

GENERAL INFORMATION

Foundations

Background and importance—Injuries to the hip and femur are quite common in the emergency setting and are associated with significant morbidity and mortality. Hip and femur pathology, while considered a disease of the elderly, actually occurs among all age groups. While elderly patients are at risk for femoral neck **fracture**s, children can have Perthe disease and slipped capital femoral epiphysis (SCFE), among other pathologies. Women are at increased risk for both femoral neck fractures and intertrochanteric fractures, with a female-to-male ratio of 4:1. More than three-quarters of all hip fractures occur in postmenopausal women over 50 years of age. Perthe disease, or avascular necrosis (AVN) of the femoral head, occurs in children between 2 and 14 years old, with a peak age of onset of 5 years old. The incidence of SCFE peaks with the onset of puberty. While fractures show a female preponderance, both SCFE and Perthe disease have a higher incidence in males.

Anatomy of the Hip and Femur

Skeletal Anatomy

The femur is the longest and strongest bone in the human body and is routinely subjected to substantial forces during powerful muscle contraction and weight transmission. It consists of the femoral head, neck, and shaft. The femoral head is firmly seated in the **acetabulum**, reinforced by the labral cartilage. The well-developed capsule, overlying ligaments, and proximal musculature of the lower extremity add strength to the joint (Fig. 47.1). Structurally, the femoral neck serves as an oblique strut between the pelvis (the horizontal beam) and the shaft of the femur (the vertical beam) (Fig. 47.2). The length, angle, and narrow circumference of the femoral neck permit substantial range of motion at the hip, but these same characteristics subject the neck to significant shearing forces.

The type of bone in the femur changes depending on location, which affects fracture patterns. The bone in the femoral head, neck, and intertrochanteric region is predominantly cancellous, which is less resistant to torsional forces. Distal to the intertrochanteric region, including the subtrochanteric region and femoral shaft, the bone is cortical, which requires increased force to fracture. At the distal metaphysis, the femur widens as the cortical bone thins, lessening its resistance to stress.

Musculature

The musculature of the hip and thigh is the largest and most powerful in the human body. Grouped according to the primary action at the hip, the muscles in this region of the body are located within three compartments, each containing associated nerves and vessels (Table 47.1). Knowledge of the major muscle actions offers insight into common injury patterns and deformities (Fig. 47.3).

Arterial Supply

The arterial supply of the femoral head, neck, and shaft arises from different sources. The major arterial supply to the femoral head and neck comes from the medial and lateral circumflex arteries, which are branches of the femoral artery (Fig. 47.4). These branches form an extracapsular arterial ring around the femoral neck. Another blood supply source to the femoral head typically arises from the obturator artery and courses through the ligamentum teres.

As the external iliac artery passes beneath the inguinal ligament, it becomes the common femoral artery. At this point, the artery is located midway between the anterior superior iliac spine (ASIS) and the symphysis pubis. Approximately 3 to 4 cm distal to the inguinal ligament, the deep femoral artery branches off. The deep femoral artery is predominantly responsible for the vascular supply of the femur. It runs posterolaterally to the superficial femoral artery, supplies the hamstrings, and terminates in the distal third of the thigh as small branches supply the belly of the adductor magnus. The superficial femoral artery continues to pass along the anteromedial aspect of the thigh and terminates at the junction of the middle and lower thirds of the thigh. Here, the superficial femoral artery passes through the adductor hiatus and becomes the popliteal artery.

Venous System

In the proximal two-thirds of the thigh, the common and superficial femoral veins lie adjacent to the common and superficial femoral arteries. At the inguinal ligament, the common femoral vein is posterior and medial to the common femoral artery and moves to the lateral position as it passes distally. The deep femoral vein and the greater saphenous

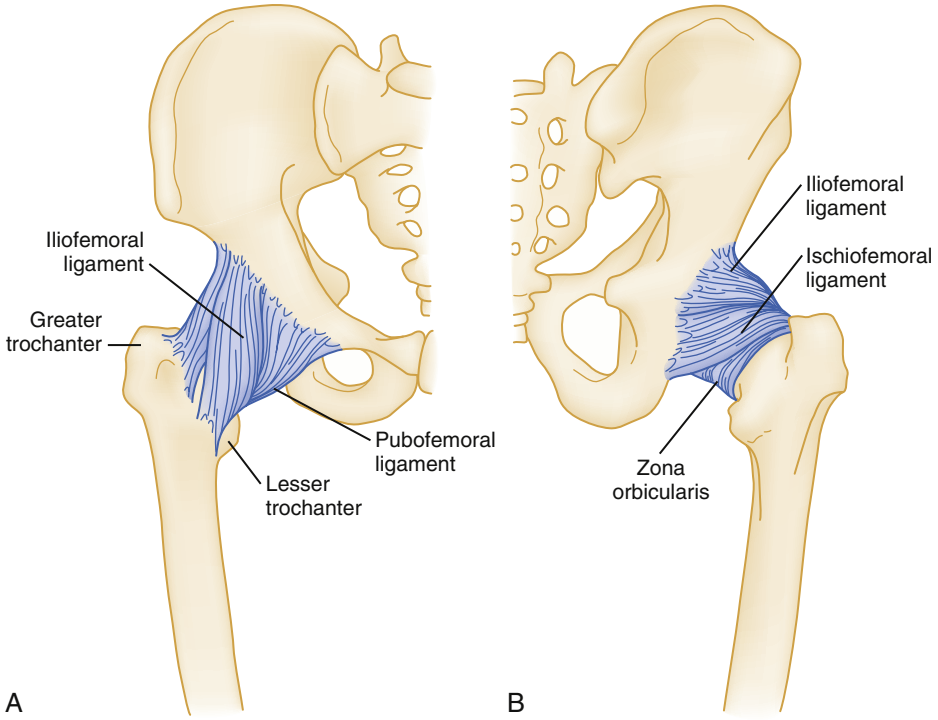

Fig. 47.1 The ligaments of the hip combine to form a tough joint capsule, as seen on both anterior (A) and posterior (B) views.

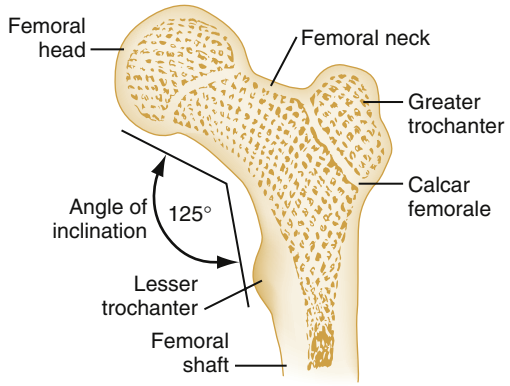

Fig. 47.2 Bony Architecture of the Proximal End of the Femur.

vein are the two main tributaries to the common and superficial femoral veins. The deep femoral vein and artery run in parallel as the vein joins the superficial femoral vein just distal to the inguinal ligament. The greater saphenous vein arises in the dorsum of the foot and ascends anterior to the medial malleolus. This vein is relatively superficial as it traverses up the medial aspect of the leg to join the common femoral vein distal to the inguinal ligament.

Nerves

The femoral and sciatic nerves are the major nerves within the thigh. The femoral nerve is the largest branch of the lumbar plexus; it passes under the inguinal ligament lateral to the femoral artery and divides into anterior and posterior branches soon after entering the thigh. The sensory divisions of the anterior branch, the intermediate and medial cutaneous nerves, supply sensation to the anteromedial aspect of the thigh. The motor division of the anterior branch innervates the pectineus and sartorius muscles. The posterior femoral branch gives off the saphenous nerve, which supplies sensation to the skin along the medial aspect of the lower part of the leg. The posterior branch also supplies motor function to the muscles of the quadriceps femoris group.

The sciatic nerve is the largest peripheral nerve in the body. It arises from the sacral plexus. The sciatic nerve exits the pelvis through the greater sciatic foramen and travels through the posterior thigh; it extends from the inferior border of the pyriformis muscle to the distal third of the thigh. The sciatic nerve gives off articular branches that supply the hip joint. In the thigh, muscular branches innervate the adductor magnus and hamstring muscles. Just proximal to the popliteal fossa, the sciatic nerve divides to form the tibial and common peroneal nerves.

Pathophysiology and Key Patterns of Injury

Fractures and Trauma of the Femur and Hip

The vast majority of hip fractures occur in elderly patients with preexisting bone disease who sustain low-energy trauma, usually a ground-level mechanical fall. In young, healthy individuals, high energy trauma, such as a motor vehicle collision (MVC) or a fall from a significant height, is responsible for most fractures.

Twenty percent of patients with hip fracture die during the first year after the injury, mostly from sequelae of the fracture rather than the fracture itself. One-third of patients require nursing home placement, and less than one-third regain their pre-fracture level of physical function. The economic impact of these fractures is significant.

Osteoporosis of the Femur

Osteoporosis is the leading cause of hip fracture. The pathophysiology of osteoporosis is not completely understood, but strong associations with hormonal changes related to aging, genetic predisposition, vitamin D deficiency, lack of physical activity, and smoking have been recognized. Severe osteoporosis and hip fractures are most common in elderly white women; however, a decrease in bone density after age 30 is seen across all demographic groups. The trabeculae of the femoral head and neck strengthen the bone and therefore support the large

TABLE 47.1 Structures Within Compartments of the Thigh

Compartment	Muscles	Nerves	Vessels
Anterior	Quadriceps femoris, sartorius, iliacus, psoas, pectineus	Lateral femoral cutaneous	Femoral artery and vein
Medial	Gracilis, adductor longus and magnus, obturator externus	Obturator	Profundus femoris artery, obturator artery and vein
Posterior	Biceps femoris, semitendinosus, semimembranosus, adductor magnus	Sciatic, posterior femoral cutaneous	Profundus femoris artery branches

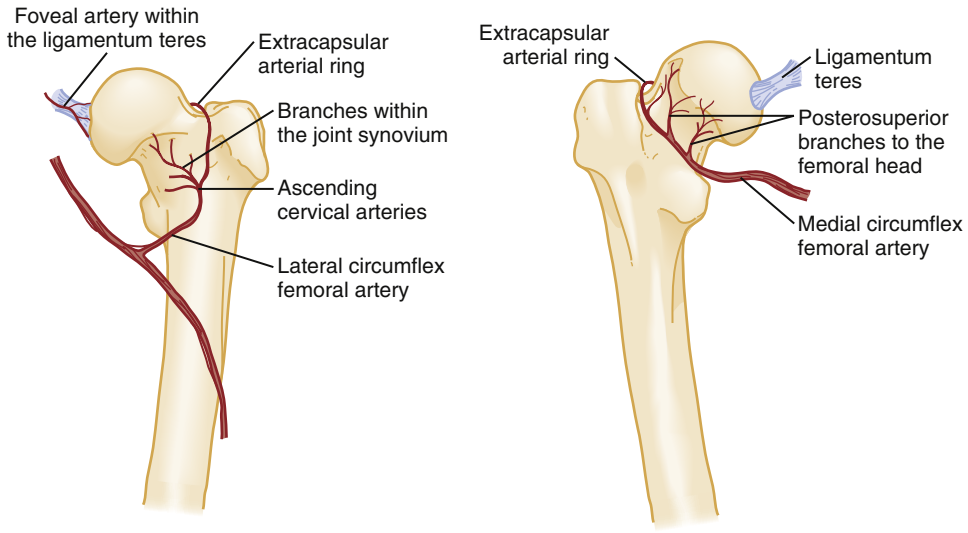

Fig. 47.4 The arterial blood supply of the femoral neck and head is provided to varying degrees by three sources: the ascending cervical arteries, the arterial branches within the marrow *(not illustrated),* and the foveal artery within the ligamentum teres.

mechanical forces produced across the hip joint. As osteoporosis progresses, the trabeculae disappear and increase the risk of fracture. Osteoporosis currently affects more than 10 million people in the United States and is projected to affect approximately 14 million adults older than 50 years by the year 2020. The number of hip fractures attributable to osteoporosis is expected to be more than 6 million by the year 2050, although the incidence in women has been decreasing in recent years. An important factor to consider is that while age standardized rates may be falling, the effects of an aging population significantly overcomes this decline, leading to an overall increase in incidence.[1,2]

Osteoarthritis of the hip. A large percentage of the American population experiences chronic pain from degenerative osteoarthritis

Fig. 47.5 Radiographic evidence of the development of osteoarthritis or degenerative joint disease of the hip is demonstrated with serial radiographs in the same patient over several years. (A) The initial symptoms are more dramatic than would be expected with the radiographic findings of increased sclerosis along the weight-bearing surface of the superior acetabulum. (B) The joint space is lost. (C) Erosion of the head and acetabular surfaces and reactive bony cystic changes are now evident.

of the hip. Disability often results from persistent pain, limited physical mobility, and sacrcopenia.[3] The progression of osteoarthritis can be demonstrated with serial radiographs of the affected hip (Fig. 47.5); however, radiographic findings do not necessarily correlate with symptoms.

Avascular Necrosis

When a patient has an increasingly painful hip, buttock, thigh, or knee and no history of recent trauma, AVN of the femoral head and sciatica should be considered. AVN has been referred to as *aseptic necrosis, ischemic necrosis,* and *osteonecrosis*. It is the result of ischemic bone death of the femoral head after compromise of its blood supply (Fig. 47.6). AVN is bilateral in 40% to 80% of patients. It is common in relatively young patients, the mean age at diagnosis being 38 years old. Although a specific causative disorder is not identified in 20% of cases, known atraumatic causes include chronic corticosteroid therapy, chronic alcoholism, hemoglobinopathy (e.g., sickle cell anemia), dysbarism, and chronic pancreatitis. AVN is an emerging complication associated with human immunodeficiency virus (HIV) infection. It is unclear whether the pathologic agent is the virus itself or an adverse side-effect of the treatment.

Traumatic AVN, a subacute manifestation after hip **dislocation** or femoral neck fracture, is a direct result of disruption of the blood supply to the femoral head. It is more common in males and African Americans. The incidence of AVN as a subacute complication is clearly related to both the initial degree of trauma and the amount of time the femoral head remains dislocated. Multiple studies have demonstrated a relationship between the length of time the hip is dislocated and the rates of AVN: it develops in about 5% of patients when **reduction** is performed within 6 hours and as many as 60% when reduction occurs after 12 hours. For this reason, *a hip dislocation is an orthopedic emergency*. The emergency clinician should perform reduction as soon as possible and definitely if orthopedic consultation will be delayed more than 6 hours.

Even with optimal treatment, owing to the tenuous blood supply to the area, femoral neck fractures can be complicated by AVN in up to 20% of cases. Immediately after fracture, bleeding may cause high intracapsular pressure and a tamponade effect on the femoral head, thereby impairing the blood supply. In contrast, intertrochanteric and subtrochanteric fractures are located in an area with a rich extracapsular arterial supply; therefore, AVN is a rare complication of these fractures.

Fig. 47.6 Avascular Necrosis of the Left Femoral Head. Note the asymmetry of the joint and the collapse of the femoral head.

Myositis Ossificans

Myositis ossificans (or heterotrophic ossification) is pathologic bone formation at a site where bone is not normally found; the thigh and hip muscles are often involved. Traumatic myositis ossificans results most commonly from a direct blow to muscle or from repeated minor trauma. Bleeding into the muscle after trauma produces a local hematoma with subsequent new bone formation within it. Depending on its location, the ossific mass might be palpable, painful, and might limit range of motion.

Myositis ossificans occurs in up to 20% of patients undergoing medical evaluation for thigh contusions, likely related to the severity of the injury. The incidence of myositis ossificans after hip surgery is approximately 2%, and these lesions are clinically significant in 10% to 20% of cases. Increased susceptibility to myositis ossificans has been described in persons with hemophilia and other bleeding disorders in conjunction with soft tissue injury. Radiographically, myositis ossificans appears as irregularly shaped masses of heterogeneous bone in the soft tissues around the joint or along fascial planes (Fig. 47.7). It can be seen as early as 10 to 21 days after injury, but radiographic evidence typically lags behind the onset of symptoms by weeks. Its

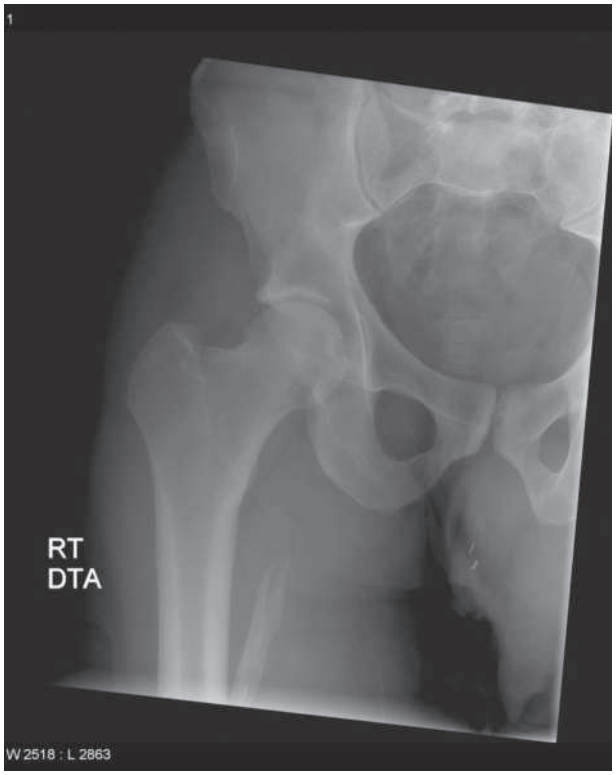

Fig. 47.7 Myositis Ossificans of the Proximal End of the Femur. Lesions can be immature or mature such as this one, with well-organized calcifications.

appearance might simulate primary bone neoplasm, especially when the periosteum is involved. Computed tomography (CT) can be helpful in distinguishing between neoplasm and myositis ossificans, because the lesions of myositis ossificans begin to calcify at the periphery and progress toward the center, and those of osteosarcoma begin to calcify at the center first.

Calcific Bursitis and Calcifying Peritendinitis

Calcification surrounding tendons and bursae or occurring in the joint capsule is referred to as *calcific bursitis* or *calcifying peritendinitis*. The cause of these lesions is unclear. No relationship has been documented between the radiographic findings and acute symptoms. Calcific bursitis of the hip is uncommon, but when it does occur, it most frequently affects the trochanteric bursa (Fig. 47.8). Other possible affected areas include the gluteal muscles and the hip flexors and adductors. The bursal calcification is seen on radiographs as an amorphous, poorly marginated line that is clearly separate from the cortex of the femur.

Neoplastic Disease in the Hip

The most common neoplastic disease of bone is metastatic, generally from breast, kidney, lung, thyroid, or prostate tumors.[4] Primary bone lesions also occur, *the most common being osteoid osteoma* (Fig. 47.9). Bone lesions can be osteoblastic or osteolytic. Patients present with significant bone pain or a large mass that has become irritated or painful (Fig. 47.10). Neoplasms place the patient at higher risk for pathologic fractures, especially if the lesions are large, lytic, or have eroded the cortex. Osteosarcoma and periosteal osteogenic sarcoma should be considered in the differential diagnoses of hip pain.

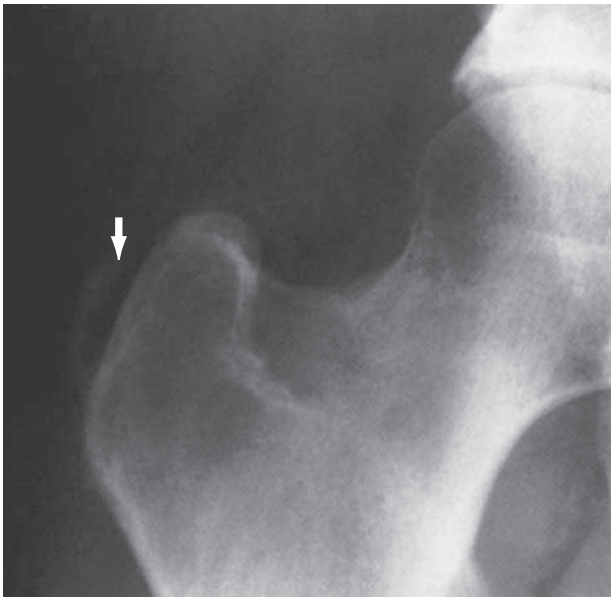

Fig. 47.8 Calcific Trochanteric Bursitis. Faint calcification *(arrow)* in the region of the trochanteric bursa is visible along the lateral cortex of the greater trochanter. (From Harris JH, Harris WH, Novelline RA. *The Radiology of Emergency Medicine*. 3rd ed. Baltimore: Williams & Wilkins; 1993.)

CLINICAL FEATURES OF HIP AND FEMUR PATHOLOGY

History

Injuries and pathologic conditions involving the femur are commonly dictated by age and gender. Pathology of the femur is commonly related to a traumatic incident because the femur is strong and can withstand normal use. Details of the mechanism of injury can aid in predicting an injury, and a detailed description of antecedent trauma or other precipitating events is helpful. Although direct trauma is a common cause of injuries, a thorough past medical history should be obtained, as certain disease entities are associated with hip pathology. Patients who recently altered their level of physical activity or exercise routine could indicate a stress reaction. Information about systemic illnesses or metabolic disorders should be elicited. A previous cancer diagnosis and its treatment with irradiation or chemotherapy could be a predisposing factor, providing clues to pathologic fractures. Any past steroid use, including inhaled steroids, is important to identify because it places patients at higher risk for osteonecrosis and changes in bone density. A linear relationship has been recognized between cumulative steroid dose and the incidence and severity of osteoporosis and hip fracture.

Determination of the location of the patient's pain is paramount, because hip pain can be referred to a number of anatomic locations. In adults, true hip joint pain can be perceived as groin pain, and children with hip pathology often have knee pain as the sole presenting complaint. The review of systems should include information that can help distinguish hip or femur pathology from another cause of the pain. Atypical causes of hip or groin pain include nephrolithiasis, pelvic inflammatory disease, osteomyelitis, malignancies, inguinal and femoral hernias, and lymphadenopathy. A history of low back pain suggests radiculopathy as the cause of the patient's pain.

The history should also focus on concomitant conditions and injuries. Elderly patients with a hip fracture sustained from a fall might be unable to summon help for hours to days. They often have associated dehydration, electrolyte abnormalities, rhabdomyolysis, and renal insufficiency. In addition, the reason for the fall should be determined,

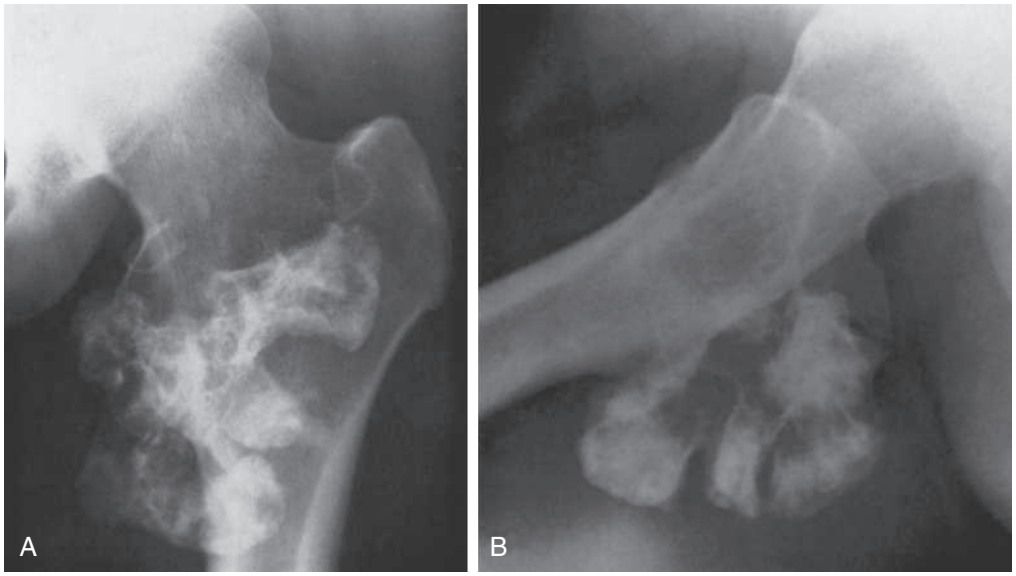

Fig. 47.9 Classic radiographic appearance of a solitary osteochondroma of the femur as seen in the antero-posterior (A) and frog leg lateral (B) views. This lesion is a cartilage-capped bony excrescence, typically arising from the cortex of long tubular bones. (From Harris JH, Harris WH, Novelline RA. *The Radiology of Emergency Medicine*. 3rd ed. Baltimore: Williams & Wilkins; 1993.)

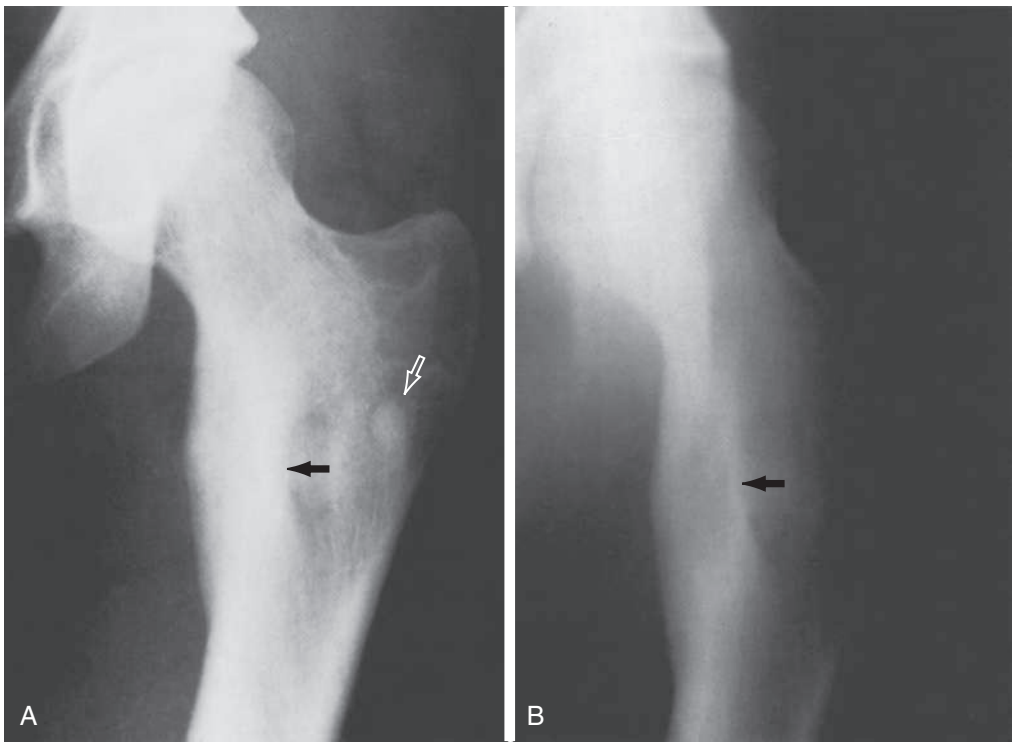

Fig. 47.10 Osteoid osteoma of the femur *(solid black arrow)*. (A) A large focal area of greater density than that of the surrounding femur represents both cortical and endosteal proliferation. The new cortical bone is smooth and sharply delineated, indicative of a nonaggressive process. The open arrow represents a bone island. (B) A frontal-view tomogram demonstrates an oval central radiolucent nidus *(solid black arrow)*. (From Harris JH, Harris WH, Novelline RA. *The Radiology of Emergency Medicine*. 3rd ed. Baltimore: Williams & Wilkins; 1993.)

as it may reveal other comorbid conditions (e.g., syncope, cardiac dysrhythmias, polypharmacy use, alcoholism). Sedative and antihypertensive medications predispose elderly patients to falling. With a fall, elderly patients might sustain additional injuries, most commonly, the fracture of a vertebral body or wrist. Cervical spine and intracranial injuries should also be considered, especially in patients taking oral anticoagulants. Forty to 75% of young patients with a hip fracture resulting from high-energy mechanisms have concomitant injuries.

Physical Examination

Patients with femoral pathology can have a multitude of presentations; therefore, a thorough physical examination is important. Due to the

major forces that are sustained in multisystem trauma, hypotension is a problem commonly encountered during the initial resuscitation. Hypotension, neurovascular compromise, or suspicion for multiple injuries are indications for transfer to a specialized trauma center.

After life-threatening conditions have been addressed, the injured extremity can be evaluated carefully. The position of the leg can offer a clue to radiographic findings. External rotation, abduction, and shortening suggest a displaced femoral neck fracture. External rotation with shortening suggests an intertrochanteric fracture. Visual inspection may reveal pallor, ecchymosis, asymmetry, or deformity. The presence of abrasions, lacerations, and open wounds may indicate forces that caused the injury and direct the evaluation for concomitant fractures. Nondisplaced fractures, including stress fractures, should not produce limb shortening or rotational deformities but will be painful on passive range of motion, particularly internal and external rotation. In patients with obvious deformities, testing range of motion should be deferred until after radiographs have been obtained and vascular integrity has been verified.

Systematic examination of the injured extremity may reveal focal tenderness or warmth suggesting injury or infection. Active and passive range of motion and assessment of muscle strength, though offering important information, are frequently limited by pain. A detailed neurovascular assessment is vital, as femoral nerve and arterial injuries often occur in conjunction with subtrochanteric and femoral shaft fractures or anterior hip dislocations. The sciatic nerve can be injured with a hip fracture or posterior hip dislocation. Neurologic examination includes evaluation of light touch, pinprick sensation, and proprioception. The examination should also assess for any signs of arterial injury indicating a rapidly expanding hematoma. Femoral, popliteal, dorsalis pedis, and posterior tibial pulses should all be assessed. Comparative blood pressures obtained by Doppler examination in the injured and uninjured extremities (arterial pressure index) are useful in diagnosing occult femoral arterial injuries. The ankle-brachial index (ABI) also can be determined by comparing the systolic pressures of the affected extremity and the ipsilateral arm. An index less than 0.9 necessitates further diagnostic studies. Although acute compartment syndrome of the thigh is rare, consideration should be given to this diagnosis if the patient sustained a severe mechanism of injury and has tense swelling in the thigh.

DIFFERENTIAL DIAGNOSES

A detailed history and physical examination often elicit the cause of the pain. Patients with hip and thigh pain can have pain referred from a multitude of other areas. If a fracture is not apparent, in patients who are experiencing hip or thigh pain, emergency clinicians should consider other causes. The differential diagnoses of hip pain without obvious fracture on radiographs are listed in Box 47.1.

In the setting of trauma, it is imperative that a thorough physical examination excludes referred pain and associated injuries. Most patients who arrive in the emergency department with hip or thigh pain can provide a clear history of a traumatic event. Hip or knee pain in the young, in athletes, and in the elderly deserves further investigation, even when minimal or no trauma has been reported. This elderly patient population commonly has an occult hip disruption, occasionally involving the femur. Senile osteoporosis is the leading cause of femoral neck fractures after minor trauma; pathologic fractures of the femur can result from metastatic, metabolic, or endocrine diseases.

BOX 47.1 Differential Diagnoses of a Painful Hip Without Obvious Fracture

- Referred pain (lumbar spine, hip, or knee)
- Avascular necrosis (AVN) of the femoral head
- Degenerative joint disease or osteoarthritis
- Herniation of a lumbar disk
- Diskitis
- Transient synovitis of the hip
- Septic arthritis
- Bursitis
- Tendonitis
- Ligamentous injuries of the knee or hip
- Occult fracture
- Slipped capital femoral epiphysis (SCFE)
- Perthes' disease
- Tumor (lymphoma)
- Deep venous thrombosis
- Arterial insufficiency
- Osteomyelitis
- Iliopsoas abscess
- Retroperitoneal hematoma
- Inguinal hernia
- Inguinal lymphadenopathy
- Genitourinary complaints
- Sports-related hernia

DIAGNOSTIC TESTING

Radiographic Evaluation

Plain radiographs, including true anteroposterior and lateral views of the femur, are usually adequate for the evaluation of potential fractures (Fig. 47.11). If possible, the femur should be internally rotated. Fracture lines can be subtle, particularly in the femoral neck. Three methods are useful for identifying these subtle fractures:

- First is the use of *Shenton line,* described in a subsequent section on hip dislocations.
- Second is a search for the normal "S" and reverse "S" curves seen on radiographs of non-fractured hips. In normal anatomic position, the convex outline of a normal femoral head smoothly joins the concave outline of the femoral neck. This produces an "S" curve and a reverse "S" curve, regardless of the orientation of the radiographic projection. In searching for a fracture of the femoral neck, the medial and lateral cortical margins of the femoral head and neck should be carefully examined for these curves (Fig. 47.12). A fracture produces a tangential or sharp angle, indicating disruption of the normal anatomic relationship.
- The third method, useful in the evaluation of unremarkable hip radiographs, is tracing the trabecular lines as they pass from the femoral shaft to the femoral head. Disruption of these lines as they pass through the fracture site is often the only subtle clue.

In impacted femoral neck fractures, the neck cortex is driven into the cancellous femoral head. Bone impaction lends a certain inherent stability (Fig. 47.13). If there is a femoral neck fracture, also obtain radiographs of the knee. *It is a basic orthopedic principle to image the joint above and below any fracture, because concomitant injuries are common.*

Occult Hip Fracture

If radiographs do not show an overt fracture or injury, the emergency clinician should assess the patient's gait. Inability to ambulate or difficulty in weight bearing suggests an occult fracture. Up to 10% of all hip fractures are radiographically "occult" on plain films. Failure to detect these injuries increases the risk of subsequent displacement of the fracture, the incidence of AVN, and the risk of death. When a painful hip prevents ambulation and plain radiographs do not reveal a fracture, advanced imaging (CT or magnetic resonance imaging [MRI])

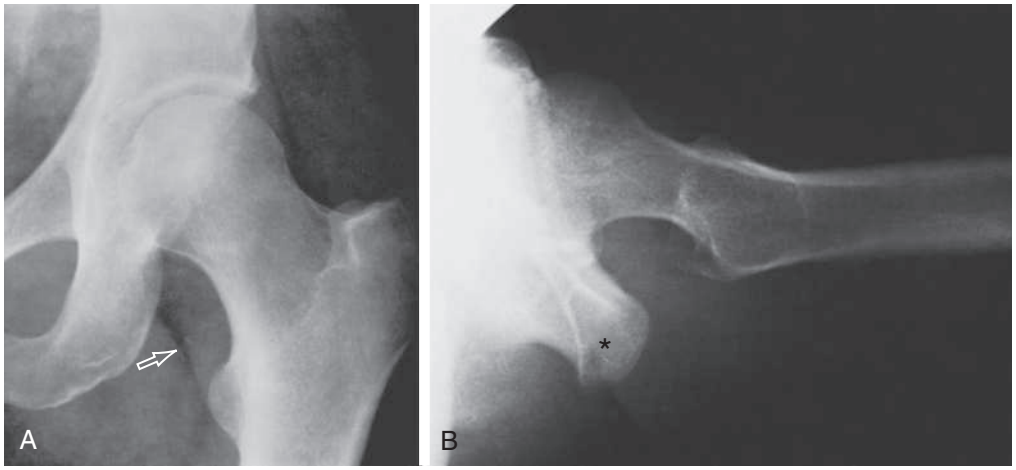

Fig. 47.11 Normal Radiographic Anatomy of the Hip. (A) Anteroposterior view of the normal adult hip. The open arrow indicates the edge of the iliopsoas muscle shadow. This muscle lies immediately on the capsule of the hip joint. The small concavity in the center of the femoral head is for the attachment of the ligamentum teres. (B) Cross-table lateral view of the hip demonstrating the normal relationship of the femoral head to the neck. *The asterisk indicates the ischial tuberosity.* (From Harris JH, Harris WH, Novelline RA. *The Radiology of Emergency Medicine*. 3rd ed. Baltimore: Williams & Wilkins; 1993.)

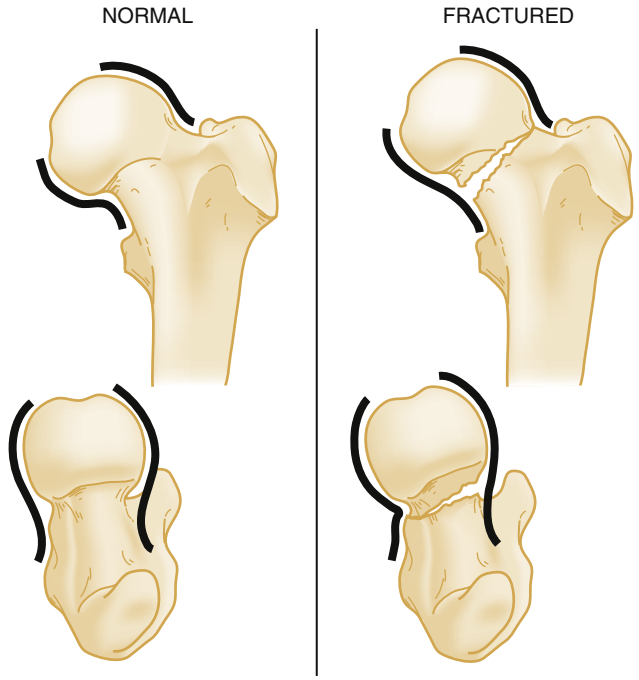

Fig. 47.12 The normal anatomic appearance of the femoral head as smooth S and reversed S lines is drawn above. The concave outline of the femoral neck meets the convex outline of the femoral head as shown here in various views. Any tangential angle suggests a fracture.

is indicated (Fig. 47.14). Elderly patients with unexplained hip pain lasting more than 3 weeks may be harboring an occult fracture even if they continue to walk. T1-weighted MRI will reveal a fracture that was imperceptible at the time of injury with nearly 100% accuracy and is cost-effective compared with other strategies. MRI is superior to CT and remains the "gold standard" for diagnosing occult hip fractures and helps guide treatment decisions (see Fig. 47.12).[5]

Bone scans have been useful in older patients with occult fractures, but they lack adequate sensitivity. To identify most occult fractures, this type of scan should be delayed for 72 hours after the injury, which limits its use in the ED setting.

Vascular assessment must be considered when there is any concern for any vascular injury including pallor, compartment syndrome, or rapidly expanding hematomas. This can include Doppler measurements including ABI. If the systolic pressure in the affected extremity is 90% or less (ratio less than 0.9) than that in the unaffected extremity, additional diagnostic studies should be performed. Vascular assessment studies include Doppler flow ultrasound imaging, computed tomography angiography (CTA), or angiography alone.

MANAGEMENT

Patients with femoral pathology often need hemodynamic stabilization. Because of the risk of blood loss—from both the injury and its subsequent operative repair—patients with traumatic fracture of the hip or femur should have a type and screen in case the necessity for transfusion arises. Original data suggested that transfusion confers a higher risk of morbidity and mortality. However, new data indicates that the need for transfusion was likely associated with injury severity, and once accounted for, the differences resolved. Hemodynamic instability can result in the loss of up to 3 units of blood into the fracture site. Elderly patients may be hypovolemic prior to the injury due to dehydration or comorbid illness, which can be exacerbated by further blood loss. Operative repair should be performed after the patient is resuscitated and in optimal preoperative condition. The preoperative stabilization of an elderly patient with a hip fracture may require a multidisciplinary approach from emergency medicine, orthopedics, internal medicine, cardiology, and anesthesiology. Comprehensive programs co-managed by geriatricians and orthopedic surgeons have been shown to improve short-term outcomes for the elderly with hip fractures and might even lower the mortality rate, highlighting the importance of the medical management of these complex patients.

Traction and Immobilization

If prehospital personnel suspect a femoral fracture, they often place a Hare splint, Sager splint, or similar device that applies traction to the leg before transporting the patient. This management strategy is popular because it provides pain relief, immobilization, and limits blood loss. However, great care should be taken to ensure the proper use of these devices as prolonged traction can cause or exacerbate neurologic

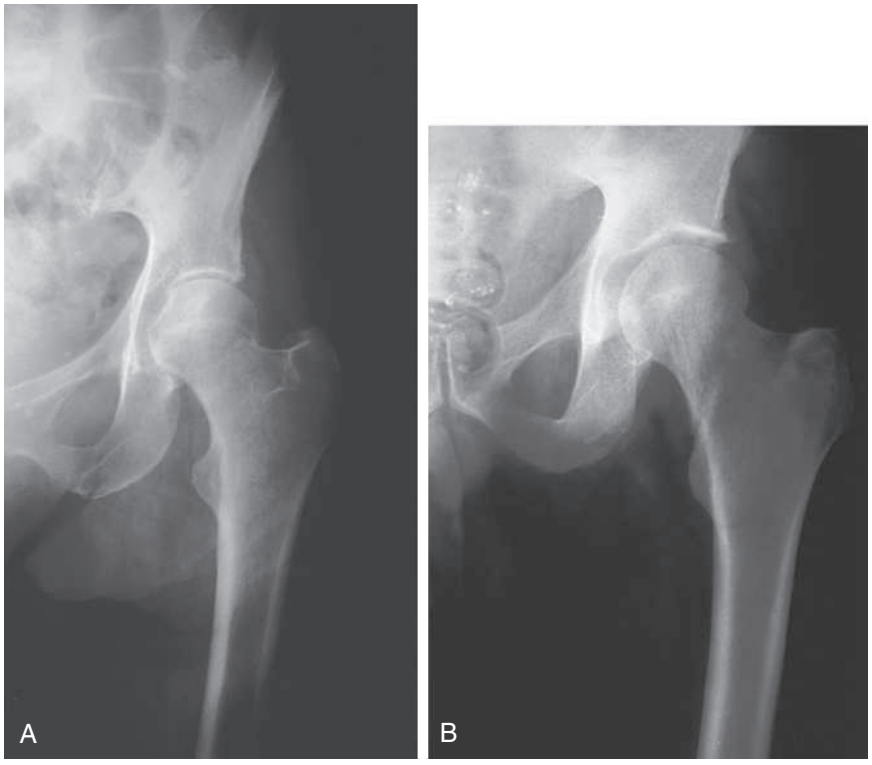

Fig. 47.13 (A) Subtle nondisplaced impacted femoral neck fracture. Use of S curves aids in identification. (B) A nondisplaced femoral neck fracture possesses no stability without impaction.

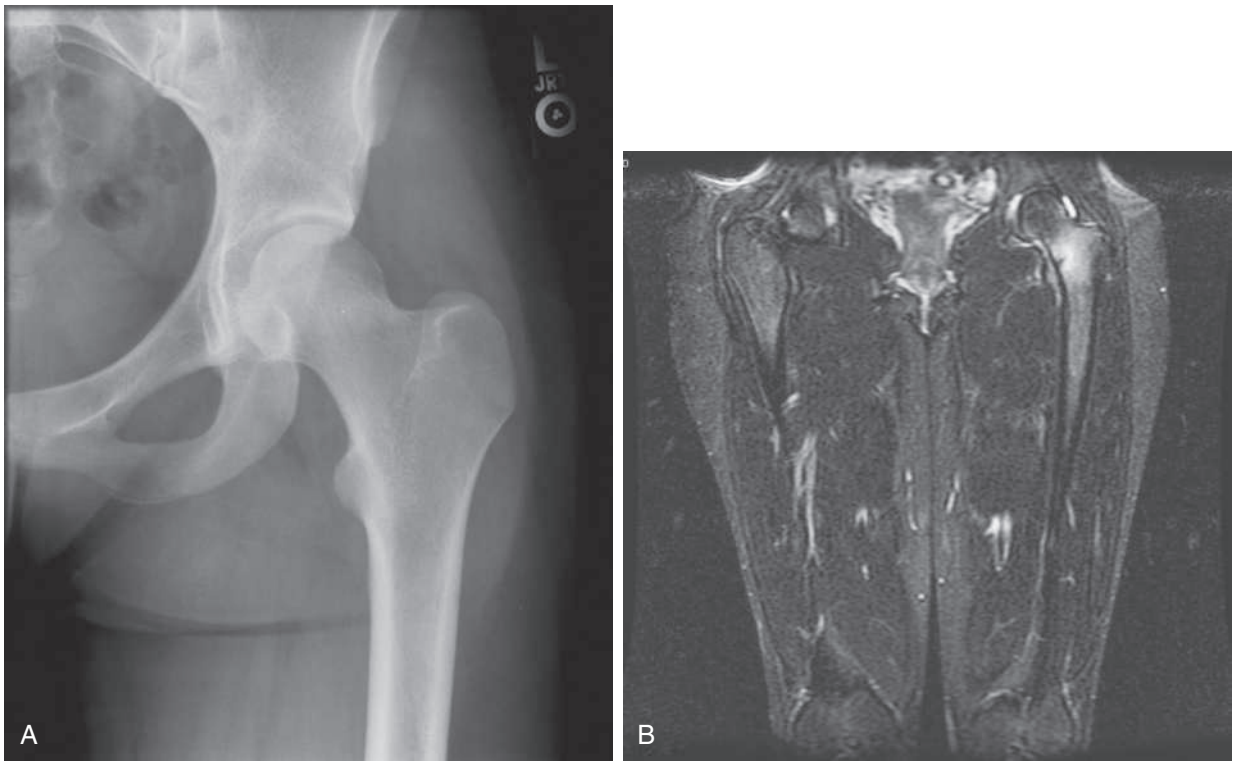

Fig. 47.14 The Patient Reported Hip Pain and Could Not Ambulate. (A) Initial radiographs failed to demonstrate a fracture. (B) A magnetic resonance image (MRI) revealed a femoral neck fracture through the compressive trabecular fibers.

injury. Traction used in the field for transport can cause skin breakdown at pressure points and might produce potentially damaging tension on the nerve. The femoral and sciatic nerves are more likely to be injured from traction or during surgery than from the femoral fracture itself.

Contraindications to the use of traction splints include suspected pelvic fractures, patellar fractures, ligamentous knee injuries, and tibia or fibula fractures. In the prehospital setting, traction should not be applied to any open fracture that has exposed bone. Such reduction pulls grossly contaminated bone fragments back into the wound before adequate irrigation. A study that evaluated patients with multisystem trauma in whom traction splints were placed in the field for femur fractures showed that nearly 40% had contraindications to the splints that were placed.

With or without traction, the injured extremity should be immobilized when the patient is moved to prevent further damage from mobile bone fragments. In the prehospital setting, this can be achieved with simple splinting. In the ED, maintaining the leg in slight flexion at the hip reduces intracapsular pressure, whereas extension of the leg increases pressure and the potential for ischemic necrosis of the femoral head. Therefore, traction for proximal femur fractures should be discontinued once the patient has arrived in the ED. The leg can be supported in a position of comfort with a pillow placed under the thigh. The theoretical advantages to continue traction in the ED are for improved pain control and facilitating fracture reduction and making operative management easier to perform. This is likely true for patients with femoral shaft fractures; however, a Cochrane systematic review found no evidence to support preoperative traction for fractures of the proximal femur in adults.

Open Fracture Care

By definition, an *open fracture* is any fracture in which a break in the integrity of the skin and soft tissue allows communication with the fracture and its hematoma. Any nearby wound or break in the skin must be considered to communicate with the fracture. The three categories of open fractures are described in Table 47.2. A bone piercing from the inside outward often causes only a small wound, after which the contaminated bone tip slips deceptively back into the soft tissue. Open wounds should be irrigated and then covered with sterile saline-moistened gauze.

For all type I open fractures, a first-generation cephalosporin (such as, cefazolin, 1–3 g IV) should be administered intravenously. Fracture types II and III might require additional gram-negative coverage depending on the amount of devitalized tissue and the extent of involvement of the groin and its gram-negative skin flora. This additional coverage could be provided by an aminoglycoside (such as, gentamicin 1.5–2 mg/kg IV). The use of perioperative first-generation cephalosporins reduces the risk of postoperative infection even in patients with closed fractures. Great care should be taken to identify tetanus-prone wounds so that patients can receive vaccination against tetanus when indicated. Immunization status should be verified in all patients and updated accordingly.

Compartment Syndrome

Because of the thigh's larger volume, compartment syndrome within the thigh is far less common than in the lower part of the leg. A large amount of bleeding into the thigh compartment is required before the pressure rises above capillary perfusion pressure. When compartment syndrome occurs in the thigh, only 50% of the cases are associated with a femur fracture. It is difficult to clinically differentiate the expected swelling after an injury from early compartment syndrome. Clinical examination and the use of direct pressure measurements can detect the development of compartment syndrome at an early stage.

TABLE 47.2 Classification of Open Fractures

Criterion	Type I	Type II	Type III
Wound size	<1 cm	1–10 cm	>10 cm
Soft tissue damage	Minimal, if any	Moderate, without nerve, arterial, or periosteal stripping	Extensive muscle devitalization; nerve and arterial involvement often classified as type IIIb
Mechanism of injury	Bone edge pierces outward	Variable	High-energy shotgun blast, high-velocity gunshots

Pain Management

Systemic Analgesia

Pain control in the ED is often inadequate. For patients with femoral fractures, opioid analgesia is often indicated in combination with other pain-relief strategies. In addition to parenteral medications, other pain-relieving strategies include immobilization of the injured extremity, placement of the injured extremity in a position of comfort, and the administration of local nerve blocks.

Pharmacologic Approaches

The classic pharmacologic treatment for pain management in patients with traumatic femoral injuries is opioid analgesics. Morphine, fentanyl, and hydromorphone are all acceptable options. Fentanyl and hydromorphone are the preferred IV opioid analgesics in patients with renal dysfunction. Due to the unpredictability of the supply chain and negative associations of opioids, many pre-hospital providers now use ketamine for pain relief. Meperidine should not be used because of unpredictable side effects, including seizures. Nonsteroidal antiinflammatory drugs (NSAIDs), while safe in younger populations, can be difficult to use, especially in the elderly, due to their renal and gastrointestinal side effects.

Femoral Nerve Block

The femoral nerve block is an excellent option as an adjunct or alternative to systemic analgesics in patients at risk for hypotension. Femoral nerve blocks significantly decrease the time to the lowest pain score compared with intravenous narcotics, and patients require significantly lower doses of narcotics. With the assistance of a peripheral nerve stimulator to localize the nerve or bedside ultrasound to directly visualize the nerve, the anesthetic is injected, safely, and under sterile conditions. The procedure can also be performed by emergency clinicians without the assistance of peripheral nerve stimulators or ultrasound.[4] If a long-acting anesthetic such as bupivacaine is used, the expected onset of analgesia is within 30 minutes and its duration (on average) is 6 to 8 hours. A Cochrane review demonstrated that regional blockade reduced pain on movement within 30 minutes after block placement, and there is moderate quality of evidence for reduced time to first mobilization, reduced cost of analgesic, and decreased risk of pneumonia.

A neurovascular examination should be performed and documented before the femoral nerve block is performed. After the nerve block, continued assessment of the femoral muscular compartments is advisable to check for the development of compartment syndrome. If an injury is considered to be at especially high risk for compartment syndrome, orthopedic surgery consultation should be obtained before the block, and measurement of compartment pressures after the block

should be considered. Because the sciatic nerve innervates the compartments of the lower limb, a femoral nerve block will not mask the clinical presentation of compartment syndrome in the lower leg.[6]

Specific Fractures of the Hip and Femur

Avulsion Fractures

Foundations. The incidence of avulsion fractures is increasing as a result of the growth of competitive sports and outdoor activities, especially in teenage athletes. The muscular origin of this type of injury commonly involves the pelvic apophyses, which might not fully ossify until age 25. Avulsion at the site of the growth plate is the result of sudden maximal muscular exertion. It can occur with rapid acceleration or sudden changes in speed or direction.

Clinical features. The athlete classically experiences a sudden piercing pain at the site of injury, along with a "snapping" or "popping" sound and frequently falls to the ground because of the intensity of the pain. The pain of avulsion injuries of the hip can manifest as referred pain to the thigh; these fractures are most common in adolescents and young adult athletes.

Differential diagnoses. The differential diagnoses of these avulsion fractures include muscle strain and tears, tendinopathy, and hip dislocations.

Management. As depicted in Fig. 47.15, avulsion at the ASIS involves the separation of a thin piece of bone as the sartorius muscle suddenly contracts (see Fig. 47.15A). The anterior inferior iliac spine (AIIS) is avulsed by the rectus femoris, and the hamstrings group can displace the ischial tuberosity (see Fig. 47.15B). Avulsion fractures of the ASIS and AIIS are managed nonoperatively. Treatment of avulsion fractures of the ischial tuberosity is more controversial. Most experts recommend conservative treatment for avulsion injuries with less than 2 cm of displacement. Fractures with more than 2 cm of displacement might benefit from operative fixation to prevent nonunion, as well as union achieved by exuberant callus formation.

Proximal Femur Fracture

Fractures of the proximal end of the femur are classified on the basis of their relationship to the hip capsule (intracapsular or extracapsular), anatomic location (neck, trochanteric, intertrochanteric, subtrochanteric, and shaft fractures), and degree of displacement.

Femoral Neck Fractures

Foundations. Femoral neck fractures are classified as either nondisplaced or displaced. Between 15% and 20% of all femoral neck fractures are nondisplaced fractures. The fracture line is often subtle. Techniques that allow detection of these fracture lines are useful for this reason. Evaluation of the continuity of the subcapital cortical lines, search for an indistinct broad band of increased subcapital density, and identification of the "S" and reverse "S" radiographic curves (see Fig. 47.12) lead to the diagnosis in most cases. With impacted femoral neck fractures, the neck cortex is driven into the cancellous femoral head. Bone impaction lends a certain inherent stability (see Fig. 47.13). Because of this stability, two management approaches have been advocated: internal fixation and early ambulation. Internal fixation reduces the length of hospitalization, improves rehabilitation, and is the preferred treatment modality. Without impaction, a nondisplaced femoral neck fracture is unstable and will become displaced without internal fixation.

Clinical presentation. On initial evaluation, a patient with a displaced fracture of the femoral neck lies with the limb externally rotated, abducted, and slightly shortened. To avoid further disruption of the blood supply to the femoral head, range-of-motion assessment should be deferred.

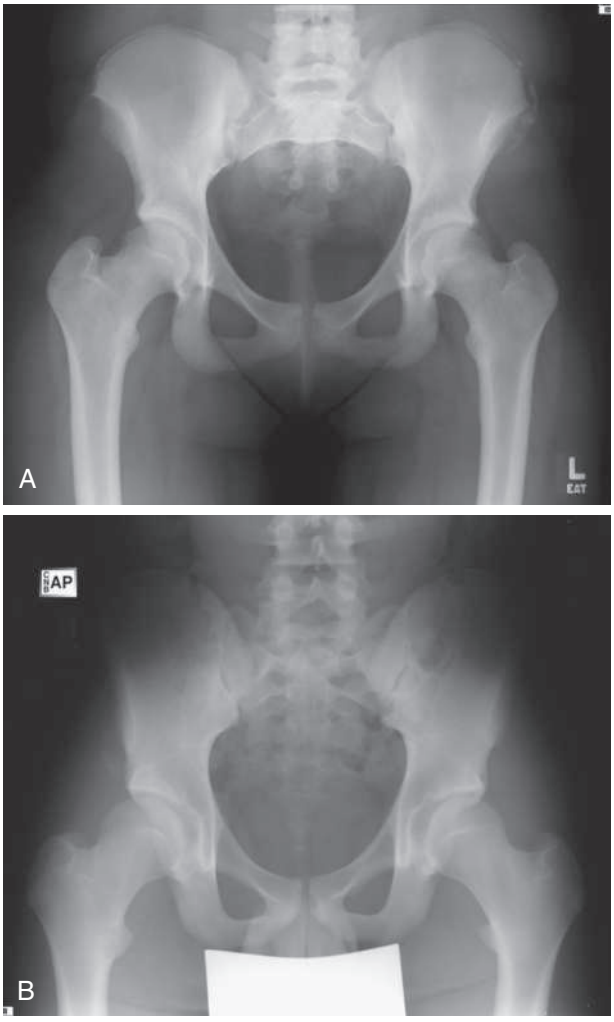

Fig. 47.15 (A) Avulsion fracture of the anterior superior iliac spine by the sartorius muscle. (B) Avulsion fracture of the anterior inferior iliac spine by the rectus femoris.

Diagnostic testing. Plain hip radiographs generally confirm the diagnosis of a femoral neck fracture.

Management. Treatment of these displaced fractures consists of open reduction and internal fixation (ORIF), hemiarthroplasty, or total hip arthroplasty (THA). In all displaced femoral neck fractures, the femoral head is rendered largely avascular, and signs of AVN and collapse might develop over the ensuing years. The mortality rate during the first year after a femoral neck fracture is 14%, compared with 9% for the control population. Factors affecting the mortality rate include age, male sex, psychiatric illness, end-stage renal disease, and congestive heart failure. Institutionalized patients have a death rate up to three times higher than noninstitutionalized patients. Complications can be minimized by early reduction, stable internal fixation, early ambulation, and close attention to medical comorbidities.

The two major complications of femoral neck fractures are AVN and nonunion. AVN is the most common complication, despite optimal treatment, because of the complex arterial anatomy. Deep infection in the form of osteomyelitis or septic arthritis is more common with femoral neck fractures, because the fracture line extends into the joint. The use of perioperative antibiotics reduces the rate of infection. Pulmonary embolism is another significant complication and is the leading cause of death 7 days after fracture. Venous thromboembolism

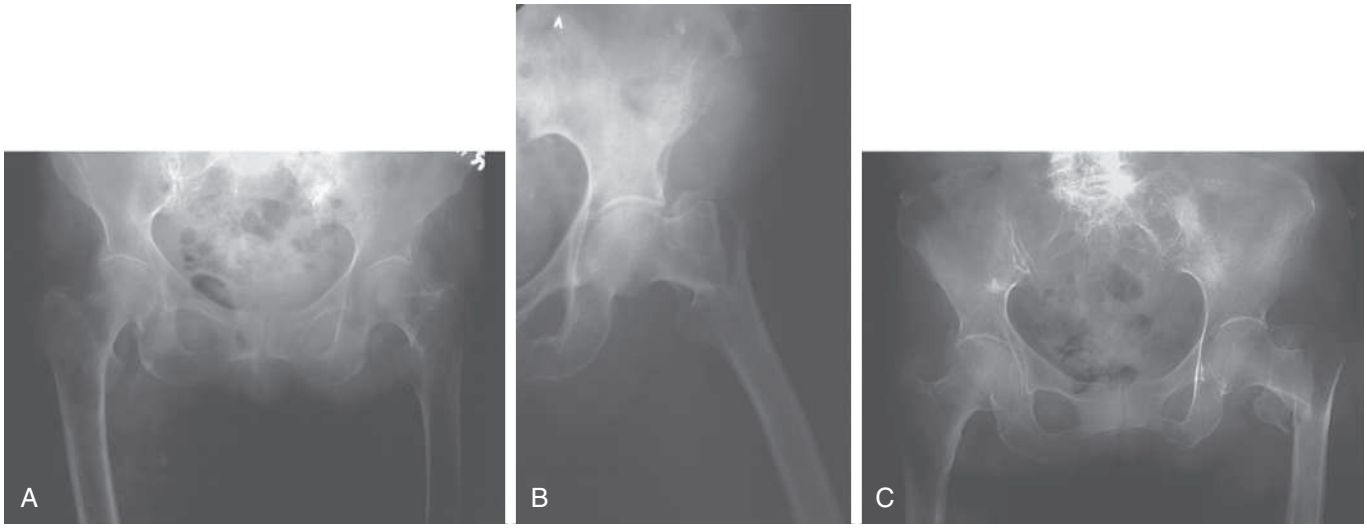

Fig. 47.16 The Number of Parts Produced by the Fracture Classifies Intertrochanteric Fractures. (A) Two-part fractures have one part connected to the femoral head and a second part attached to the shaft. (B) The greater or lesser trochanter also is fractured with three-part fractures. A greater degree of instability is produced because the attached muscles continue to act on the fractured trochanter. (C) Four-part intertrochanteric fractures involve both trochanters.

prophylaxis with anticoagulation therapy such as low molecular weight heparin or direct oral anticoagulants is recommended for 7 to 28 days, depending on the type of injury or surgical intervention.

Disposition. Patients with femoral neck fractures should be admitted for operative repair.

Intertrochanteric Fractures

Foundation. The fracture line of intertrochanteric fractures extends between the greater and lesser trochanters of the femur. These injuries are considered extracapsular fractures. The fracture line extends through cancellous bone, which has an ample blood supply. The hip's short external rotators remain attached to the distal fracture fragment, and the internal rotators are attached to the proximal fracture fragment.

A large number of classification systems for intertrochanteric fractures have been proposed to predict the likelihood of achieving and maintaining stable reduction. A useful system designates the fracture according to the number of bone fragments (Fig. 47.16).

Intertrochanteric fractures often are associated with other, distant fractures caused by the same trauma, such as a mechanical fall. Associated fractures of the distal radius, proximal humerus, ribs, and lumbar and thoracic spine are often overlooked because the femoral fracture distracts the attention of both patient and clinician. Nutrition status, chronic diuretic use, and decreased oral intake prior to the injury contribute to dehydration, and a greater requirement for resuscitative fluids.

Clinical presentation. The strong action of the iliopsoas muscle causes the leg to be shortened and externally rotated.

Diagnostic testing. Plain hip radiographs generally confirm the diagnosis of intertrochanteric fractures.

Management. A substantial majority of intertrochanteric fractures require internal fixation. Such fixation brings rapid mobilization, decreased hospital length of stay, reduced mortality, and improved function. The procedure should be performed on an urgent, rather than an emergent basis, because the patient should be fully resuscitated prior to operative repair. The risk of death increases when the patient is taken to the operating room on the day of injury; however, early repair within 24 to 48 hours improves the 1-year mortality rate. Preoperative medical optimization by multidisciplinary medical teams can decrease the 1-year mortality rate in these patients.[7]

Patients with intertrochanteric fractures have a mortality rate of up to 30% in the first year. Life expectancy returns to normal among patients who survive that year. Survival is most commonly related to the patient's age and preexisting medical conditions. Additional risks associated with operative treatment include mechanical failure, implant migration, and infection. Mechanical failures and nonunion are much more common in patients with unstable fractures and those whose fractures were not adequately reduced. Approximately half of patients who sustain these fractures are eventually able to regain their original level of ambulation. Outpatient yearly infusion of zoledronic acid (a bisphosphonate) beginning within 90 days after hip fracture repair reduces the incidence of new fractures and decreases the overall mortality rate.

Disposition. Patients with intertrochanteric fractures should be admitted for operative repair.

Isolated Fractures of the Greater or Lesser Trochanter

Foundations. Isolated fractures of the greater or lesser trochanter are rare. They occur in women more often than in men and are the result of a fall directly onto the trochanter or avulsion by the iliopsoas muscle. There may be a comminuted fracture involving only part of the greater trochanter or subtler impaction of the lateral cortex. If an avulsion is present, the fragments are displaced superiorly and posteriorly (Fig. 47.17).

Clinical presentation. Patients present with hip pain and tenderness over their trochanter.

Diagnostic testing. Plain hip radiographs generally confirm the diagnosis of these isolated fractures.

Management. Treatment consists of pain control and early mobilization with crutches; weight bearing is allowed as tolerated.

Disposition. Satisfactory outpatient management of this injury is possible because the healing process and prognosis is generally good.

Subtrochanteric Fractures

Foundations. Subtrochanteric fractures occur between the lesser trochanter and the proximal 5 cm of the femoral shaft. They may accompany intertrochanteric fractures. The subtrochanteric region is composed almost entirely of cortical bone, which lacks the vascularity needed for new bone growth and repair. When fractured, it is more

Fig. 47.17 Isolated Fracture of the Greater Trochanter. Note that the trochanter is displaced in the typical posterior and superior direction.

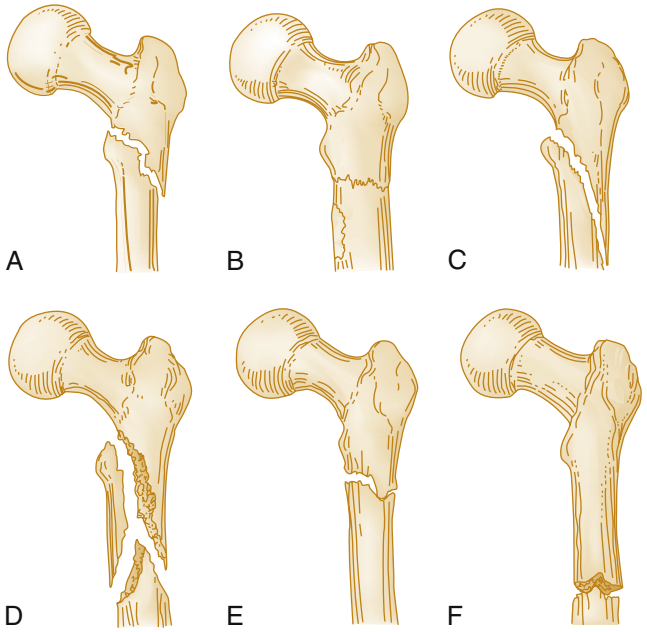

Fig. 47.18 Variants of Subtrochanteric Fractures. (A) Short oblique fracture. (B) Short oblique fracture with comminution. (C) Long oblique fracture. (D). Long oblique fracture with comminution. (E). High transverse fracture. (F) Low transverse fracture.

likely to be comminuted compared to bones with a higher cancellous content. In addition, the greater portion of the biomechanical forces of the femur is transmitted down the curved medial cortex of the femoral shaft. If this cortex is disrupted, the metal hardware undergoes the majority of the stress. This mechanism accounts for the increased incidence of hardware failure when the medial cortex is largely involved.[8]

These fractures characteristically are deformed because of the unbalanced muscle forces. In displaced fractures, the attachments of the iliopsoas, gluteal, and external rotator muscles consistently produce flexion, abduction, and external rotation of the proximal fragment.

Subtrochanteric fractures account for approximately 10% of all fractures of the proximal end of the femur. Although a small percentage of these fractures are caused by penetrating trauma, the usual mechanism of injury is direct blunt trauma. There is a bimodal distribution of injuries. The first group comprises victims of extreme high-energy trauma. In these patients, the subtrochanteric fracture is rarely an isolated injury because of the force required to produce it. Thirty to fifty percent of patients with subtrochanteric fractures have associated fractures of the pelvis, spine, or other long bones. The second group consists of elderly patients who experience a mechanical fall, in whom the fracture occurs through an area of weakened cortical bone. Pathologic fractures from metastatic lesions, Paget disease, renal osteodystrophy, osteogenesis imperfecta, and osteomalacia are well-recognized clinical entities in these patients. Stress fractures can occur in this region but are extremely uncommon. Various classification systems for these fractures have been proposed, although none is widely accepted. From a practical standpoint, it is best to define and describe these fractures by location (proximal or distal), angle (transverse or oblique), and the presence of comminution (Fig. 47.18).

Hemodynamic instability can result from blood loss at the fracture site. Although such blood loss can lead to hypovolemic shock, other causes of hypotension in a trauma patient need to be considered due to the forces required to obtain these injuries. Open fractures are rare and, when present, are accompanied by significant soft tissue injury. Vascular and neurologic injuries are also less common.

Diagnostic testing. Plain hip radiographs confirm the diagnosis of most subtrochanteric fractures.

Management. Definitive management of subtrochanteric fractures is complex. Maintaining limb length and controlling rotation are difficult. ORIF is the treatment of choice. However, in the rare case of a severely comminuted or an open, grossly contaminated fracture, nonoperative management may be preferable. Children younger than 10 years old also can be managed nonoperatively. The amount of remodeling and growth stimulation occurring in children of this age usually ensures good results without internal fixation.[8]

The bone in the subtrochanteric region is largely cortical and relatively avascular compared with the cancellous intertrochanteric region. As a result, healing is comparatively slow. Comminuted and distal subtrochanteric fractures carry a worse prognosis.

Complications include fat embolism in patients of all ages and the adverse effects of prolonged immobilization in the elderly. The mortality rate from subtrochanteric fractures is approximately 10%. The significant force and commonly associated traumatic injuries contribute to the high mortality among patients who sustain these fractures.

Disposition. Patient with subtrochanteric fractures should be admitted for operative repair.

Femoral Shaft Fractures

Foundation. Femoral shaft fractures are common injuries in young adults after high-energy trauma. As is the case with other femoral cortical fractures, considerable force is required to produce a fracture in a normal shaft. Automobile and motorcycle accidents, falls, and pedestrians being struck by vehicles account for a majority of femoral shaft fractures. The femoral shaft usually fails under tensile strain, resulting in a transverse fracture. Higher forces produce varying degrees of segmentation. Open fractures of the femoral shaft are less frequent and are often the result of a penetrating gunshot wound.

Pathologic fractures occur from a low-mechanism force that produces torsion and spiral fractures.

Depending on the age of the patient, if seemingly trivial trauma has resulted in a spiral femoral shaft fracture in a child, non-accidental trauma or pathologic fractures should be considered. Common causes of pathologic fracture include unicameral bone cysts, fibrous dysplasia, osteogenesis imperfecta, and malignancy.[9]

There is no commonly accepted or easily recalled classification system for femoral shaft fractures. The location and geometry of the fracture line should be used to describe them. Useful terms include transverse, oblique, spiral, wedge, and comminuted fractures.

Clinical presentation. Patients often arrive with the injured extremity immobilized by traction devices, which should be removed while immobilization of the limb is maintained. Neurovascular injuries are rarely associated with closed femoral shaft fractures. Significant hemorrhage into the thigh can occur with a femoral shaft fracture, just as with intertrochanteric and subtrochanteric fractures. Common concomitant injuries in patients with femoral shaft fractures include hip fractures, fracture-dislocations, femoral neck fractures, supracondylar femoral fractures, and patellar fractures. Almost half of femoral shaft fractures have associated ligamentous damage to the knee. If the patient has a femoral fracture, pain often prevents adequate evaluation of knee stability. Any attempt to evaluate the stability of the knee acutely will cause additional pain and hemorrhage without providing useful, diagnostic information.

Diagnostic testing. Plain hip radiographs including full length views of the femur confirm most femoral shaft fractures.

Management. Internal fixation with intramedullary rods has been demonstrated to shorten both hospitalization and total disability time after most femoral shaft fractures. The vast majority of femoral shaft fractures heal well in time, regardless of the mode of treatment. Severely comminuted fractures are more likely require closed reduction.[10]

Femoral shaft fractures have a union rate close to 100%, and most patients are able to return to work after approximately 6 months. Even a minor amount of limb shortening, or misalignment can result in arthritis of the hip or knee or chronic back pain. Refracture is a rare occurrence that is most likely to occur during early healing and callus formation. Refracture may also occur during the postoperative period after any hardware is removed. In this scenario, the unsupported bone is required to bear the entire weight of axial loading and is at risk for refracture.

Disposition. Patients with femoral shaft fractures should be admitted for operative repair.

Stress Fractures

Foundation. Femoral neck stress fractures or reactions occur when normal bone is subjected repeatedly to submaximal forces. This recurring stress stimulates the bones to remodel and strengthen. In a stress fracture, osteoblasts are unable to lay down new bone and remodel fast enough, so the bone fails. Stress fractures can also occur in diseased bone when it is subjected to repeated minimal stress.

Clinical presentation. The symptoms of a stress fracture of the femoral neck are often subtle and can be mistaken for a muscle strain or an overuse injury. Early symptoms frequently include morning stiffness and aching in the hip on the first steps after a period of rest. The pain gradually increases during prolonged exercise and may reach the point at which the patient is unable to bear weight. Pain typically radiates to the groin or along the medial aspect of the thigh toward the knee.

Patients with these stress fractures usually limp because of pain. Their antalgic gait is characterized by shortening of the stance phase of the injured extremity. No obvious external rotation or shortening of the leg is seen; the patient experiences minor discomfort with active or passive motion, except at the extremes of flexion and internal rotation. Tenderness is minimal because of the large amount of soft tissue coverage at the femoral neck.

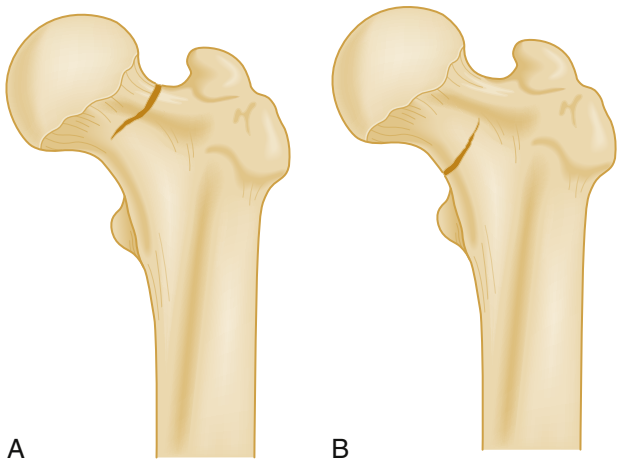

Fig. 47.19 Femoral neck fractures through the tensile (A) and compressive (B) trabecular fibers.

Diagnostic testing. Radiographs are helpful if they demonstrate a fracture, but findings are often negative until 10 to 14 days after the symptoms begin. Endosteal or subperiosteal callus develops at the fracture site during this period. In addition to the standard anteroposterior and lateral views of the hip, oblique views may delineate the fracture line. Particular attention should be paid to the trabecular fibers of the femoral neck. A stress fracture is often identified as an isolated disruption of the trabecular fibers on either the tensile (lateral aspect of the femoral neck) (Fig. 47.19A) or the compressive (medial aspect of the femoral neck) (Fig. 47.19B). If a fracture is suspected clinically but radiographic findings are negative, the next recommended diagnostic modality is MRI. If a fracture is found, the contralateral hip should be concomitantly evaluated because of the significant incidence of bilateral stress fractures.

Management. Treatment of stress fractures of the femoral neck is based on involvement of the compressive or tensile aspect. Compressive-side fractures involving less than half of the cortex are inherently stable and can be treated conservatively with partial weight bearing and crutches. Tension-side fractures and compressive-side fractures involving more than half the cortex are considered unstable and at risk for displacement. These fractures should be treated operatively with screw and hardware fixation.

Disposition. Urgent orthopedic consultation for decision of operative versus nonoperative treatment is recommended for these types of stress fractures.

Dislocations and Fracture-Dislocations of the Hip and Femur

Hip Dislocations

Foundations. Dislocations and fracture-dislocations of the hip are true orthopedic emergencies. The hip joint possesses impressive inherent strength and stability; therefore, considerable force is required to produce these injuries. With this understanding, a hip dislocation serves as a "red flag" for multisystem injury and should prompt a diligent search for other injuries. As many as 70% of patients with a dislocation have an associated acetabular fracture. Knee fractures, ligamentous injuries, and dislocations are present in up to 30% of patients who have sustained a hip dislocation. It is recommended that,

in the presence of this type of injury, patients be managed as major trauma victims. The incidence of hip fractures and dislocations are increasing in young patients, often as a result of high-energy trauma. Up to 50% of children with a hip dislocation have fractures elsewhere. In small children, dislocation of the hip is more common than femoral neck fractures. The force required to dislocate a pediatric hip is much less than that required in an adult because the acetabulum is less completely developed.[11] Seemingly negligible trauma, such as tripping or a minor fall, can dislocate the femoral head in a young child. In a school-age child, athletic injuries are the major cause of traumatic hip dislocation; in the teenage years, MVCs predominate.

Traumatic hip dislocations occur primarily in patients sustaining severe multisystem trauma, most often as a result of a high-speed MVC. Failure to use seat belts is a significant risk factor. Less common mechanisms include mechanical falls, sports injuries, and pedestrians struck by automobiles.

The vast majority of posterior dislocations are the result of MVCs. A seated vehicle occupant typically has the hip adducted, flexed, and internally rotated at the time of impact. As the knee strikes the dashboard, the force is transmitted through the femoral shaft to the femoral head. With sufficient force, the femoral head dislocates posteriorly. Anterior dislocations result from forceful extension, abduction, and external rotation of the femoral head. These forces lever the head up and out of the acetabular cup.

The relationship of the femoral head to the acetabulum is used to classify dislocations into anterior, posterior, central, and inferior types. A fracture-dislocation includes an associated fracture of the acetabulum or femoral head. Posterior dislocations (Fig. 47.20) account for 80% to 90% of dislocations. Anterior dislocations (Fig. 47.21) are seen in 10% to 15% of patients. In anterior dislocations, the femoral head can dislocate medially toward the obturator foramen (obturator dislocation) (Fig. 47.22) and laterally toward the pubis (pubic dislocation) or the iliac crest. Central dislocations, which occur in 2% to 4% of cases, are not true dislocations, since the entire femoral head is forced centrally through a comminuted fracture of the acetabulum. Inferior dislocation of the hip associated with inversion of the femoral shaft *(luxatio erecta femoris)* is a rare condition that occurs with or without associated trochanteric fracture.[11]

The precarious blood supply to the femoral head is particularly important with regard to the long-term consequence of hip dislocations. The development of AVN of the femoral head has been reported in up to 15% of dislocations. Other risk factors for the development of AVN include the total dislocation time, the severity of the injury, the number of reduction attempts, and the presence of comorbid conditions.

Clinical presentation. The position of the injured extremity might provide valuable clues in the evaluation of a hip dislocation. A patient with a posterior dislocation typically holds the hip flexed, adducted, and internally rotated. The knee of the affected extremity rests on the opposite thigh. The extremity generally is shortened, and the greater trochanter and buttock may be unusually prominent. In contrast, a patient with an anterior dislocation holds the hip in abduction, slight flexion, and external rotation, and the leg may appear lengthened. These physical findings might be absent in patients with an associated ipsilateral femoral shaft fracture.

The neurovascular examination should focus on the sciatic nerve and femoral vessels. Sciatic palsy is present in approximately 10% of patients with hip dislocation and most commonly involves the peroneal nerve branch. The most sensitive clinical sign of peroneal nerve palsy is weakness of the extensor hallucis longus; other signs include weakness of dorsiflexion and numbness or tingling over the dorsum of the foot. The femoral vessels and nerve are particularly prone to injury after an anterior dislocation.

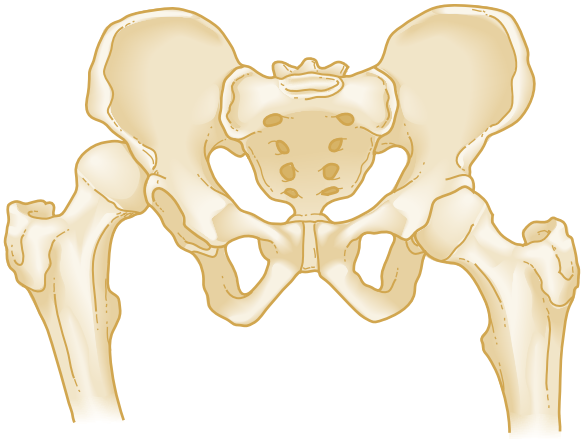

Fig. 47.20 In a posterior dislocation, the hip is internally rotated, and the lesser trochanter is superimposed on the femoral shaft. Failure to visualize the lesser trochanter on the anteroposterior projection identifies a posterior dislocation.

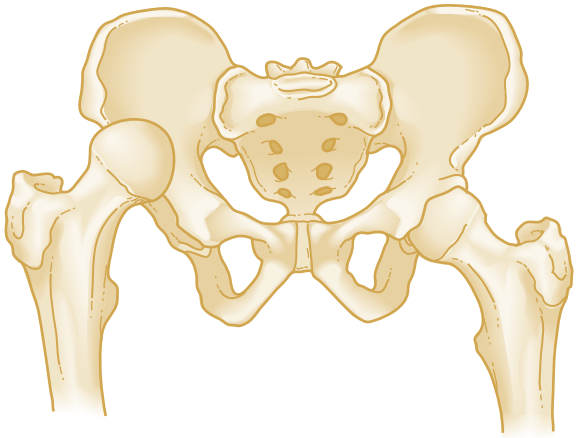

Fig. 47.21 In an anterior dislocation, the hip is externally rotated and the lesser trochanter appears in profile. The hip is farther from the x-ray cassette than the unaffected side and may appear larger because of the beam's projection.

Fig. 47.22 Obturator Dislocation.

Diagnostic testing. Radiologic investigation begins with an anteroposterior view of the pelvis. This view alone will identify the majority of hip dislocations. An anteroposterior pelvis film should be obtained in all trauma patients with the aforementioned deformities. The anteroposterior radiograph should include the entire pelvis and the proximal third of the femur to allow comparison of both hips. When a dislocation is found or suspected, a lateral view of the hip will provide additional definition of the injury.

Although most hip dislocations are seen clearly with these two views, several key radiographic signs can assist emergency clinicians in making a diagnosis. The first indicator involves the position of the lesser trochanter. Because a posteriorly dislocated hip is internally rotated, the lesser trochanter is superimposed on the femoral shaft and is not seen on the anteroposterior projection. By contrast, an anteriorly dislocated hip is externally rotated, and the lesser trochanter appears in profile. The second clue is found in the size of the femoral head. Because a posteriorly dislocated hip is closer than the unaffected side to the x-ray cassette, it appears smaller. The converse is true in anterior dislocations, in which the hip is farther from the x-ray cassette than the contralateral side is and thus appears larger. The third finding relates to the integrity of *Shenton line* (Fig. 47.23), a smooth, curved line drawn on the radiograph along the superior border of the obturator foramen and medial aspect of the femoral metaphysis. Disruption of this line should raise suspicion for a femoral neck fracture or hip dislocation.

An obvious dislocation might distract the clinician from a search for concomitant fractures. Examination of the trabecular pattern can identify associated fractures of the acetabulum and femoral head, neck, or shaft. It is important to identify acetabular fractures before closed reduction is attempted because intra-articular bone fragments could interfere with effective reduction. Although these fractures might make the reduction more difficult, their presence is not a contraindication to the procedure.

Management. *Hip dislocations constitute a true orthopedic emergency, and reduction should be performed within 6 hours.* The incidence of AVN, traumatic arthritis, permanent sciatic nerve palsy, and joint instability increases logarithmically with the length of time the hip remains dislocated.

The timing and method of reduction depend on the overall condition of the patient, the type of dislocation, and the presence or absence of associated fractures. In cases of simple dislocation, closed reduction should be attempted first. Although some clinicians recommend that this procedure be performed with the patient under general anesthesia, this delay, with its associated increase in the rate of AVN, is not warranted when timely procedural sedation in the ED is available. If the emergency clinician chooses to attempt closed reduction, the principles of procedural sedation and monitoring should be followed as described in Chapter 7. The primary relative contraindication to closed reduction is the presence of a femoral neck fracture. Another relative contraindication is the presence of fractures in the dislocated extremity, because such fractures preclude application of traction to the limb. Techniques of closed reduction are described next.

The Stimson and Allis techniques have been used most commonly for reduction of posterior hip dislocations (Fig. 47.24). *The Allis technique* usually is effective for both posterior and obturator dislocations (Fig. 47.25). It is the most commonly used method for hip reductions in the ED. On the negative side, it places the clinician at risk of slipping and falling off the bed, places strain on the lower back, and can be extremely difficult for smaller practitioners.

The Allis technique for reduction of posterior hip dislocations is performed by the following steps and technique:

1. To reduce harm to the clinicians, place the patient on a backboard that is lowered to the floor, instead of standing on the stretcher or bed.

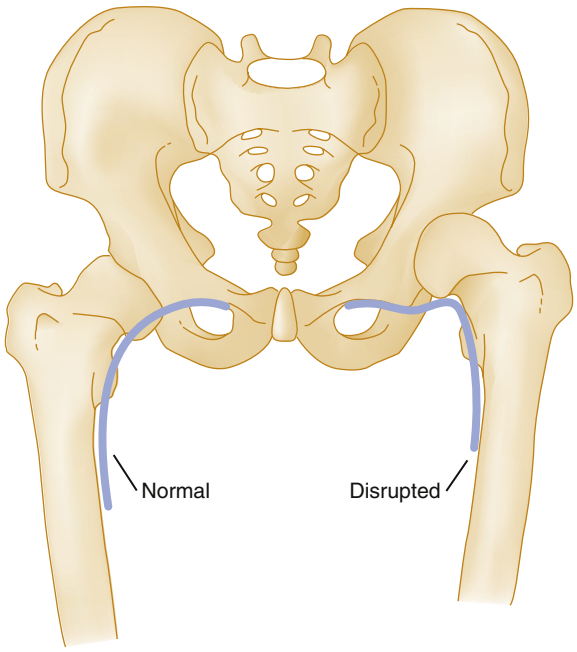

Fig. 47.23 Shenton line is a smooth curved line drawn along the superior border of the obturator foramen and medial aspect of the femoral metaphysis. Disruption of this line should raise suspicion of a femoral neck fracture or hip dislocation.

Fig. 47.24 Radiograph of posterior dislocation identified by loss of the lesser trochanter on the anteroposterior view.

2. Place the patient in the supine position, with the pelvis stabilized by an assistant. We suggest using a sheet or strap to secure the patient to the bed or backboard. Place the strap over the ischial wings and pubic symphysis.
3. With the knee flexed, apply steady traction in line with the deformity.
4. Slowly bring the hip to 90 degrees of flexion while applying steady upward traction and gentle rotation.
5. The assistant pushes the greater trochanter forward toward the acetabulum.
6. Once reduction has been achieved, bring the hip to the extended position while maintaining traction.

The Stimson technique (Fig. 47.26) uses the weight of the limb and the force of gravity to reduce the dislocation and is relatively atraumatic.

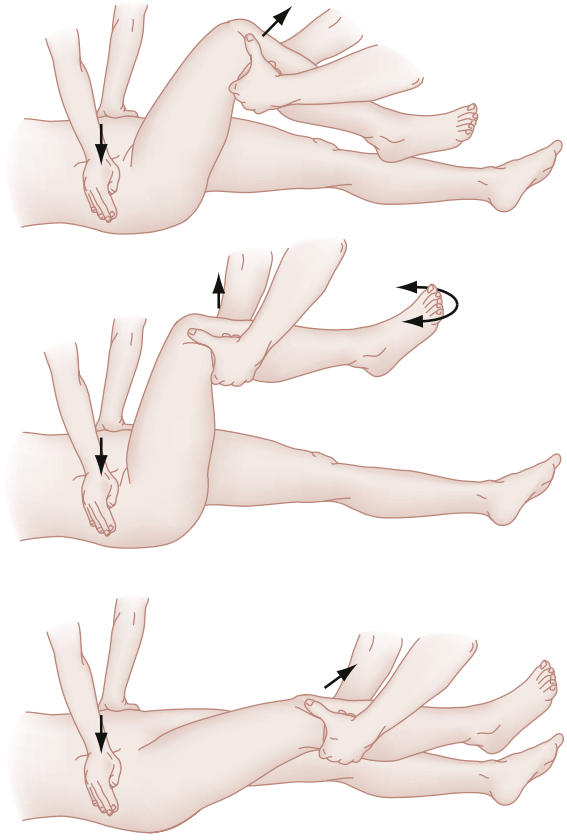

Fig. 47.25 The Allis Technique for Hip Reduction.

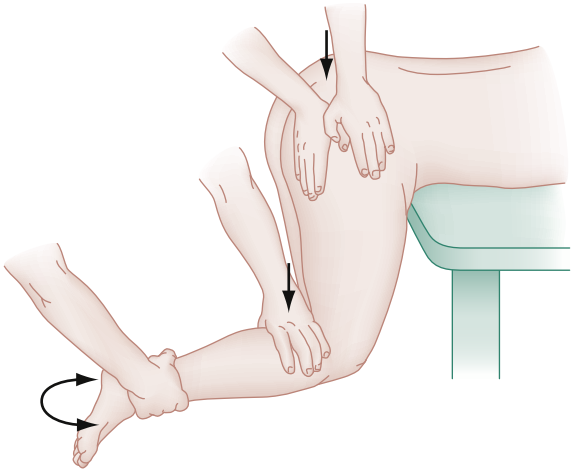

Fig. 47.26 Stimson's Technique for Hip Reduction.

Although Stimson's technique generally is effective, placing a patient with multiple traumatic injuries in the required prone position is not recommended. Radiographic clearance of the spine has not yet been accomplished, and the administration of sedatives and analgesics to a prone patient has potential adverse side effects.

To perform the Stimson technique for reduction of posterior hip dislocation:

1. Place the patient in a prone position, with the leg hanging over the edge of the bed. The hip and knee are flexed at 90 degrees.
2. Ask an assistant to stabilize the pelvis and secure the patient to the stretcher or bed with a sheet or strap. Place the strap over the ischial wings and pubic symphysis.

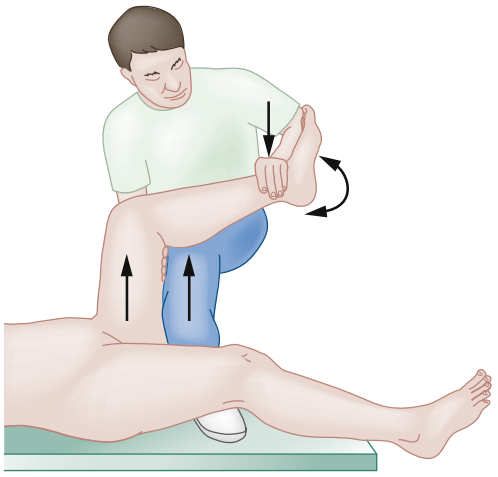

Fig. 47.27 Captain Morgan Technique for Hip Reduction. (Redrawn from Hendey GW, Avila A. The Captain Morgan technique for the reduction of the dislocated hip. *Ann Emerg Med.* 2011;58:536–540.)

3. Apply steady downward traction in line with the femur.
4. Gently rotate the femoral head while the assistant pushes the greater trochanter anteriorly toward the acetabulum.
5. Once reduction has been achieved, bring the hip to the extended position while maintaining traction.

The Stimson and Allis techniques are being replaced by newer methods of reduction that are considered safer and equally as effective. These include the Whistler and Captain Morgan methods.[12] These techniques use the power of the provider's leg muscles to reduce the hip, instead of relying on lower back and arm strength. The Captain Morgan and Whistler techniques use the provider's knee and arm, respectively, as a fulcrum to apply force and reduce the hip. The Captain Morgan technique has a success rate of 95%, but there are reports that excessive downward force on the ankle has caused ligamentous injuries in the knee.

To perform the *Captain Morgan technique* for reduction of posterior hip dislocation, the following steps are recommended: (Fig. 47.27):

1. With the patient supine on the stretcher in its lowest position, secure the pelvis to the stretcher with a bed sheet or strap. Place the strap over the ischial wings and pubic symphysis. This prevents the clinician from lifting the patient off the bed and is more effective than having an assistant try to secure the pelvis.
2. Stand at the side of the bed and place one foot up on the bed (like Captain Morgan standing on a rum barrel). If additional height is needed, consider using a stable cardiopulmonary resuscitation (CPR) stool.
3. Place the patient's ipsilateral leg over the clinician's leg so the knee is resting in the patient's popliteal fossa.
4. While holding the ankle in position with slight downward pressure (this is done only to lock the patient's leg onto the clinician's leg and is not meant to be a fulcrum), lift up with both legs to apply traction on the femur and reduce the hip.
5. If traction alone does not work, the clinician's hands are used to internally and externally rotate the leg to achieve the reduction.

The Whistler technique often works better for practitioners who are of shorter stature and have difficulty getting their leg in proper position for the Captain Morgan technique. In this method, the clinician uses their stabilized arm under the ipsilateral knee to lift the leg using the leg muscles.

To perform the Whistler technique for reduction of posterior hip dislocation (Fig. 47.28):

Fig. 47.28 Whistler Technique for Hip Reduction. (From Walden PD, Hamer JR. Whistler technique used to reduce traumatic dislocation of the hip in the emergency department setting. *J Emerg Med.* 1999;17:441–444. Used with permission.)

1. Start with the patient lying supine on the bed, and secure the patient's hips to the bed, as for the Captain Morgan technique.
2. Bend the contralateral leg so that the patient's knee is flexed 90 degrees and the foot is on the bed.
3. Bend the ipsilateral leg to the same position.
4. The clinician's arm is placed under the ipsilateral knee and rests on top of the contralateral knee.
5. The clinician's body is rotated perpendicular to the patient and looking at their feet. This causes the clinician to assume a squatting position.
6. While holding the patient's ipsilateral ankle with other hand, the clinician slowly lifts up with the legs, while keeping the arm straight and strong. This puts traction on the femur and should reduce the dislocation.
7. If reduction is not achieved with traction alone, the hand that is on the ankle can be used to internally or externally rotate the leg to achieve the reduction.

Other techniques for closed reduction of posterior hip dislocations include the Rochester method and the traction-countertraction technique.

Closed reduction of a pubic dislocation can be challenging. The anterior position of the femoral head will resist flexion, making the Allis maneuver technically impossible. The following sequence of maneuvers is recommended.

To perform the technique for reduction of pubic dislocation:

1. Place the patient in the supine position.
2. Apply longitudinal traction in line with the deformity.
3. Hyperextend and internally rotate the hip while an assistant applies downward pressure on the femoral head.

Although prompt anatomic reduction is clearly desirable, multiple attempts at reduction in the ED should be avoided because of potential damage to the articular surface. The incidence of osteonecrosis increases with the number of attempts at reduction, as well as the duration of the dislocation. Difficulty with reduction is usually the result of incarceration of a tendon, a capsular structure, or an osteochondral fragment that is blocking reduction. In the case of a nonreducible dislocation, closed reduction with the patient under general anesthesia or an open reduction procedure is often required.

After closed reduction, the hip should be tested for stability, which is accomplished by gently taking it through its full range of motion to see whether it will re-dislocate. After testing has ensured stability, the injured extremity should be placed in a knee immobilizer and an abduction pillow should be applied to prevent a repeat dislocation. An anteroposterior radiograph of the pelvis should be obtained to verify the adequacy of reduction. The radiograph should be inspected carefully to verify that the femoral head is in the acetabulum, the shaft of the femur is in neutral position, Shenton line is intact, and the profile of the lesser trochanter is well visualized. The intra-articular space should be symmetrical and when measured, at the same depth as in the unaffected joint. Asymmetry signals an entrapped intra-articular fragment and is an indication for CT imaging.

Disposition. Most patients with a native hip dislocation will require admission to the hospital and urgent orthopedic referral for serial examinations and to ensure that no additional injuries are present.

Fracture-Dislocation of the Femoral Head

Foundations. Hip dislocations can be associated with fractures of the femoral head (Fig. 47.29A). Femoral head fracture occurs in 35% to 55% of anterior hip dislocations and in 10% to 16% of posterior hip dislocations. These injuries are almost always the result of high-speed vehicular trauma. Because of the significant force required to produce this injury pattern, coexistent multisystem trauma is the rule.

Clinical presentation. When a femoral head fracture and hip dislocation coexist, patients assume the position typical for the dislocation. Hip mobility is markedly reduced, and pain is usually severe. After initial stabilization, the involved extremity should be examined for associated fractures of the femoral shaft and knee. The neurovascular examination should assess for femoral or sciatic nerve injury.

Diagnostic studies. Radiographs should be evaluated for any femoral head fracture in patients with hip dislocations. Evidence for fracture of the femoral head can be subtle. These fractures can be detected on radiographs by following the curve of the dislocated head and the acetabular cup to search for a small fragment that could otherwise be overlooked. Known or suspected injuries can be further defined by CT scanning or MRI.

Management. In most cases, satisfactory results can be obtained with closed reduction (see Fig. 47.29B). Several experts recommend obtaining a CT scan of the hip before closed reduction to further define the injury and locate fracture fragments. If the hip cannot be reduced by manipulation or if reduction of the femoral head fragment is unsatisfactory, open reduction will be indicated.

Disposition. Patient with fracture-dislocation of the femoral head should be admitted for operative management.

Dislocation of Hip Prosthetics

Foundations. An increasing number of patients have undergone hip arthroplasty. In addition to those procedures performed for treatment of femoral neck fractures, nearly 250,000 patients undergo elective primary THA each year. Postoperative dislocation occurs in 0.5% to 3% of patients with primary THA and in 5% to 25% of patients with a revised THA. Although most dislocations take place within 3 months of surgery, "late dislocations" have been reported up to 10 years after the operative procedure; such dislocations can result from major trauma or from trivial events (e.g., rising from a seated position). Posterior dislocations account for 75% to 90% of cases (see Fig. 47.30).

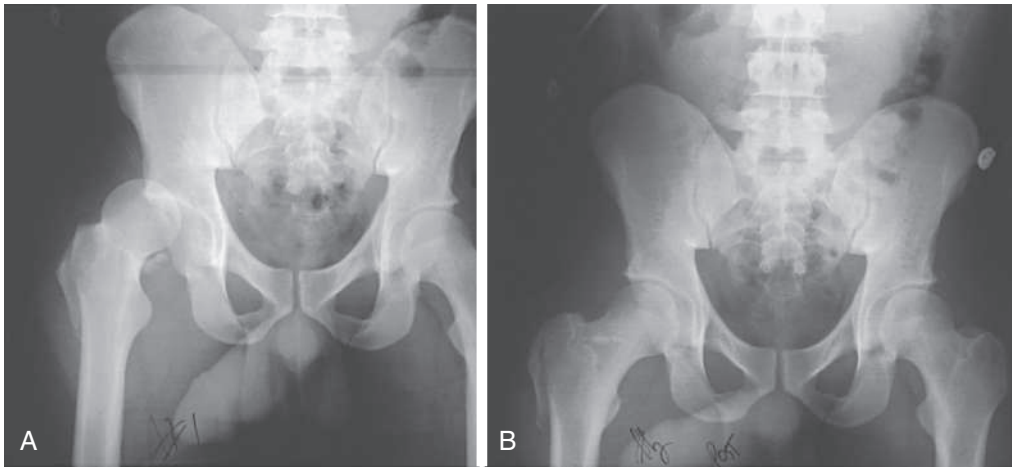

Fig. 47.29 (A) Anterior hip dislocation is identified as the lesser trochanter is brought into profile. Note the fracture of the lateral aspect of the greater trochanter. (B) A post-reduction radiograph demonstrates adequate reduction with symmetrical joint spaces.

Fig. 47.30 Dislocation of the femoral prosthesis in a patient who had undergone total hip arthroplasty (THA). The femoral head often becomes caught on the rim of the acetabular cup, thereby preventing reduction. Reduction can disrupt or dislocate the acetabular cup.

Clinical presentation. Most patients will present with inability to bear weight with associated hip or groin pain. The affected leg with be externally rotated and shortened. They will have increased pain if the leg is internally rotated or flexed.

Diagnostic studies. Radiologic investigation begins with an anteroposterior view of the pelvis. See the Hip Dislocation section in this chapter for further details on diagnostic studies.

Management. Reduction techniques for prosthetic hip dislocations are identical to those described earlier but are not as time dependent as native hip dislocations. Most patients can be placed in a straight leg knee immobilizer, which will prevent them from re-dislocating their prosthetic hip.

Disposition. Consultation with an orthopedic surgeon is recommended for development of a long-term treatment plan for the patient as chronic dislocation may require operative repair. Reduction of the prosthesis does not carry the same urgency as for reduction of a dislocated native hip because there is no risk for the development of AVN once the femoral head has been replaced. Traction on the sciatic nerve can occur, however, making early reduction more compelling. In addition, the reduction itself carries the risk of loosening of the components, fracturing of the surrounding bone, and movement of the acetabular cup. Reduction is best performed in consultation with an orthopedic specialist.

Soft Tissue Injuries

Soft tissues can be subject to muscle or tendon strain or contusions from overuse or trauma. Rupture, hemorrhage, or myositis ossificans can develop in muscles.

Muscular Injuries

Foundations. Strenuous exercise by a poorly conditioned person, sudden exertion, and direct trauma all can injure soft tissues. Cold temperature, vascular or infectious disease, fatigue, and inadequate training are predisposing conditions for muscular injury.

Clinical features. Partial tears are reversible injuries that are aggravated by movement or tension. Mild spasm, swelling, ecchymosis, and tenderness cause minor loss of function and strength. Complete tears produce a palpable depression, and the torn muscle edge is often palpable. Other possible findings include severe spasm, swelling, ecchymosis, tenderness, and loss of muscle function. In significant muscle strains, radiographs are needed to evaluate for the possibility of an accompanying bone avulsion injury. Extremely strenuous exercise can lead to rhabdomyolysis and compartment syndrome in rare cases.

Differential diagnoses. Differential diagnoses of these soft tissue injuries include muscle strain, partial and complete muscle tears, ligamentous or tendon strains, avulsion injury, and compartment syndrome.

Diagnostic testing. In the ED, plain radiographs can be obtained to exclude any fractures. Bedside ultrasound is also helpful in evaluating for partial and complete ligamentous or tendon tears. Patients may eventually require an MRI to fully evaluate their injury. MRI has the best sensitivity and specificity for soft tissue injuries but does not need to be done emergently. If there is a concern for compartment syndrome, compartment pressures should be measured with orthopedic consultation.

Management. Initial management of incomplete tears traditionally includes the local application of ice for the first 48 hours, followed by heat. Compressive wraps can exacerbate distal venostasis, with the potential for distal venous clot formation, and do not significantly decrease recovery time. A regimen of nonsteroidal antiinflammatory agents to achieve sufficient analgesia is important for recovery and patient satisfaction. Muscle relaxants may be useful when the injury is accompanied by muscular spasm. In general, complete rest of the affected muscle should be maintained, with the recommendation of "weight bearing as tolerated." This progressive muscle loading can be started within 3 to 5 days once a sufficient scar has formed. To prevent reinjury, muscle loading should be limited by the patient's pain.

Disposition. Any patient with significant injury should be referred for physical therapy. A complete muscle tear requires follow-up care with an orthopedic surgeon or sports medicine specialist.

Some common specific muscular injuries are shown in Table 47.3

TABLE 47.3 Soft Tissue Injuries—Muscle Strains

Injury	Foundations	Clinical Features	DDx	Diagnostic Testing	Management	Disposition
Hamstrings	Common injury in athletes from accidents or overtraining. Common in sports involving running/ sudden acceleration (e.g., track and field or basketball.)	Sudden intense pain in the posterior aspect of the thigh. Active or passive motion at the hip is poorly tolerated due to pain	Ischial avulsion fractures	Pelvic radiographs should be obtained if the examination reveals bony tenderness	Crutches and toe-touch weight bearing are recommended until the patient is evaluated by a physician trained in sports medicine. Appropriate weight-training programs speed rehabilitation of this injury.	Complete recovery from a hamstring muscle strain can take weeks to months.
Quadriceps	Most common muscular group to sustain complete tears. This injury occurs when the muscles are contracted suddenly against the body's weight, as may occur when an athlete slips or stumbles and attempts to avoid a fall.	Ambulation is significantly affected. There is pain with active and passive knee extension. In significant tears, the patient might be unable to actively extend the knee or maintain its extension against gravity. A palpable depression just proximal to the superior pole of the patella suggests a complete tear.	Patellar Fracture can give similar issues with extension	Ultrasound can also be used to diagnose quadriceps tears.	Knee immobilizer and urgent surgical referral for operative repair	Refer to orthopedics or sports medicine.
Iliopsoas strain	Gymnasts and dancers are the athletes most likely to experience an injury to the iliopsoas as a result of sudden forceful hip flexion against resistance.	Severe pain often is experienced in the groin, thigh, or low back. Severe intra-abdominal pain is common at the muscle origin and might dominate the clinical picture. Examination reveals groin tenderness and pain with active hip flexion.	Pelvic fracture Sacroiliitis	Radiographs of the femur should be obtained to identify an avulsion fracture of the lesser trochanter. CT frequently demonstrates a large hematoma.	Bed rest with partial flexion at the knee and hip generally is required for 7–10 days.	Discharge with supportive care. Sports medicine vs. orthopedic follow up
Hip adductor strain	Injury to the hip adductors occurs as the thigh is forcefully abducted, as in a straddle injury.	Pain in the groin, the pubic region, and the medial proximal aspect of the thigh. Abduction and adduction often are limited because of pain. Swelling and skin discoloration may confirm presence of the tear. If the tear is complete, a defect in the muscle can be felt by the examiner along the medial aspect of the thigh near the groin.	Pelvic fracture Femoral avulsion fractures	Pelvic CT vs. MRI	Treatment is conservative, with patients initially benefiting from rest, with gradual progression in a stretching and strengthening program.	Discharge with PT, orthopedics, and/or sports medicine
Gluteus muscle strain	Vigorous or forced hip extension, as seen in track-and-field jumping events.	The pain typically is less severe. than that associated with injuries to other muscle groups. The hip is tender when extended or abducted.	Pelvic fractures	X-rays if indicated	Treatment is conservative, with patients initially. benefiting from rest, with gradual progression in a stretching and strengthening program.	Discharge with supportive care

Tendon Injuries

Foundations. Clinically, tendinopathies tend to have a more insidious onset than that typical for muscle strains. These strains occur at the attachment of the muscles to the superior or inferior pubic ramus, the pubic symphysis, the ischium, and the femur.

Clinical features. Local pain over the tendon, exacerbated by stretching of the tendon, is a common physical examination finding. Pain may radiate down the muscle and limb.

Adductor strains tend to be the most common groin injury in athletes, with 60% of the cases involving the adductor longus muscle. The adductor magnus and brevis and the pectineus often are involved as well. This injury commonly occurs in skaters and cross-country skiers when an accidental stress abducts the thigh during a powerful contraction of the adductors. These muscles also can be injured from overuse in an unconditioned patient. Local pain is noted at the inferior pubic ramus and the ischial tuberosity. Extension, abduction, and adduction of the hip are painful, with pain radiating to the back of the thigh.

Pain over the greater trochanter could represent tendon strain of the attachments of the gluteus medius, gluteus minimus, tensor fasciae latae, or piriformis. The pain is aggravated by resisted abduction. Tenderness in the groin and painful hip movement suggest a strain of the iliopsoas tendon at its attachment to the lesser trochanter.

Differential diagnoses. Differential diagnoses of these tendon injuries include avulsion fractures, partial or complete tears of the muscles or tendons, tendinopathies, peritendinitis, trochanteric bursitis, AVN, and oncological disorders.

Diagnostic studies. Ultrasound imaging may lend additional diagnostic information. MRI can provide a definitive diagnosis but is not indicated in the ED setting.

Management. Treatment of a tendon strain is similar to that for other soft tissue injuries. The use of crutches with weight bearing as tolerated is recommended for the first 2 weeks. Antiinflammatory agents or a short course of opioid analgesics may be given. Complete tendon disruption might require surgical repair.

Disposition. Most patients will require follow up with an orthopedic or sports medicine specialist within a week.

Osteitis Pubis

Foundation. Osteitis pubis is characterized by pubic symphysis pain and joint disruption and is most common in distance runners and soccer players. The adductor muscles act as a "compression strut," displacing forces across the hip. The most likely mechanism is repetitive pulling of the adductor muscles, causing increased shearing at the pubic symphysis.

Clinical features. Clinically, patients have groin pain of insidious onset, with most reporting pain at the symphysis and adductor muscles. Pain usually can be elicited on palpation of the symphysis and provoked by adduction of the hip or by doing sit-ups.

Differential diagnoses. Osteitis pubis has been associated with spontaneous cases of pubic symphysis osteomyelitis and should be considered in the differential diagnosis.

Diagnostic testing. Plain radiographs show widening of the symphysis, irregular contour of the articular surfaces, or periarticular sclerosis (a delayed finding) (Fig. 47.31). These features are not specific and in one study were seen in 75% of asymptomatic soccer players. MRI is the imaging study of choice and will show marrow edema on T2 images during the acute phase of the disease.

Management. Treatment is conservative since in most cases the process is self-limited. Patients benefit from activity modification, wearing supportive shoes, and from therapy addressing flexibility and strength of the pelvic and hip musculature. Average time to heal has been reported to be up to 9 months.

Fig. 47.31 Plain radiograph showing irregular articular surfaces and periarticular sclerosis consistent with osteitis pubis.

Disposition. Owing to the length of healing associated with these injuries, follow-up care should be arranged at the time of initial injury to an orthopedics or sports medicine specialist.

Vascular Injuries

Foundations. Hip dislocations and femoral fractures may have associated arterial injury. The vessel can be partially lacerated, dissected, completely severed, or thrombosed. A lack of distal arterial flow might also represent a stretched vessel in spasm. The superficial femoral artery is most commonly injured with trauma to the hip and thigh. The common and the deep femoral arteries are less frequently injured. In the acute setting, penetrating trauma is the usual mechanism of injury. Arterial injury with a femoral shaft fracture is rare. Anterior and superior dislocations can produce femoral artery injury.

Clinical features. Patients may have decreased pulses, poor capillary refill, cold extremities, paresthesias and increased pain.

Differential diagnoses. The differential diagnoses of these vascular injuries include arterial thrombus, arterial dissection, and complete or partial vascular tears.

Diagnostic testing. Ultrasound or CT angiogram are indicated for evaluating the vasculature.

Management. Orthopedic or vascular surgery consultation is recommended if any partial or complete vascular tear is found. Fracture reduction may restore blood flow if the vessel is being compressed.

Disposition. Most patients with these vascular injuries will require admission for their femoral fracture repair.

Neurologic Injuries

Foundation. Peripheral nerve injuries can be caused by trauma, external compression, infection, and degenerative disease. In trauma, nerves can be injured by a blunt object that causes a contusion, by a sharp penetrating object that produces a partial or complete tear, or by stretching. Nerves are particularly vulnerable to prolonged ischemia, which can lead to necrosis. Compression of the nerve

TABLE 47.4 Nerve Injuries

Nerve	Foundation	Clinical Features	Management	Disposition
Femoral nerve	The femoral nerve is most often traumatized in penetrating trauma of the pelvis, groin, or thigh. Femoral neuropathy occasionally results from compression by a hematoma within the abdominal wall or the iliopsoas as a complication of hemophilia, anticoagulant therapy, or severe trauma. When the femoral nerve is injured, the iliac and femoral arteries are commonly involved because of their anatomic proximity.	Marked weakness of knee extension. The patient is able to walk on level ground yet has extreme difficulty walking upstairs or an incline. Patients cannot rise from a sitting position because of significant proximal muscle weakness. The sensory deficit varies but is localized along the anterior aspect of the thigh and medial lower aspect of the leg. The most reliable spot for testing for a sensory deficit is just superior and medial to the patella. The deep tendon reflex of the knee is diminished or absent with such deficits.	Urgent orthopedics consultation. Reduce any fractures that may be compressing nerve. Control hemorrhage if due to a hematoma.	Urgent orthopedics consultation
Sciatic injury	Sciatic injury is rare with femur fractures, but occasionally it may be the result of traction used to stabilize the fracture during the initial management period. Complete traumatic injury can result from a deep penetrating wound in the hip, thigh, or buttock. Posterior hip dislocations and fracture-dislocations produce sciatic neurapraxia in 10% to 14% of patients with these injuries.	Patients with complete sciatic neuropathy have paralysis of the hamstring muscles and all muscles below the knee. With partial injury, a peroneal palsy with weakness of the extensor hallucis longus muscle is the most sensitive clinical sign. There is sensory loss below the knee and along the posterior aspect of the thigh. The deep tendon reflex at the ankle is absent or diminished. Sciatic nerve palsy from inadvertent injection into the nerve or secondary to intraneural or extraneural hemorrhage in patients taking anticoagulants has been described.	Urgent orthopedics consultation	The prognosis is poorest when the injury is proximal and complete. Even with optimal repair, recovery often is inadequate. Sciatic neuropathy is a disabling problem. Obvious atrophy of the lower part of the leg and foot develops, followed by ulceration of the sole of the foot and infection. A below-the-knee amputation frequently is necessary in these cases.

from a hematoma or a dislocated femoral head may also appear as a neurapraxia manifested by transient loss of conductivity.

Clinical features. Patients present with sensory loss or motor weakness. Mild cases may present with paresthesias.

Diagnostic testing. No specific testing in the emergency department is indicated other than a focused physical examination, though MRI may be able to identify injury to a larger nerve.

Management. Treatment of neurovascular compromise from a hip dislocation or a displaced femoral fracture consists of immediate reduction to ensure limb viability. Whenever possible, reduction should be accomplished before the patient is transferred to another treatment center.

If traumatic neuropathy is suspected, orthopedic consultation should be obtained. Nerve exploration and repair generally are indicated for penetrating trauma and for direct impingement on the nerve by bone fragments or hematoma. Surgical exploration may be required for drainage of a hematoma that is impinging on the femoral nerve.

Disposition. Most traumatic nerve injuries will be observed in the hospital or require urgent orthopedic consultation. Neurapraxia from compression often resolve with time and can be evaluated by orthopedics in 2 to 3 days.

For specific nerve injuries see Table 47.4.

CHAPTER 47: QUESTIONS AND ANSWERS

1. Which of the following fractures has the best outcome and lowest rate of complications?
- **a.** Femoral neck fracture
- **b.** Insufficiency fracture
- **c.** Intertrochanteric fracture
- **d.** Lesser trochanteric fracture
- **e.** Subtrochanteric fracture

Answer: d. Treatment of a lesser or greater trochanteric fracture consists of pain control and early mobilization with crutches; weight bearing is allowed as tolerated by pain. Outpatient management of this injury is possible with a satisfactory social situation. The prognosis is good, and healing is generally excellent. The mortality rate during the first year after a femoral neck (also known as an *insufficiency fracture*) fracture is 15%. Intertrochanteric fractures have an associated mortality rate of 10% to 30% in the first year. The reported mortality rate from subtrochanteric fractures ranges from 10% to 15%.

2. A 40-year-old man complains of persistent thigh pain that worsens over 2 weeks after an assault with a baseball bat. His pain is worse with knee extension. On physical examination, you note that there is a small palpable mass at the mid-anterior thigh. What should be your next confirmatory test?
- **a.** Bone scan for fracture
- **b.** Bone scan for stress fracture
- **c.** Computed tomography (CT) scan for tumor
- **d.** Magnetic resonance imaging (MRI) for evaluation of torn muscle
- **e.** Radiograph for heterotropic calcification

Answer: e. Myositis ossificans (heterotrophic ossification) is pathologic bone formation at a site where bone is not normally found. Traumatic myositis ossificans results most commonly from a direct blow to muscle. It should be suspected when symptoms persist past 10 to 14 days or if symptoms intensify several weeks after the trauma. The ossific mass is often palpable and may limit motion, depending on its location.

3. An 80-year-old woman presents complaining of pain in her right leg after a motor vehicle collision (MVC). Emergency medical services (EMS) noted a swelling and a deformity to her thigh, so they placed a traction device on her leg. Her blood pressure is 80/40 mm Hg; heart rate, 110 beats/min; and respiratory rate, 18 breaths/min. What is the most appropriate next step in the management of the patient's fracture?
- **a.** Femoral nerve block and leave the traction device in place
- **b.** Femoral nerve block and remove the traction device
- **c.** Intravenous morphine and leave the traction device in place
- **d.** Intravenous narcotic pain medication and remove the traction device
- **e.** Immediate orthopedic consult to take the patient to the operating room for an open reduction and internal fixation (ORIF)

Answer: b. Although the patient may ultimately need to go to the operating room, the patient is currently unstable and requires resuscitation and evaluation for other injuries. A femoral nerve block is a valuable adjunct or alternative to systemic analgesics in a patient at risk for hypotension and has been underused by emergency clinicians. Prolonged traction during the assessment and management of other injuries can cause or worsen serious neurologic injury in the thigh by producing potentially damaging tension on the sciatic or femoral nerves.

4. What is the most common complication of a proximal femur fracture?
- **a.** Avascular necrosis (AVN)
- **b.** Myositis ossificans
- **c.** Osteomyelitis
- **d.** Pulmonary embolism
- **e.** Septic arthritis

Answer: a. AVN is the most common complication of proximal femur fractures (despite optimal treatment) because of the complex arterial anatomy. Deep infection in the form of osteomyelitis or septic arthritis is more common with femoral neck fractures because the fracture line extends into the joint. Pulmonary embolism is another significant complication and is the leading cause of death 7 days after fracture in orthopedic patients.

5. A 60-year-old woman presents complaining of right hip pain after a trip and fall at home. The patient denies loss of consciousness or other symptoms. You note that the patient's right leg is internally rotated, and the thigh is adducted and flexed at the hip joint so that the ipsilateral knee is resting on the opposite thigh. Which is the correct maneuver?
- **a.** Apply traction and splint the leg in full extension.
- **b.** Apply traction to an extended knee and flexed hip at 90 degrees with a gentle rotational component.
- **c.** Consult orthopedics immediately to take the patient to the operating room.
- **d.** Provide analgesia and Holter monitor for discharge when ambulatory.
- **e.** Use the Allis maneuver and place the patient in a knee immobilizer.

Answer: e. A patient with a posterior dislocation typically holds the hip flexed, adducted, and internally rotated. The knee of the affected

extremity rests on the opposite thigh. The Allis technique is usually effective for both posterior and obturator dislocations. With the knee flexed, the operator applies steady traction in line with the deformity. The hip is slowly brought to 90 degrees of flexion while steady upward traction and gentle rotation are applied.

6. A mother brings her 11-year-old boy for evaluation of left knee pain that is worse after physical activity. Radiographs of the knee were negative. What is the most appropriate next step in the patient's management?
- **a.** Hip radiograph with frog-leg views
- **b.** Joint aspiration for evaluation of transient synovitis
- **c.** Place a knee immobilizer and ensure follow-up in 1 week
- **d.** Radiograph of right knee for comparison
- **e.** Rest, ice, compression, elevation, and orthopedic follow-up urgently

Answer: a. This patient may have a slipped capital femoral epiphysis (SCFE), which most commonly develops in boys 10 to 17 years old during their period of rapid growth. Referred pain to the knee is a classic manifestation, and patients frequently present with groin, thigh, or knee pain rather than hip pain. Initially, anteroposterior, lateral, and frog-leg lateral radiographs of the hip should be obtained. The frog-leg lateral projection shows the hip in a plane midway between the anteroposterior and lateral views.

7. A 75-year-old woman presents after a fall from standing. She has right hip pain and tenderness to palpation but no obvious deformity. Right knee and ankle examinations are normal, without tenderness, deformity, or external signs of trauma. Hip and pelvis radiographs are negative for fracture, but the patient is unable to bear weight on her right leg. The next appropriate step in management is:
- **a.** Admit to the hospital for bed rest.
- **b.** Discharge the patient home with analgesia and a walker.
- **c.** Obtain magnetic resonance imaging (MRI) of the hip to assess for fracture not identified by radiographs.
- **d.** Obtain radiographs of the rest of her right leg to ensure no occult fracture is present.

Answer: c. With hip injury, if radiographs do not show a fracture or suggestion of injury and the patient is unable to ambulate, further imaging studies should be obtained to evaluate for occult fracture. Two percent to 10% of all hip fractures are radiographically occult. Failure to detect these fractures results in increased morbidity and mortality.

8. Which of the following injuries is appropriate for traction splinting by prehospital providers?
- **a.** Femoral fracture with bone protrusion through the skin
- **b.** Posterior hip dislocation
- **c.** Severe crush injury of leg with obvious deformity of the knee
- **d.** Suspected closed mid shaft femoral fracture

Answer: d. Traction splints can provide pain relief, immobilization, and limit blood loss when applied correctly to a femoral fracture. However, contraindications to the use of traction splints include pelvic fractures, patellar fractures, ligamentous knee injuries, and tibia or fibula fractures. Traction in the prehospital setting should not be applied to any open fracture that has exposed bone. Such reduction pulls grossly contaminated bone fragments back into the wound before adequate débridement can be undertaken in the operating room.

9. A 15-year-old female gymnast presents after experiencing the sudden onset of severe groin pain during a dismount when she landed in a flexed-hip position. The pain radiates into her abdomen, and flexion of the hip produces pain, but there is no deformity noted. What is the most likely radiographic finding?
- **a.** Avascular necrosis (AVN) of the femoral head noted on magnetic resonance imaging (MRI) scan
- **b.** Diastasis of the pubic symphysis on anteroposterior pelvis radiographs
- **c.** Femoral neck fracture on dedicated anteroposterior hip radiograph
- **d.** Iliopsoas muscle with some associated hemorrhage on computed tomography (CT) scan

Answer: d. Gymnasts and dancers are the group of athletes most likely to experience an injury to the iliopsoas as a result of sudden forceful hip flexion against resistance. Severe pain often is experienced in the groin, thigh, or low back region. Severe intra-abdominal pain is common at the muscle origin and may dominate the clinical picture. Examination reveals groin tenderness and pain with active hip flexion. Radiographs of the femur should be obtained to identify an avulsion fracture of the lesser trochanter. CT scan frequently will demonstrate a large hematoma. Bed rest with partial flexion at the knee and hip generally is required for 7 to 10 days. With severe strains, symptoms may persist for 2 to 3 months. Referral to a sports medicine specialist is appropriate.

10. A 45-year-old male presents with a posterior hip dislocation after a motor vehicle crash (MVC) noted on radiographs. After sedation of the patient and reduction of the dislocated hip, what is the most appropriate next step in the patient's management?
- **a.** Have the patient ambulate to assess the stability of the joint.
- **b.** Measure the femoral compartment pressure.
- **c.** Obtain post-reduction hip radiographs to assess for additional injuries and adequate reduction.
- **d.** Place a traction splint.

Answer: c. Obtaining post-reduction radiographs to ensure adequate reduction and evaluate for associated injuries is essential. After closed reduction, the hip should be tested for stability, which is accomplished by gently taking it through a full range of motion to see whether it will re-dislocate. After testing has ensured stability, the injured extremity should be placed in a knee immobilizer, and an abduction pillow should be applied to prevent repeat dislocation.

48

Knee and Lower Leg Injuries

Moira Davenport and Vanessa S.Franco

KEY CONCEPTS

- Knee dislocation often causes vascular injury to the popliteal artery. Early revascularization is crucial. Hard signs of vascular injury include absent pedal pulses, cool mottled foot, expanding popliteal hematoma, or popliteal hemorrhage. When any of these are present, angiography or emergent surgical exploration is indicated.
- Soft signs of popliteal artery injury include asymmetric pedal pulses and foot or leg paresthesias. Computed tomography (CT) angiography or duplex ultrasound study is indicated when these are present.
- In the absence of signs of popliteal injury, the knee dislocation patient can be observed for 24 h, with measurement of the ankle-brachial index (ABI) every 3–4 h. An ABI >0.9 over a 24-h period effectively excludes significant popliteal artery injury.
- Tibial plateau fractures should be considered in patients with a traumatic knee injury and inability to bear weight. Fractures may be radiographically occult, so CT imaging should be considered if clinical suspicion is high. In general, if a patient is unable to bear weight after a knee injury but no acute fracture is identified in the emergency department (ED), advanced imaging should be considered.
- Extensor mechanism injuries such as patellar and quadriceps tendon injuries are important to recognize, as delayed diagnosis is associated with substantial morbidity. A palpable defect in the quadriceps tendon or patellar tendon or over the patella and an inability to perform a straight leg raise should raise suspicion for such injuries. Knee immobilization and urgent orthopedic follow-up are advised.
- A dislocated patella will be fixed in a position superolateral to its normal position. Reduction is performed by gentle knee extension with medially directed or valgus directed pressure on the displaced patella.
- Injuries to the cruciate and collateral ligaments may not be detectable on initial examination because of effusion and splinting. Emergent diagnosis is not necessary, but the patient should undergo a follow-up examination by an orthopedist within a week.
- Lipohemarthrosis is an uncommon and subtle sign of occult fracture but should be sought on radiographs of traumatized knees.
- Compartment syndrome is a serious complication of tibial shaft fracture, usually occurring 24–48 h after injury. Orthopedic consultation or measurement of compartment pressure should be obtained when the patient's pain is increasing despite immobilization and support of the fracture.

KNEE INJURIES—FOUNDATIONS

Background and Importance

The critical responsibility of the emergency physician in evaluating patients with knee pain includes identifying neurovascular injuries, reducing dislocations, stabilizing fractures, and administering antibiotics when indicated. Definitive treatment of less urgent problems can be referred to the outpatient setting.

Anatomy, Physiology, and Pathophysiology

The knee is a modified hinge, diarthrodial synovial joint that consists of the tibiofemoral and patellofemoral joints. The head of the fibula, although not part of this articulation, is closely approximated laterally and provides a site for the attachment of muscles and ligaments. Joint stability is provided primarily by ligaments, although surrounding muscles and the joint capsule contribute as well (Fig. 48.1). The capsule of the knee joint is reinforced at multiple sites—anteriorly, by the ligamentum patellae; medially and laterally, by the medial and lateral patellar retinacula; and posterolaterally, by a combination of structures termed the *posterolateral corner.*

Femur

The distal femur terminates in the medial and lateral condyles. A condyle is a rounded prominence at the end of a bone where it interfaces with another bone. An epicondyle is a prominence on a condyle where a ligament or tendon attaches. The femoral condyles protrude anteriorly, leaving a vertical groove between them, forming the femoral trochlea. *Trochlea* is the term for an anatomic structure that resembles a pulley. The patella slides up and down in the groove during knee extension and flexion. The femoral condyles articulate with the superior surface of the tibia and tibial condyles.

The Tibia

The proximal end of the tibia expands into the medial and lateral condyles. Together they make up approximately three-quarters of the proximal tibial surface, and their integrity is important for normal knee alignment, stability, and motion. The plateau normally slopes 10 degrees from anterior to posterior.

The intercondylar eminence, or tibial spine, is the central portion of the proximal tibial surface. The spine has two prominences, the medial tubercle and lateral tubercle. The medial tubercle is larger and more anterior. Two intercondylar fossae are present on the proximal tibial surface, one anterior and one posterior to the intercondylar eminence. The anterior cruciate ligament (ACL) and anterior horns of the medial and lateral menisci attach in the anterior intercondylar fossa. The posterior cruciate ligament (PCL) and posterior horns of the menisci attach in the posterior intercondylar fossa. The tibia is anchored to the femur by four strong ligaments, the ACL, PCL, medial collateral ligament (MCL), and lateral collateral ligament (LCL).

Cruciate Ligaments (ACL and PCL)

The cruciate ligaments are so named (Latin *crus,* meaning "cross") because they cross each other between their attachments. They are the primary stabilizers for anterior and posterior displacement of the tibia on the femur. The ACL arises from the medial surface of the lateral femoral condyle and inserts on the anterior surface of the tibial plateau within the tibial intercondylar notch. The ACL prevents excessive

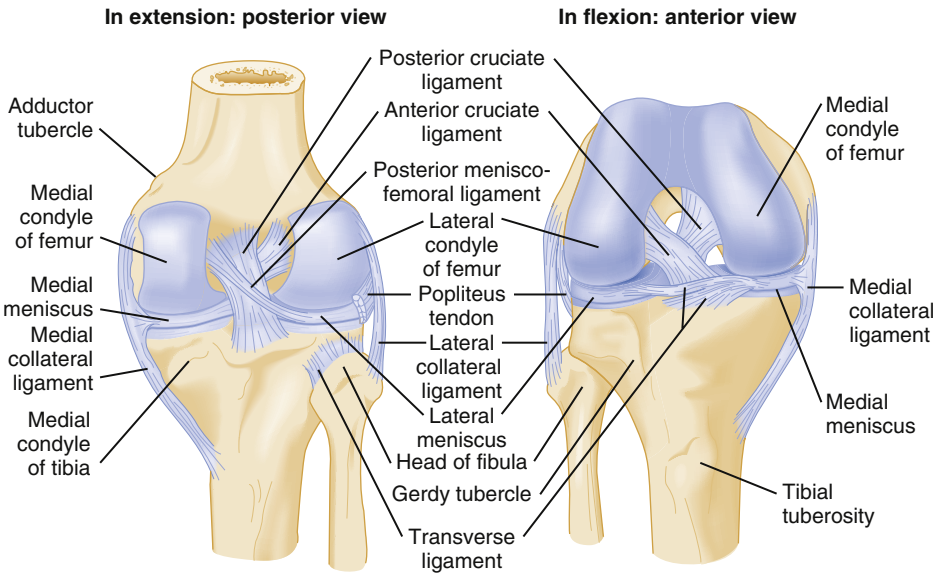

Fig. 48.1 Posterior and Anterior Views of the Right Knee.

anterior displacement of the tibia on the femur and helps to control rotation and hyperextension of the knee during twisting and turning activities. *It is the most commonly injured major ligament of the knee.*

The PCL originates from the medial femoral condyle and inserts on the posterior surface of the tibial plateau within the intercondylar notch. The PCL prevents excessive posterior displacement of the tibia on the femur, especially during flexion. The PCL is considerably stronger than its anterior counterpart and is thus less frequently injured than the ACL. The cruciate ligaments have a rich blood supply, and injury typically results in a hemorrhagic knee effusion.

Collateral Ligaments (MCL and LCL)

The medial stabilizers of the knee include the joint capsule, MCL, and the semimembranosus and pes anserinus. These structures resist valgus laxity and medial rotary instability. Like the ACL and PCL, the MCL is made up of two distinct entities, the long superficial fibers and the deep capsular fibers. The MCL originates from the medial femoral condyle and inserts onto the medial tibia. The deep capsular bundle inserts at the medial meniscus, further stabilizing this structure.

Lateral knee stability is anatomically similar to the medial aspect of the knee, with the LCL and the lateral joint capsule serving as the main restraints to varus deformity. The LCL originates from the lateral femoral condyle and inserts onto the fibula. Additional stability is provided by the iliotibial (IT) band, the biceps tendon, and portions of the posterolateral corner, particularly the popliteus tendon. Resistance to varus stress is provided mainly by the LCL. The lateral ligaments are under tension during standing and walking, when they are at or near maximal extension.

Knee Compartments

Functionally, the knee joint can be divided into three compartments—patellofemoral, medial tibiofemoral, and lateral tibiofemoral. These compartments, defined anatomically by the articulation of the bones, are contained within the same joint capsule. The patellofemoral compartment, located anteriorly, contains the quadriceps tendon, which envelops the patella, continues inferiorly as the patellar tendon, and inserts on the tibial tubercle. The fibers of the medial and lateral retinacula are found on either side of the patella, originating from the vastus medialis and vastus lateralis.

The medial tibiofemoral compartment is located on the medial aspect of the knee and consists of the medial femoral condyle, concave medial tibial condyle (plateau), medial meniscus, MCL, adductor tubercle, and pes anserinus.

The lateral tibiofemoral compartment encompasses the lateral half of the knee joint and includes the lateral femoral condyle and epicondyle, lateral tibial condyle (plateau), LCL, lateral meniscus, and popliteus tendon. The fibular head can be palpated posterolaterally and inferiorly to the joint line but is not usually considered a structure of the lateral tibiofemoral compartment.

Fabella

The fabella, present in some patients, is a sesamoid bone located in the lateral head of the gastrocnemius muscle and should not be mistaken for an intra-articular loose body or fracture fragment.

Popliteal Fossa

A hollow in the posterior aspect of the knee, the popliteal fossa is bound laterally by the biceps femoris tendon, medially by the semimembranosus and semitendinosus muscles, and inferiorly by the two heads of the gastrocnemius muscle. Found within the popliteal space are the popliteal artery, popliteal vein, and peroneal and tibial nerves.

Popliteal Artery

The popliteal artery is the continuation of the femoral artery beyond the adductor hiatus. It descends across the posterior aspect of the knee joint and terminates at the level of the tibial tubercle, where it divides into the anterior and posterior tibial arteries. The peroneal artery then branches from the posterior tibial artery. Together, the three arteries are termed the *trifurcation of the popliteal artery.* The popliteal artery is anchored firmly at the proximal and distal ends of the popliteal fossa, which explains the high incidence of arterial injury with knee dislocations. Blood supply to the knee joint comes from the popliteal artery by way of the geniculate arteries.

Tibial Nerve

The tibial nerve, along with one of its branches, the common peroneal nerve, is responsible for innervation of the knee. The tibial nerve joins the artery and vein in the popliteal fossa. The common peroneal nerve wraps around the head of the fibula and continues inferiorly as the deep and superficial peroneal nerves. Common peroneal nerve injury may occur in association with tibiofemoral dislocation

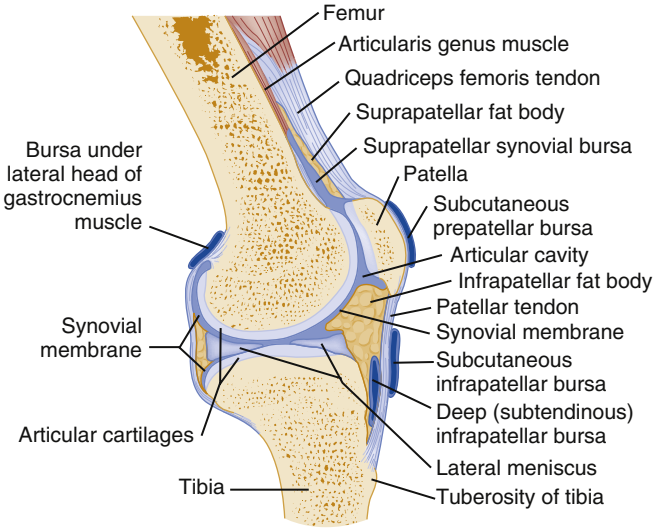

Fig. 48.2 Parasagittal section (lateral to midline) of the knee showing extensor mechanisms and relevant structures.

or injury to the head of the fibula or may be caused by prolonged compression.

Extensor Mechanism

The quadriceps muscles, quadriceps tendon, medial and lateral retinacula, patella, patellar tendon, and tibial tubercle comprise the extensor mechanism of the knee (Fig. 48.2). The patella is the largest sesamoid bone in the body. It is held in place by the quadriceps tendon, patellar tendon, and medial and lateral retinacula. As an integral part of the extensor mechanism, the patella increases the effective lever mechanism of the quadriceps by providing anterior displacement of the quadriceps tendon. The quadriceps tendon is a continuation of the quadriceps femoris muscle, which consists of the rectus femoris, vastus medialis, vastus lateralis, and vastus intermedius, which extend the knee.

Meniscus

The medial and lateral menisci are crescent-shaped fibrocartilaginous cushions that sit on the superior articular surface of the tibia and provide a gliding surface for the femoral condyles. They function as shock absorbers and aid in the distribution of stress across the joint surface by providing a larger area of contact. They also act as secondary stabilizers by deepening the tibial plateau. Normal tibiofemoral articulation and function depend on meniscal integrity. Meniscal damage or loss may lead to osteoarthritis. The medial meniscus is firmly attached anteriorly and posteriorly to the joint capsule. The lateral meniscus is less firmly attached to the capsule and more mobile. The menisci move slightly forward with extension and backward with flexion. Because of its greater mobility, the lateral meniscus is less vulnerable to injury. The meniscus is avascular except at the peripheral third, which has the greatest potential to heal after injury.

The Iliotibial band

The IT band is a fascial bundle that originates on the iliac crest and inserts on the lateral tibial tubercle. It connects the lateral femoral condyle and lateral tibia and stabilizes the knee joint in extension.

The Popliteus

The popliteus is a small flat muscle that originates on the lateral femoral condyle and inserts on the posteromedial tibia, capsule, and lateral meniscus. It passes beneath the lateral head of the gastrocnemius. Its tendon is surrounded by a bursa that separates it from the fibular collateral ligament, femoral condyle, and capsule. Functionally, it prevents external rotation of the tibia and withdraws the lateral meniscus during flexion to prevent impingement between the femur and tibia. A third function, along with the quadriceps and PCL, is to stabilize the knee by preventing forward displacement of the femur on the tibia.

Bursae

The knee has several bursae, which decrease friction between moving structures. They usually are thin but, with repeated stress, may become thickened and fluid filled. The prepatellar bursa is located between the patella and skin. The superficial infrapatellar bursa is located between the tibial tubercle and skin. The deep infrapatellar bursa is located between the posterior margin of the distal part of the patellar tendon and anterior aspect of the tibia. The suprapatellar bursa is not a true bursa but rather is an extension of the tibiofemoral joint capsule. Therefore it expands in conditions that cause knee effusion. The prepatellar bursa is anterior to the patella and does not communicate with the tibiofemoral joint.

The anserine bursa separates the pes anserinus from the distal portion of the MCL and medial tibial condyle. Pes anserinus means "goose foot" and anserine means "related to the pes anserinus." The term *pes anserinus* derives from the fact that the bursa underlies the anserine tendon, a three-forked structure constituting the insertion of the gracilis, sartorius, and semitendinosus muscles.

KNEE INJURIES—CLINICAL FEATURES

The initial assessment of a painful knee includes a history and physical examination. On history, immediate deformity noted by the patient, hemarthrosis, or instability after a traumatic injury suggests an intraarticular fracture, cruciate ligament injury, vascular injury, or dislocation. A complaint of giving way may indicate instability or involuntary muscle inhibition secondary to pain. This is a nonspecific symptom and may be reported in association with arthritis or patellofemoral disorders when inhibition of quadriceps function occurs in association with episodic pain.

The knee examination should be focused on specific locations of tenderness to palpation, visible deformity, abnormalities in range of motion (ROM), stability of the joint, and signs of external trauma such as effusion and ecchymosis, in addition to signs of infection such as warmth, swelling, erythema and purulent drainage. The femur, hip, and tibia should also be examined as pain from injuries to these regions may be referred to the knee. Patients with radiculopathy of the third, fourth, or fifth lumbar roots also may report knee pain. Children with a slipped capital femoral epiphysis, toxic tenosynovitis, toddler's fracture, or septic hip frequently complain of knee pain as well.

Physical Examination

Proper examination of the knee requires the patient to be supine, with both legs exposed. Examination of the knee begins with visual inspection (Box 48.1), followed by palpation. On initial inspection, localized swelling should be distinguished from the presence of a joint effusion. If a large joint effusion is present, the patella is elevated from the femur by fluid. Loss of the medial peripatellar concavity may be the only sign of a small knee effusion. Swelling in the prepatellar bursa or infrapatellar bursa, termed bursitis, is found just beneath the skin, superficial to or just inferior to the patella, respectively. Bursitis should not be confused with a knee effusion, because they have different etiologies and treatments.

Inspection should also include assessing for erythema of the joint, which may suggest an inflammatory or infectious process. Obvious deformities or open wounds should also be noted during visual

BOX 48.1 Examination of the Knee

1. Assess neurovascular integrity of the foot.
2. Determine whether a knee effusion is present, and assess for gross deformity or open wounds.
3. Identify signs of infection—redness, warmth, and effusion out of proportion to mechanism of injury.
4. Localize tenderness.
5. Assess for range of motion, stability, and the integrity of the extensor mechanism.

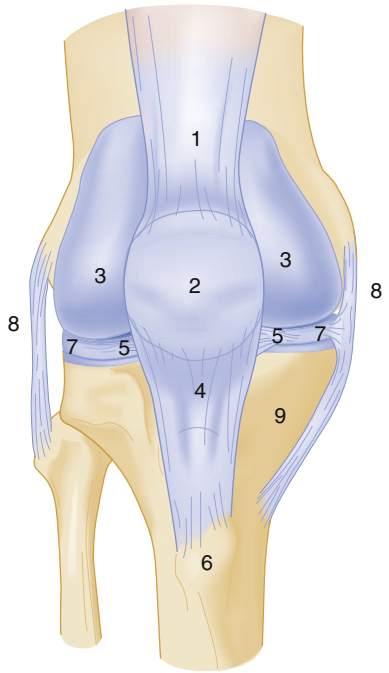

Fig. 48.3 Sites for Palpation of Tenderness in the Knee. *1,* Quadriceps tendon injury; *2,* prepatellar bursitis, patella pain; *3,* retinacular pain after patella subluxation; *4,* patella tendon injury; *5,* fat pad tenderness; *6,* tibial tubercle pain as in Osgood-Schlatter, but also consider tibial plateau fracture in the right setting; *7,* meniscus pain or arthritis; *8,* collateral ligament pain; *9,* pes anserine tendinitis-bursitis. (Adapted from Cailliet R. Knee pain. In *soft tissue pain and disability*. 3rd ed. Philadelphia: FA Davis; 1976:411.)

assessment. The posterior aspect of the knee should be examined for fullness.

After inspection, palpation of the knee should be performed (Fig. 48.3). The bony prominences of the knee (patella, tibia, fibula) should be palpated to assess for fracture or overuse injuries. The quadriceps tendon and the patellar tendon should be palpated for palpable defects that might suggest tendon rupture. The joint line should be palpated for tenderness. The posterior aspect of the knee should be palpated for tenderness or palpable defects. The vascular integrity of the knee should be assessed with the dorsalis pedis (DP) and posterior tibial (PT) pulses in the foot.

Accurate diagnosis of knee injuries based on examination alone is challenging in the acute phase because of pain and swelling. Thus the main goals are to relieve pain, ensure proper location and stability of the joint, assess for neurovascular injury, determine the need for radiography, and identify infections and inflammatory conditions.

A number of maneuvers have been developed to aid the emergency clinician in diagnosing ligamentous and meniscal injuries using only the physical examination (see later). However, interpretation of these maneuvers is limited by pain, splinting, or effusion and has been found to be variably accurate when compared with magnetic resonance imaging (MRI) or arthroscopy findings. Accuracy of these maneuvers is improved if they are done after pain and swelling have resolved. The primary goals in emergency care are to identify whether fracture, dislocation, or vascular injury is present, ensure weight-bearing status, and refer for reevaluation by a primary care provider or orthopedist in a timely manner.

TABLE 48.1 Differential Diagnoses for Various Knee Injuries

Injury	Differential Diagnostic Conditions
Knee dislocation	Patellar dislocation, distal femur fracture, tibial plateau fracture
Distal femur fracture	Tibial plateau fracture, knee dislocation, quadriceps tendon rupture
Tibial plateau fracture	Distal femur fracture, knee dislocation, patellar fracture, patellar dislocation, tibial spine fracture, patellar tendon rupture
Tibial spine fracture	Tibial plateau fracture, patellar tendon rupture, anterior cruciate ligament (ACL) injury
Osteochondritis dissecans	Distal femur fracture, tibial plateau fracture, meniscal injury
Osteoarthrosis	Distal femur fracture, tibial plateau fracture, meniscal injury, chronic ACL deficiency, osteochondritis dissecans
Injury	**Differential Diagnostic Conditions**
Quadriceps/patellar tendon injury	Patellar fracture, patellar dislocation, distal femur fracture, tibial spine fracture, tibial plateau fracture
Patellar fracture	Patellar dislocation, quadriceps/patellar tendon rupture
Patellar dislocation	Patellar fracture, quadriceps/patellar tendon rupture
Cruciate ligament injury	Meniscal injury, collateral ligament injury, distal femur fracture, tibial plateau fracture, tibial spine fracture
Collateral ligament injury	Posterolateral corner injury, meniscal injury, cruciate ligament injury, distal femur fracture, tibial plateau fracture
Meniscal injury	Collateral ligament injury, cruciate ligament injury, osteochondritis dissecans, distal femur fracture, tibial plateau fracture
Overuse syndromes	Cruciate ligament injury, collateral ligament injury, osteochondritis dissecans

KNEE INJURIES—DIFFERENTIAL DIAGNOSES

Differential diagnoses for patients presenting with knee pain is vast and varies depending on history as well as location of pain. Tenderness in specific regions can be suggestive of different etiologies (see Fig. 48.1 and Table 48.1). Focal bony tenderness in the absence of x-ray findings should raise suspicion for a stress fracture or occult traumatic fracture depending on history. Associated fractures of the femoral neck, hip dislocation, and acetabular fractures should always be considered in traumatic knee pain as well.

Dislocation

A patient presenting with a history of self-reduced knee "dislocation" may have suffered an actual knee dislocation or a patellar dislocation.

It is imperative to clarify both the mechanism of injury and what the patient observed to ascertain whether the patella or knee was dislocated, because these two diagnoses have very different management but may self-reduce prior to arrival.

Effusion

Differential diagnoses for patients presenting with a large effusion in the setting of trauma include a distal femur fracture, an ACL or a PCL injury, dislocation, and a tibial plateau or spine fracture. Examination in these patients is often difficult, so the mechanism of injury as well as the location of tenderness and x-ray findings may help the clinician to differentiate between these entities. An atraumatic knee effusion commonly results from osteoarthritis. A focused history and physical examination are important as the differential diagnoses includes insufficiency fracture, septic arthritis, inflammatory arthritis (e.g., gout), hemarthrosis or lipohemarthrosis from occult fracture, avascular necrosis, a ruptured Baker cyst, or possible malignancy. Arthrocentesis may be used for diagnosis.

Anterior Knee Pain

Patellofemoral pain is one of the most common causes of anterior knee pain in children and adults but is usually not associated with bony tenderness. Tenderness over the tibial tubercle in a pediatric patient may indicate Osgood-Schlatter disease, but underlying fracture should be considered in the setting of acute trauma. In an adolescent, pain along the femoral or tibial epiphysis after trauma may represent a Salter-Harris type I fracture, a fracture through the physis. Tibial tenderness in an adult may suggest a tibial plateau fracture.

Gradual-onset pain over the anterior femoral condyle in pediatric patients should raise suspicion for osteochondritis dissecans (OD). The anterior knee should also be inspected for any sign of septic or aseptic bursitis over the prepatellar bursa. Acute onset, traumatic pain over the anterior aspect of the knee should raise suspicion for an extensor mechanism injury, such as patellar tendon rupture, quadriceps tendon rupture, or patellar fracture. A straight leg raise is useful in assessing the integrity of the extensor mechanism. More insidious onset of pain over the patellar or quadriceps tendon may be more suggestive of tendinitis.

Medial and Lateral Pain

Acute-onset medial or lateral joint line pain after a twisting mechanism should raise suspicion for a meniscus injury. Differential diagnoses for meniscal tears are extensive and include loose bodies, osteochondrotic lesions, and tibial fractures. Medial knee pain is also seen with medial tibial stress fractures, proximal medial tibial stress syndrome (MTSS), pes anserine bursitis/tendinopathy, or MCL strain. Lateral knee pain is typically associated with LCL strain, IT band dysfunction, popliteal tendinitis, or proximal fibular stress fracture.

Posterior Knee Pain

Baker cysts are a common cause of posterior knee pain. However, differential diagnoses should include a deep vein thrombosis (DVT), hamstring injury, or popliteal artery pseudoaneurysm.

KNEE INJURIES—EXAMINATION MANEUVERS

Anterior Drawer/Lachman Test

The anterior drawer test seeks to identify tears of the ACL. The test is performed with the patient in a supine position, hip flexed at 45 degrees, and knee flexed at 90 degrees. While stabilizing the patient's foot, the examiner places his or her thumbs over the joint line while pulling the tibia forward. The thumbs are used to palpate for any translation of the tibia relative to the femur. A positive test result is defined as greater anterior translation of the tibia relative to the femur as compared with the other knee. The test is poorly sensitive but fairly specific. *The Lachman test* is a more accurate test for ACL injuries, with a high sensitivity and specificity. The Lachman test is done with the knee flexed 20 to 30 degrees while the examiner uses one hand to grasp and stabilize the femur. The tibia is then pulled anteriorly, and the examiner notes tibial excursion. The examiner records "firmness" or a "soft end point." The end point can be graded as 1+ (0 to 5 mm more displacement than on the normal side), 2+ (5 to 10 mm), or 3+ (>10 mm). The PCL must be intact for the test results to be valid.

Posterior Drawer Test

The posterior drawer test assesses for PCL injury. The posterior drawer test can be accomplished with the patient's knee flexed at 90 degrees and the foot stabilized by the examiner. A smooth backward force is applied to the tibia. Posterior displacement of the tibia more than 5 mm, or a soft end point, indicates injury to the PCL. The posterior drawer test result may be positive in only 85% of patients with PCL insufficiency documented operatively. The affected knee should be compared with the normal knee because patients may have increased laxity at baseline.

Posterior Sag Sign Test

The posterior sag sign test is a second method of determining PCL integrity. Sensitivity in the acute phase is 79%. To perform this test, the patient is placed in a supine position, and a pillow is placed under the distal thigh for support while the heel rests on the stretcher. The knee is flexed to 45 or 90 degrees. If the tibia sags backward, the test result is considered to be positive, indicating PCL insufficiency. It is possible to obtain a false-positive result on the anterior drawer test if the examiner fails to recognize the posterior sag sign, as the tibia will translate forward across the femur simply because its starting position is more posterior. Posterior sag also may be appreciated during passive elevation of the leg in a fully extended position, with the examiner applying the elevating force at the ankle. As the leg is elevated, the tibia may fall back on the femur if the PCL is ruptured.

Collateral Ligament Stress Test

The collateral ligament stress test is used to test the integrity of the MCL and LCL. With the patient lying supine, the examiner applies varus and valgus stress with the knee at 0 and 30 degrees of flexion. Joint line opening is the amount of movement produced between the tibia and femur; this can be palpated and estimated in millimeters. The normal knee should be subjected to the same amount of valgus and varus stress; the joint line opening is then compared with that in the injured knee. Isolated collateral ligament tears are detected only with the knee in slight flexion because, in extension, the cruciate ligaments, capsule, and lesser ligaments of the knee provide significant lateral stability. Laxity in full extension implies complete collateral ligament tear and also injury to the cruciate ligaments or other structures. Laxity may be graded as grade I (some laxity), grade II (marked laxity), and grade III (total laxity).

Assessing for Meniscal Tears

McMurray Test

The McMurray test is used to help identify meniscal tears. The patient is placed in a supine position with the knee hyperflexed. The examiner grasps the foot with one hand and the knee with the other. The

examiner flexes and extends the knee while simultaneously internally and externally rotating the tibia on the femur and providing slight varus and valgus stress. A positive test is the occurrence of clicking palpable along the joint line, pain, or locking of the knee.

Apley Test

This test also aids in diagnosing meniscal tears. With the patient prone, the knee is flexed to 90 degrees, and the leg is internally and externally rotated with pressure applied to the heel. Pain elicited by downward pressure suggests meniscal pathology. The pain should be relieved with distraction of the knee and rotation of the leg back to a neutral position. Although relatively specific, the Apley test is not sensitive.

KNEE INJURIES—DIAGNOSTIC TESTING

Radiologic Evaluation

X-rays can be used to assess for radiopaque foreign bodies, subluxation, dislocation, fracture, and joint space narrowing. Note that on a straight anteroposterior (AP) view, the anterior and posterior portions of the normal tibial plateau may not appear to be at the same level.

Some plain film findings may be suggestive of ligamentous injuries as well. An effusion can be seen as a radiolucent area (with density similar to that of fat) distending the joint capsule. The presence of a linear interface between two different densities within an effusion suggests *lipohemarthrosis* (Fig. 48.4), in which the effusion contains not only blood but also fat. This feature results from the entry of marrow fat into the joint cavity and is suggestive of fracture.

Clinical decision rules help to decrease unnecessary radiography. The Ottawa Knee Rules and the Pittsburgh Knee Rules are the most commonly used (see Table 48.2). Patients meeting any listed criteria should have knee x-rays performed. The Ottawa Knee Rules are meant to be applied only to acute injuries (<7 days old).

When the two rules are compared, both are more than 95% sensitive, but the Pittsburgh rule may be more specific, allowing fewer radiographs to be done without sacrificing sensitivity. Compliance with knee rules is poor in academic emergency departments (EDs) for various reasons. We recommend considering the use of either decision rule as support in evaluating patients with knee pain in the ED. However, neither rule is meant to supersede clinical judgment, because neither rule is 100% sensitive or specific for fracture.

In the evaluation of knee trauma, knee x-rays should include a standard AP, lateral, and "sunrise" view. Tunnel views, which image the intercondylar notch, are used to detect tibial spine fractures and loose bodies within the notch. Oblique views can be helpful in identifying tibial plateau fractures. Sunrise views are essential in evaluating for patellar fractures.

Because the sensitivity of radiographs for acute knee injuries is low, we recommend computed tomography (CT) or knee immobilization and urgent orthopedic referral reevaluation when fracture is suspected and plain films are negative. MRI may also be used to detect fractures and is the imaging gold standard (comparable with arthroscopy findings) for soft tissue injury but is rarely indicated in the evaluation of knee and leg trauma in the ED.

Vascular Imaging

CTA has largely replaced catheter-based angiography in assessing for popliteal artery injury after knee dislocations because it carries less risk without sacrificing a high sensitivity and specificity in detecting arterial injury. MR angiography and duplex ultrasonography can also be used for evaluation of the popliteal artery after tibiofemoral dislocation, but their roles in the ED setting are less well defined.

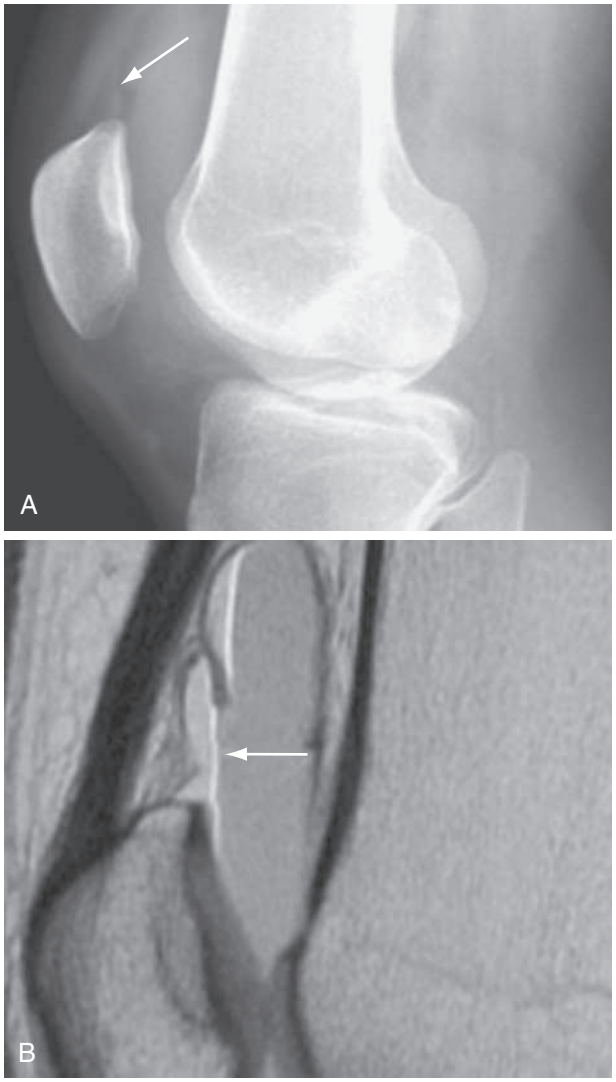

Fig. 48.4 Lipohemarthrosis. (A) Lateral plain film of the knee of a young woman with a nondisplaced patella fracture. The only radiographic abnormality is an effusion that contains a linear interface *(arrow)* between two soft tissue densities, suggesting lipohemarthrosis. (B) Magnetic resonance imaging scan from the same patient shows plainly the presence of blood and fat in the effusion *(arrow).* The nondisplaced patella fracture is not seen.

TABLE 48.2 Clinical Decision Rules for Knee Injury

Ottawa Knee Rules	Pittsburgh Knee Rules
Age >55	Age <12 or >50
Isolated patellar tenderness	Inability to walk 4 steps
Isolated fibular head tenderness	
Flexion <90 degrees	
Inability to weight bear 4 steps immediately after injury or in the emergency department	
98.5 sensitivity, 49% specificity	100% sensitivity, 79% specificity

Arthroscopy

Arthroscopy is a nonemergent but useful modality in the diagnosis and treatment of knee injuries, including injuries of the meniscus, cruciate

ligaments, articular cartilage, capsule, and synovium. Arthroscopy is superior to MRI for the diagnosis of meniscal tears and other soft tissue injuries, and the diagnosed problem can be repaired immediately. The need for arthroscopy need not be determined in the emergent setting as long as appropriate and timely referral to an orthopedist is made.

Joint Injection

An open joint is considered a surgical emergency. When violation of the joint capsule is suspected but not obvious, studies suggest that CT imaging performs better than the sterile saline load test in identifying traumatic knee arthrotomies. The sterile saline load test involves the injection of 200 mL of sterile saline into the joint capsule while observing the laceration to see if the saline emerges from the laceration. Methylene blue has not been shown to be more accurate than saline, can interfere with arthroscopy, and may cause an inflammatory reaction; therefore it is not advised. For open joints, we recommend orthopedic consultation, emergent antibiotics, and CT imaging to confirm diagnosis. Of note, there is mounting literature that CT imaging is sensitive for an open joint and less painful than infusing a saline load into the involved joint.

Arthrocentesis

Aspiration of fluid from the knee joint can be diagnostic as well as therapeutic by reducing pressure from an effusion. Arthrocentesis may be performed if the injured knee is greatly distended with a tight effusion and can be useful to perform if the cause of the joint effusion is unclear. Analysis of the aspirate can differentiate simple effusion, hemarthrosis, lipohemarthrosis, rheumatologic conditions, and septic arthritis and often provides significant relief of pain for the patient. *Arthrocentesis should be avoided in the setting of overlying cellulitis*.

SPECIFIC KNEE INJURIES

Knee Dislocations—Foundations

Knee dislocation refers to tibiofemoral dislocation and should not be confused with patellofemoral dislocation, a relatively minor injury. Knee dislocation is a limb-threatening emergency due to the risk of popliteal artery injury. Knee dislocations are always associated with significant ligamentous injury. The joint capsule is disrupted, with accompanying trauma to the muscles and tendons. Injury to the popliteal artery is the most severe complication and is the primary cause of morbidity and limb loss.

Knee dislocation is relatively uncommon but should be considered in the setting of an appropriate injury mechanism because many dislocations spontaneously reduce before the patient arrives in the ED. Importantly, reduction before ED arrival does not lessen the likelihood of vascular injury, and these patients should be evaluated for vascular injury, particularly if the patient is obese, has an associated distracting injury, or if the injury involved in a high-energy mechanism.

The neurovascular bundle, which is composed of the popliteal artery, popliteal vein, and common peroneal nerve, runs posteriorly behind all bony and ligamentous structures in the popliteal fossa. The popliteal artery is fixed in the fibrous tunnel of the adductor magnus hiatus proximally and traverses the fibrous arch of the soleus and interosseous membrane distally. In essence, it is tethered to the femur and tibia, and its inherent immobility renders it susceptible to injury during dislocation. Because of the parallel course of the popliteal vein and peroneal nerve, they are often injured simultaneously.

Anatomically, dislocations are described according to the displacement of the tibia relative to the femur. They are classified into five types—anterior, posterior, medial, lateral, and rotary. Most knee dislocations are anterior and result from hyperextension. Posterior dislocations are the second most common type and usually result from high-velocity direct trauma to the flexed knee, often in association with vehicular trauma (e.g., automobile dashboard impact).

Knee Dislocations—Clinical Features

The diagnosis of knee dislocation is based on the mechanism of injury and clinical and radiographic findings. When a dislocation is present and has not reduced spontaneously, it is usually clinically obvious. However, there may be no effusion after reduction because the ruptured capsule allows blood and joint fluid to escape into the thigh and leg.

Popliteal artery injury most commonly occurs with posterior dislocations. The collateral geniculate arteries around the knee also may be damaged directly or may be secondarily compressed by hematoma formation after the dislocation. Direct arterial injury, decreased collateral circulation, and elevated compartment pressures all may compromise limb perfusion.

Findings associated with peripheral vascular injury and management approaches are described in Chapter 40. The PT and DP pulses should be evaluated, but popliteal artery injury may still be present in some patients with palpable pulses.

Isolated intimal tears are not detectable on physical examination and are seen only angiographically or with duplex ultrasound. Although these tears are usually managed nonoperatively, a vascular surgeon should be consulted when identified. Injuries to small branches of the popliteal artery can be managed by observation and serial examinations.

As with all limb injuries, neurologic integrity should be assessed and documented. The peroneal nerve is at risk for injury, especially in posterolateral dislocations. Peroneal nerve function is evaluated by determining sensation of the dorsum of the foot and by having the patient dorsiflex the ankle. Less commonly, the posterior tibial nerve may be injured, which causes diminished plantar sensation and inability to flex the foot. Complete nerve palsy in the acute setting is associated with a poor prognosis for recovery.

Delayed complications associated with traumatic knee dislocations include DVT, compartment syndrome, pseudoaneurysm, and arterial thrombosis. Compartment syndrome may develop within 24 to 48 hours of the initial injury. Pseudoaneurysms are rare but may form several hours to months after popliteal artery injury. Heterotopic ossification is a poorly understood syndrome of calcification of the soft tissues of the knee. It has been observed in uninjured knees of patients who have sustained major trauma. In its most severe form, heterotopic ossification can cause severe decrease in knee mobility. Almost half of dislocated knees are found to have subsequent heterotopic ossification.

Knee Dislocations—Diagnostic Testing

The diagnostic evaluation begins with an understanding of two crucial facts. First, half of all tibiofemoral dislocations are reduced before presentation, and injury to the popliteal artery should be assumed with tibiofemoral dislocation regardless of spontaneous reduction. Therefore the diagnostic strategy is applied to all patients with known knee dislocation, multiligament knee injury, or high-force trauma to the knee. The intubated or unresponsive multitrauma patient with ecchymosis around the knee may harbor an occult popliteal injury.

Popliteal artery injury can be assessed by measurement of the ankle-brachial index (ABI) with serial physical examinations, CTA, and duplex ultrasonography. Formal angiography is rarely used. Of note, increased body mass index (BMI) is associated with a greater risk

of vascular injury after knee dislocations.[1] Serial palpation of the pedal pulses is not sufficiently sensitive for an injury with such potentially devastating consequences. Adding measurement of the ABI improves sensitivity. The ABI is the ratio of the systolic blood pressure measured in the standard humeral location relative to the systolic pressure measured at the ankle. An ABI more than 0.9 has a negative predictive value for popliteal artery injury, approaching 100% in knee dislocation. There is recent evidence that palpable dorsalis pedis and posterior tibial pulses combined with an ABI of 0.9 or greater is 100% sensitive in detecting clinically relevant popliteal artery injuries after knee dislocations[2]; however, the diagnostic strategy depends on the patient's presentation. In a patient with hard signs of vascular injury (see Table 48.3), emergent surgical exploration is warranted. If the patient has asymmetric pulses or distal pulses are present but ABI is less than 0.9, then CTA is warranted. If the distal pulses are both present and ABI is greater than 0.9, we advise admission for serial neurovascular examinations every 3 to 4 hours for at least 24 hours.[2] An algorithm for management is depicted in Fig. 48.5.

TABLE 48.3 Hard and Soft Signs of Vascular Injury

Hard Signs of Vascular Injury	Soft Signs of Vascular Injury
Lack of distal pulses	Decreased pulse relative to uninjured side
Palpable thrill	
Pulsatile hemorrhage	Significant hemorrhage at time of injury
Expanding hematoma	Nonexpanding hematoma
The classic 5 Ps (pain, pallor, paresthesia, poikliothermia, paralysis)	Peripheral nerve deficits

Knee Dislocations—Management and Disposition

The dislocated knee should be reduced at the earliest opportunity during the secondary survey. The neurovascular status documented before and after reduction. For patients being transferred from a nontrauma center to a trauma center, reduction should be attempted prior to transfer. Reductions usually can be accomplished with simple traction-countertraction, almost always requiring procedural sedation in the alert patient. Lateral pressure may be required. For an anterior dislocation, the femur can be pushed posteriorly while the tibia is pulled anteriorly, with special care taken not to apply undue pressure to the popliteal fossa. Posterolateral dislocations may not be reducible because the medial femoral condyle and MCL may secure the dislocated joint in place, in which case emergent open reduction in the operating room is indicated. Because many reductions are unstable, the limb should be immobilized in a long leg posterior splint with the knee in 15 to 20 degrees of flexion after reduction; serial neurovascular assessments will be necessary, warranting admission.

Disability is minimized by expedient revascularization and primary arterial repair, and thorough wound débridement. Open joints require prophylactic antibiotics, such as intravenous (IV) cefazolin 2 g. If the neurovascular structures remain intact after dislocation, the knee joint

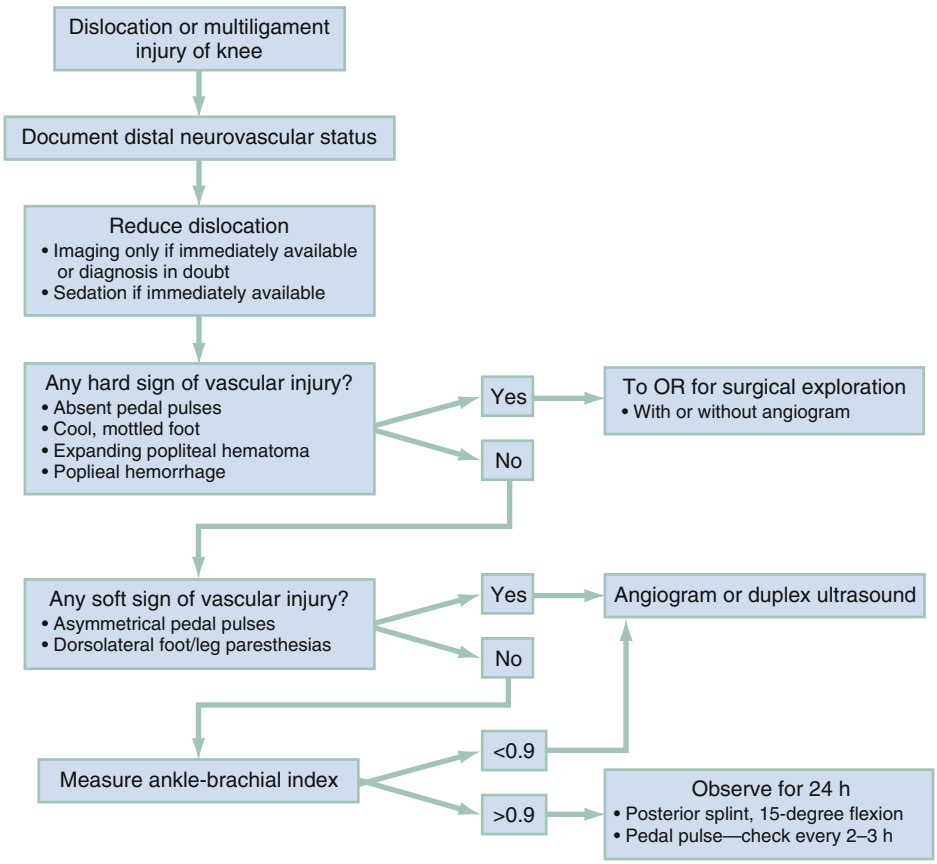

Fig. 48.5 Algorithm for the Management of Knee Dislocation. (From Nicandri GT, Dunbar RP, Wahl CJ. Are evidence-based protocols which identify vascular injury associated with knee dislocation underutilized? *Knee Surg Sports Traumatol Arthrosc.* 2010;18:1005–1012.)

is reduced, splinted, and allowed to rest for 2 to 3 days before reconstruction of the torn ligaments.

Distal Femur Fractures—Foundations

Distal femur fractures are uncommon and usually result from a high-energy mechanism. An isolated fracture of the femoral condyle may occur, or the fracture may extend in a T or Y pattern to include the intercondylar or supracondylar region of the femur. Condylar fractures are intraarticular and may result in disruption of the articular surface, with subsequent arthritis. See Chapter 47 for more detailed discussion of femoral shaft and proximal femur fractures.

Distal Femur Fractures—Clinical Features

Patients with condylar or intercondylar fractures have pain and swelling in the distal femur and suprapatellar region and often are unable to bear weight. Examination may reveal shortening, rotation, and angulation of the extremity and tenderness to palpation along the medial or lateral joint line. Acute hemarthrosis is common and may be caused by intra-articular extension of the fracture or associated ligamentous injury. Distal neurovascular status should be documented. Any laceration in the region of the fracture represents an open fracture until proven otherwise. Distal femur fractures may be associated with thrombophlebitis, fat embolus syndrome, delayed union or malunion if reduction is incomplete or not maintained. Intra-articular or quadriceps adhesions if the fracture is intraarticular, angulation deformities, and osteoarthritis, particularly in the patellofemoral articulation are some potential long-term complications.

Distal Femur Fracture—Diagnostic Testing

Routine AP and lateral views should be obtained and usually show the fracture pattern and any significant displacement of fragments. In high-energy injuries, radiographs of the ipsilateral hip and tibia are recommended to exclude associated fractures. Occasionally, CT imaging or MRI may be required to diagnose a nondisplaced fracture. If signs of vascular impairment are present, consultation for angiography or surgical exploration should be obtained emergently.

Distal Femur Fractures—Management and Disposition

Distal femur fractures are extremely painful. Ultrasound-guided femoral nerve blocks can be considered to reduce the need for opiates. After the initial examination, the leg should be splinted to prevent excessive motion and reduce pain at the fracture site. Emergent orthopedic consultation is advised. In a stable patient with an uncomplicated fracture dislocation, reduction may be done with skeletal traction, followed by immobilization. Intraarticular fractures generally are treated with open reduction and internal fixation. Virtually all patients with distal femur fracture require admission.

Tibial Plateau Fractures—Foundations

Tibial plateau fractures often are intra-articular. The most common mechanism of injury is a strong valgus force with axial loading. Severe high-energy tibial plateau fractures occur primarily in younger patients often after motor vehicle collisions (MVCs) or falls from heights. These fractures may be open and occur in concert with other associated injuries. Fatigue stress fractures of the tibial plateau occur mostly in older and obese adults. These low-energy fractures are the result of compression forces in osteoporotic bones.

The *Segond fracture* represents a bone avulsion of the lateral tibial plateau (Fig. 48.6). The avulsion occurs at the site of attachment of the lateral capsular ligament. On radiographs, an oval-shaped fragment can be seen adjacent to the lateral tibial plateau. Segond fractures are usually accompanied by ACL disruption. Most Segond fractures are caused by sports injuries; the mechanism is almost always knee flexion with excessive internal rotation and varus stress.

Fig. 48.6 Segond Fracture. Anteroposterior view of the left knee shows lateral curvilinear avulsion fracture *(arrow)* and joint effusion. (From Kerr HD. Segond fracture, hemarthrosis, and anterior cruciate ligament disruption. *J Emerg Med*. 1990;8:29–33.)

Tibial Plateau Fractures—Clinical Features

Tibial plateau fractures cause pain, tenderness, ecchymosis, soft tissue swelling, and hemarthrosis when intra-articular. A valgus or varus limb deformity may be present and usually indicates a depressed fracture or concomitant leg fracture. The most important aspect of the initial examination is assessment of neurovascular status. Many tibial plateau fractures cause vascular complications. The popliteal artery may be injured by fragments from bicondylar or comminuted fractures involving the subcondylar area. Displaced fractures of the lateral condyle may cause peroneal nerve paralysis or anterior tibial artery injury. Stretch of the peroneal nerve is the usual cause of injury. Ligamentous injuries frequently accompany tibial plateau fractures, most often involving the ACL and MCL. Of note, these patients are also at high risk for compartment syndromes.

Tibial Plateau Fractures—Diagnostic Testing

Lipohemarthrosis, seen as a fat-fluid level on a plain film, suggests an occult fracture and is caused by entry of marrow fat into the joint space (see Fig. 48.4). Lipohemarthrosis may also be detected on aspiration of a joint effusion. All knee radiographs should be examined closely for avulsion fragments from the fibular head, femoral condyles, and intercondylar eminence because these may indicate ligamentous injury. Widened joint spaces associated with a fracture of the opposite condyle also may indicate concomitant ligamentous injury.

CT imaging and MRI are more sensitive than plain radiography and quantify the amount of depression in displaced fractures and extent of articular surface involvement in comminuted fractures. In a patient with acute traumatic knee pain characterized by tibial tenderness to

palpation and inability to bear weight, a CT scan should be done to rule out fracture if x-rays are nondiagnostic.[3]

Tibial Plateau Fractures—Management and Disposition

All patients with a tibial plateau fracture should be referred for evaluation by an orthopedist, which often occurs with direct consultation in the ED. Absolute indications for emergent orthopedic consultation would include joint instability, open fracture, neurovascular compromise, and compartment syndrome. If orthopedic consultation is not obtained in the ED, acute fractures should be immobilized in a noncircumferential splint such as a knee immobilizer and the patient should not bear weight on the limb until evaluated by an orthopedist, preferably within the week. Patients should be given strict return precautions for compartment syndrome. Stable nondisplaced fractures may be treated with immobilization alone, but instability or significant depression or disruption of the joint surface requires surgical management. CT scanning is often required for surgical planning, even when indications for surgery are evident based on the clinical examination and x-ray.

Prolonged immobilization can result in DVT. Prophylactic treatment with low-molecular-weight heparin can reduce the risk of DVT but remains controversial. According to a Cochrane review,[4] there is moderate-quality evidence that low-molecular-weight heparin could reduce the incidence of DVT following immobilization of the leg. However, both the heparin and placebo groups exhibited a wide range of venous thromboembolism (VTE) across studies. A recent randomized controlled trial failed to show evidence that heparin reduced the incidence of VTE after casting of the lower leg.[5] Given the controversy surrounding this topic, we suggest that the decision to anticoagulate patients requiring lower limb immobilization be made on an individual basis after engaging in shared decision making with the patient and orthopedic specialist. Scoring systems have recently been developed to assist the physician in deciding whether to anticoagulate when immobilizing the lower extremity[6] but have not been externally validated.

Fractures of the Intercondylar Eminence (Tibial Spine)—Foundations

A fracture of the anterior tibial spine usually is associated with an ACL rupture. Tibial spine fractures are more common in children than in adults because the ligaments are stronger than the adjacent physeal plates in the immature skeleton. This fracture may be an isolated injury in the presence of open physes.

Most tibial spine fractures occur as a result of abrupt knee twisting, hyperflexion, hyperextension, or valgus-varus forces generated during MVCs or athletic activities. Tibial spine fractures occur by twisting knee movements, whereas hyperextension or hyperflexion forces may cause avulsion of the intercondylar eminence or cruciate ligaments from their tibial attachments.

Tibial Spine Fractures—Clinical Features

After a tibial spine fracture, the patient reports pain and swelling of the knee and may be unable to bear weight on the affected extremity. The examination confirms an acute hemarthrosis which may impair full knee extension. Tense effusion will limit ROM, hinder physical examination, and mask ligament disruption. ACL laxity is expected.

Tibial Spine Fractures—Diagnostic Testing

Radiographic evaluation should include standard AP and lateral views. A tunnel view provides a better look at the intercondylar area and may reveal the diagnosis. Joint margins should be examined closely for evidence of collateral ligament or capsular bone avulsions. CT scanning is sometimes required to show the location and displacement of the fracture.

Fig. 48.7 Osteochondritis Dissecans. A subcortical radiolucency *(arrow)* is seen in the knee of an adolescent female with chronic medial knee pain.

Tibial Spine Fractures—Management and Disposition

The knee should be immobilized, and the patient should be given non–weight-bearing instructions and referred to an orthopedist within 3 to 7 days. Most patients are managed conservatively with good results, although some require surgical repair particularly when reduction cannot be achieved, or there is significant ligamentous disruption.

Osteochondritis Dissecans—Foundations

OD is a rare orthopedic disorder of unclear etiology (Fig. 48.7). The disorder is found mainly in adolescents. OD is characterized by a partial or total separation of a segment of articular cartilage and subchondral bone from the underlying bone. It is commonly unilateral, involving the non–weight-bearing lateral aspect of the medial femoral condyle and may be related to acute or chronic trauma, genetics, or ischemia.

Osteochondritis Dissecans—Clinical Features

Patients often have pain, swelling, and giving-way episodes.

Osteochondritis Dissecans—Diagnostic Testing

Routine radiographic views usually are diagnostic. A subcortical lucency (see Fig. 48.7) can be appreciated, and an osteochondral fragment may be seen separated from the underlying bone. Rarely indicated in the ED, CT or MRI may aid in determining the exact location and extent of the osteochondrotic lesion.

Osteochondritis Dissecans—Management and Disposition

ED patients with suspected OD should not bear weight on the affected extremity and should be instructed to limit their activity until seen by an orthopedist within 3 to 5 days.

Extensor Mechanism Injuries: Quadriceps and Patellar Tendon Ruptures—Foundations

Disruptions of the extensor mechanism may occur at any level, from the quadriceps muscle to the patellar tendon insertion on the tibial tubercle. Injury generally occurs as a result of sudden vigorous contraction of the quadriceps muscle with the knee in a flexed position, a laceration, or direct blow.

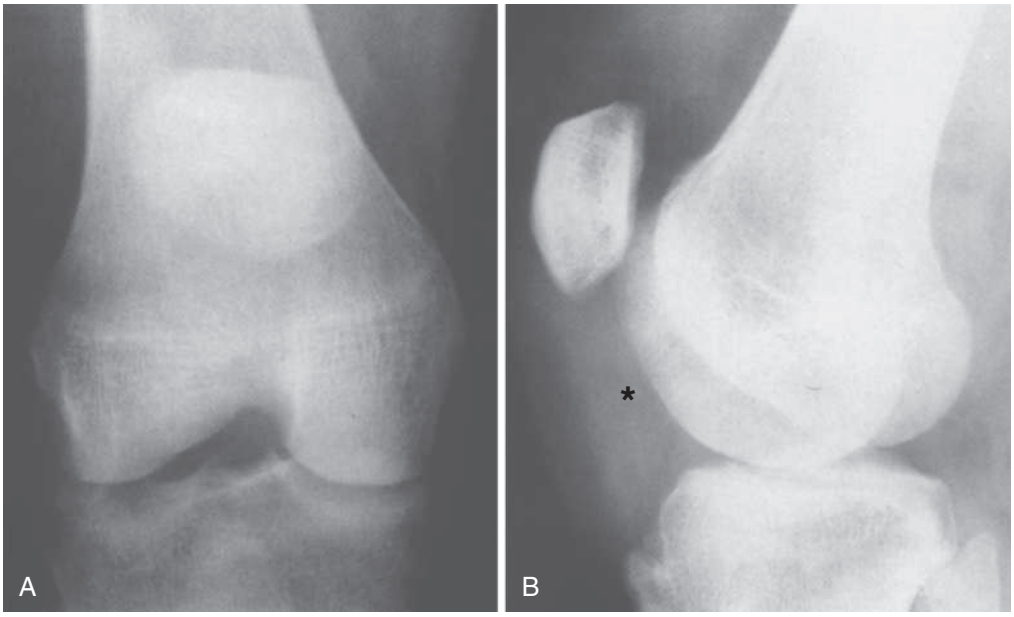

Fig. 48.8 Rupture of the patellar tendon, resulting in the high-riding patella in frontal (A) and lateral (B) projections. (B) The normally lucent infrapatellar portion of the joint space is dense *(asterisk),* representing blood within the anterior compartment. (From Harris JH Jr, Harris WH. *The radiology of emergency medicine.* 3rd ed. Baltimore: Williams & Wilkins; 1993.)

Chronic systemic conditions, including rheumatoid arthritis, gout, systemic lupus erythematosus, hyperparathyroidism, and iatrogenic immunosuppression in organ transplant recipients, may increase the risk of tendon rupture. Several studies have implicated the use of steroids or fluoroquinolones in tendon rupture. In children, quadriceps and patellar tendon ruptures are rare, and muscle tears are more common. In adolescents, patellofemoral dysplasia, chronic tendinitis, and use of steroids are predisposing factors. Dysplasia may cause extensor mechanism injury by repetitive tensile overloading. Corticosteroids seem to weaken collagen ultrastructure and impair the reparative process.

Quadriceps and Patellar Tendon Ruptures—Clinical Features

Clinical evaluation can elicit the correct diagnosis in most cases of complete disruption of the extensor mechanism. Patients with extensor disruption may have the following signs and symptoms: (1) acute onset of pain, and ecchymoses over the anterior aspect of the knee and a palpable defect in the patella, quadriceps tendon, or patella tendon; (2) loss or limitation of active leg extension with extension lag noted during the last 10 degrees of the maneuver; (3) high-riding patella *(patella alta),* with patellar tendon rupture and superior retraction; and (4) low-riding patella *(patella baja),* with quadriceps tendon rupture and inferior retraction. Partial disruptions may be difficult to diagnose on clinical examination and may require MRI for confirmation. Loss of active extension of the knee and inability to maintain a passively extended knee against gravity are the hallmarks of quadriceps and patellar tendon rupture, which otherwise may be clinically occult.

Quadriceps and Patellar Tendon Ruptures—Diagnostic Testing

Standard AP and lateral radiographs should be obtained and may reveal characteristic findings, including obliteration of the quadriceps or patella tendon, poorly defined suprapatellar or infrapatellar soft tissue mass, soft tissue calcific densities, or displaced patella (Fig. 48.8). Patella alta may be sought on the lateral radiograph with use of a ratio of patellar length to patellar tendon length (known as the Insall-Salvati ratio). If this ratio is less than 0.8, patella alta is present. The degree of flexion should not affect this ratio, which relies on the inelasticity of the patellar tendon. A soft tissue mass represents proximal or distal retraction of the torn tendon. Calcific densities may represent avulsed bone fragments of the patella or tibial tubercle or dystrophic calcifications in the substance of the tendons. The correct diagnosis is infrequently made by plain radiography in cases of incomplete quadriceps tendon rupture. MRI visualizes the entire extensor mechanism and is the best imaging modality.

Quadriceps and Patellar Tendon Ruptures—Management and Disposition

Treatment of acute extensor mechanism injuries produces a better clinical outcome if instituted early, within 2 to 6 weeks of the initial injury. All patients with acute partial or complete tears of the extensor mechanism should be placed in a knee immobilizer, made non-weight bearing, and referred for urgent orthopedic care within 1 week.

Patients with delayed diagnosis of patellar tendon rupture may experience significant retraction of the patella proximally and subsequent development of quadriceps contractures or adhesions. Surgical intervention is required for reattachment of complete tendon ruptures, and repair should be performed as soon as possible after injury for the best recovery.

Patellar Fractures—Foundations

Patellar fractures are classified as transverse, stellate, or comminuted, longitudinal or marginal, proximal pole or distal pole and, rarely, osteochondral. They may be displaced or nondisplaced and occur from direct or indirect forces or from dislocation. The most common fracture pattern is the transverse fracture (accounting for 50% to 80% of cases). This type often is seen in young adults and usually results from a powerful contractile force transmitted from the quadriceps tendon. This force may pull the superior portion of the patella upward, leading to wide displacement. In such cases the medial and lateral retinacula are usually disrupted, resulting in significant functional disability; active extension is impossible.

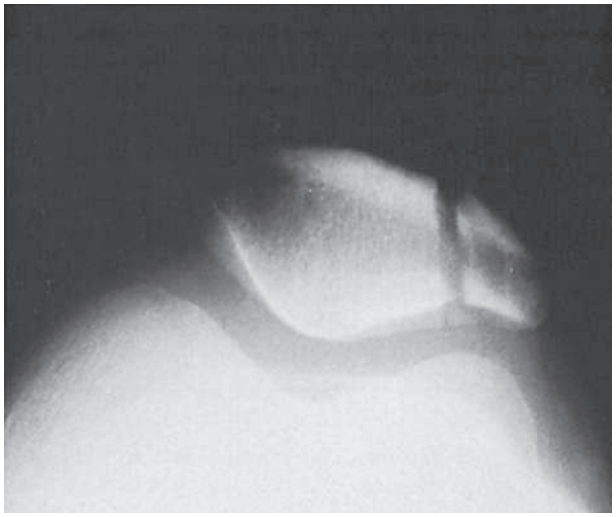

Fig. 48.9 Patellar Fracture, Sunrise View. The sharp nonsclerotic margins identify this as an acute fracture and not a congenital finding. (From Rosen P, et al. *Diagnostic radiology in emergency medicine*. St. Louis: Mosby; 1992:196.)

Nondisplaced transverse patellar fractures usually are caused by a direct blow to the anterior aspect of the patella (e.g., a fall on the knee or a direct blow sustained in vehicular trauma). The retinaculum and extensor mechanism usually remain intact, and the patient retains limited functional ability for active extension. Stellate and comminuted fractures often appear as separated fragments on plain radiographs but are held in place and supported by the medial and lateral retinacula and the overlying soft tissues. Small proximal fragments are at risk for avascular necrosis because the patellar blood supply is distributed centrally and inferiorly. Longitudinal or marginal vertical patellar fractures are less common and usually the result of direct blunt injury.

Patellar Fractures—Clinical Features

On physical examination, tenderness, swelling, and ecchymosis over the patella and prepatellar bursa may be noted. Active extension may be limited or absent, depending on the fracture pattern and amount of fragment displacement. Associated injuries may include fractures of the femoral neck, dislocation of the hip, and acetabulum fractures. Persistent patellofemoral pain and osteoarthritic symptoms may be late sequelae of patellar fractures.

Patellar Fractures—Diagnostic Testing

Radiologic evaluation of patellar fractures should include standard AP, lateral, and sunrise views. Most patellar fractures are obvious on plain radiographs, but vertical marginal fractures may be difficult to identify because they are obscured by the femur on the AP view and not visualized on the lateral view. Close examination of sunrise views may reveal an osteochondral avulsion fragment or marginal fracture (Fig. 48.9). Bipartite and multipartite patellae are common normal variants and should not be confused with fractures. Ossification centers are found at the upper outer quadrant of the patella and have smooth cortical margins, but differentiating physeal lines from fractures can be difficult. Comparison radiographs may be helpful because these anatomic anomalies are often bilateral. In some cases, MRI may be needed to identify occult marginal fractures or free osteochondral fragments.

Patellar Fractures—Management and Disposition

For initial management of nondisplaced fractures, a knee immobilizer may be used. Patients should be instructed to use crutches, with partial weight bearing as tolerated, and should be referred for orthopedic evaluation within 1 week. For widely displaced transverse fractures, open reduction and internal fixation are necessary for optimal results. A knee immobilizer can be used initially to stabilize the extremity before definitive care is provided. Treatment options for displaced comminuted fractures include open reduction, internal fixation, and partial or complete patellectomy.

Patellar Dislocation—Foundations

Patellar dislocations are commonly seen in both adult and pediatric patient populations, although they are more common in children. Most cases are lateral, and the mechanism of injury usually is a direct blow to the anterior or medial surface of the patella. The injury may also occur when a valgus stress is exerted on a flexed knee, resulting in external rotation of the leg. As these forces are dissipated, the medial retinaculum is typically torn, resulting in a lateral patella dislocation. Subluxation usually indicates a stretched medial retinaculum.

Patellar Dislocation—Clinical Features

Patients with patellar dislocations typically present to the ED with acute pain, noting difficulty ambulating and flexing the knee. There may be a history of previous dislocation. Physical examination typically reveals a defect anteriorly with the patella deviated laterally. A knee effusion may develop hours after the injury but may not be immediately evident. Effusions are typically more pronounced after the patellar dislocation has been reduced, which may occur spontaneously prior to the patient arriving in the ED. The forces that result in patellar dislocations may cause osteochondral fractures of the patella. These fractures are highly variable, sometimes involving only the cartilage (chondral fracture) and other times involving the underlying bone as well. Effusions, particularly hemarthroses, are more commonly seen with patellar dislocations with associated osteochondral fractures.

Patellar Dislocation—Diagnostic Testing

Standard AP and lateral x-ray views are usually sufficient to diagnose a patellar dislocation. Sunrise views are typically difficult to obtain prereduction due to pain and inability to flex the knee. Expected findings on x-ray include an empty trochlear groove, a displaced patella and an effusion. Radiographs should be examined for avulsion fracture. If a lipohemarthrosis is seen, it is important to look for fracture fragments.

Patellar Dislocation—Management and Disposition

Patellar dislocation is typically managed with closed reduction. To perform this reduction, the knee should be passively extended while an inferomedially directed pressure is applied to the patella. If the dislocation is difficult to reduce, gentle downward pressure may be applied to the lateral aspect of the patella in an effort to open the medial patellar facet. This procedure does not typically require conscious sedation and can be performed with analgesics only, depending on the patient's anxiety and pain level. As with every reduction, a neurovascular examination should be performed after the procedure. Postreduction knee x-rays, including a sunrise view, should be performed to confirm that the patella is in the trochlear groove. The clinician should also ensure that no osteochondral avulsion fragments are seen on x-ray, because these may require arthroscopy for removal.

Once the patella dislocation has been successfully reduced, patients should be placed in a knee immobilizer positioned in full extension. Patients should follow up with orthopedics within 1 to 2 weeks of the injury. Follow-up care is important due to the significant rate of recurrent patellar dislocation. Despite physical therapy, many patients will sustain another patellar dislocation. Recurrent dislocation or persistent

pain and laxity following dislocations may warrant surgical intervention. However, surgically and conservatively managed patients generally have similar functional long-term outcomes.[7,8]

Cruciate and Collateral Ligament Injuries—Foundations

Ligamentous injuries to the knee may range in severity from mild sprains to complete tears. Collateral ligament injury usually causes tenderness and pain along the joint line. Cruciate injuries pose more of a diagnostic dilemma because they are intra-articular.

Cruciate and Collateral Ligament Injuries—Clinical Features

The ACL is commonly injured in sports. Although direct contact with a flexed knee can result in an ACL tear, the injury is more common in noncontact sports, with the plant and pivot or stop and jump mechanisms predominating. A direct blow to the flexed knee, as may occur in MVCs (from the dashboard), and turf injuries with the knee flexed and the ankle plantar-flexed can also result in an ACL injury.

Given the force required to injure an ACL, it is common to see concurrent meniscal injuries. The traditional "unhappy triad" of ACL, MCL, and medial meniscal injury is actually less common than the combination of ACL, MCL and lateral meniscal injury. Patients with an acutely injured ACL will often report hearing a "pop" that is followed by pain. An effusion typically develops within the first 1 to 3 hours after the injury. Patients may also note knee instability with the sensation of the "giving out" or may be unable to bear weight on the injured leg. The anterior drawer test can be used to diagnose an ACL tear; however, the Lachman test is more sensitive and more specific.

The anatomic location of the PCL and its relative strength make isolated PCL injuries rare. The typical mechanism for PCL injury is a posterior force applied to a flexed knee, either from a fall or from contact with a dashboard. PCL injury can also occur when multidirectional forces are applied to a knee, resulting in a knee dislocation. Unlike ACL injuries, patients with PCL injuries do not typically report an audible pop and significant instability is not immediately appreciated. Later, the patient may complain of feeling the femur "fall off" the tibia. Knee pain and effusion are seen with PCL injuries. The posterior drawer test is still the clinically preferred diagnostic maneuver.

The MCL usually is injured by a direct blow or impact to the lateral aspect of the knee, which imposes a valgus stress. Despite the amount of force required to injure the MCL, these injuries are typically treated nonoperatively.

The LCL usually is injured by a mechanism of hyperextension with varus stress, commonly accompanied by a direct blow or rotation. LCL injuries are not as common as MCL injuries, because the contralateral leg provides significant protection against varus forces and the lateral compartment is inherently more stable than the medial compartment. If an LCL injury is suspected, a neurovascular assessment should be performed based on the proximity of the peroneal nerve to the LCL. The accuracy of the knee examination for ligamentous damage is enhanced if done immediately after injury before the onset of swelling and pain, but the patient may not tolerate the examination and muscle spasms may obscure findings. Ligamentous injuries are not emergencies and can be diagnosed definitively after the acute phase has subsided.

Cruciate and Collateral Ligament Injuries—Diagnostic Testing

A full knee x-ray series should be obtained, including AP, lateral, sunrise, and intracondylar notch views. X-rays should be evaluated for associated fractures, loose bodies, or avulsion injuries. The Segond fracture is an avulsion off the posterior aspect of the lateral tibial plateau and is classically seen with ACL tears (see Fig. 48.6). Ultrasonography can also be used to diagnose meniscal injuries, LCL injuries, and ACL injuries; however, the sensitivity and specificity of this modality vary greatly based on the type of probe used and the skill of the examiner. Although MRI is the preferred imaging modality to identify ligamentous injuries, it is not routinely necessary in the ED to evaluate for collateral and cruciate ligament injuries.

Cruciate and Collateral Ligament Injuries—Management and Disposition

All patients with suspected isolated ligamentous knee injuries should be placed in a fully unlocked, hinged knee brace with weight bearing as tolerated with orthopedic follow-up in 1 week. Crutches can be provided as needed. It is imperative not to place the patient in a knee immobilizer for isolated ligamentous injuries, because use of this brace significantly decreases quadriceps strength, which negatively affects surgical outcomes in ACL-injured patients. Orthopedic follow-up is needed to facilitate physical therapy, MRI imaging, and surgery, when needed.

Patients with isolated PCL injuries or isolated MCL injuries are typically treated conservatively with hinged knee brace, orthopedic follow-up, and physical therapy. If they are associated with multiligament or avulsion injuries, they may require surgery as an outpatient, so expedited orthopedic follow-up is advised. Isolated LCL injuries can be managed in the ED with a hinged knee brace and orthopedic follow-up. Operative intervention for patients with LCL injuries is usually not necessary but may be required if other structures within the posterolateral corner of the knee are involved or if there is substantial instability.

Definitive management of ACL tears depends on a combination of the patient's age, lifestyle, and the mechanism of injury. Younger, athletically active patients are more likely to undergo operative reconstruction, whereas older, less active patients may be managed with conservative measures. In the ED, a suspected ACL tear should be managed with a hinged knee brace, crutches, and urgent orthopedic follow-up.

Meniscal Injuries—Foundations

When a meniscal injury does occur, the posterior aspect is more commonly injured than the anterior portion due to the increased forces placed upon the posterior horn with knee flexion. Meniscal blood supply should also be considered when evaluating a potential meniscal injury. Branches of the inferior and middle geniculate arteries provide blood flow to the meniscus. These vessels enter the lateral aspect of the meniscus and then diffuse towards the medial aspect of the structure, effectively rendering the medial aspect of the meniscus avascular. Unfortunately, the medial aspect of the meniscus is the most commonly injured, and healing is impaired due to the lack of blood supply.

Meniscal Injuries—Clinical Features

An isolated meniscal tear should be suspected in a patient with a history of intermittent locking, effusion, giving way, and pain and physical examination findings of joint line tenderness. A torn meniscus more commonly is associated with delayed onset of swelling over 12 to 24 hours. Locking of the knee typically results from a meniscal tear or other loose body trapped within the joint, thereby preventing full extension. The cardinal sign of a meniscal tear is local pain and tenderness along the joint line. Joint line pain and tenderness are especially apparent with extremes of flexion and extension. Not all tears of the menisci are symptomatic. Degenerative lesions are relatively common in middle age and later and may be asymptomatic. Effusions are not typically seen based on the limited blood supply to the meniscus. Patients may note clicking or locking as the meniscus fragment slides or gets wedged between the tibia

and the femur. Acute and chronic injuries typically result from twisting on a flexed knee; however, minimal force may be required to convert a chronic degenerative tear into a complete tear.

Meniscal Injuries—Diagnostic Testing

With the exception of ultrasound, there are limited ED-based imaging options to assess a possible meniscal tear. Meniscal injury cannot be diagnosed by plain radiography or CT scanning. Arthroscopy is the gold standard for diagnosis; MRI is an alternative but may miss minor meniscal tears.

Meniscal Injuries—Management and Disposition

Patients with meniscal tears should be discharged from the ED similarly to those with ligamentous knee injuries with an unlocked hinged knee brace, crutches, and orthopedics follow-up. The patient should be weight bearing as tolerated. Patients with a locked knee due to a meniscal tear require further treatment prior to ED discharge. The emergency physician can attempt to unlock the knee by providing adequate analgesics (intra-articular lidocaine, intravenous analgesics, or conscious sedation) and then gently repeatedly performing the McMurray maneuver. An orthopedics consult can also be obtained to assist in unlocking the knee. In the absence of mechanical symptoms such as locking or catching, physical therapy is currently preferred to surgical management as definitive treatment for many meniscal injuries.[9–11]

OVERUSE SYNDROMES

Overuse syndromes result from repetitive motion and the subsequent inflammation that may result from repeated activity. The typical complaint is knee pain, often localized to one of three particular areas—the medial aspect, lateral aspect, or peripatellar region. The location of the pain varies based on the areas of inflammation associated with a given activity. Medial knee pain is commonly seen with medial tibial stress fractures, proximal MTSS, pes anserine bursitis, tendinopathy, or MCL strain. Lateral knee pain is typically associated with LCL strain, IT band dysfunction, popliteal tendinitis, or proximal fibular stress fracture. Anterior knee pain may be due to patellar tendinitis, bursitis, quadriceps tendinitis, or patellofemoral syndrome.

Patellofemoral Pain Syndrome—Foundations

The patellofemoral pain syndrome refers to the clinical presentation of anterior knee pain related to changes in the patellofemoral articulation. Chondromalacia patellae describes deterioration or softening of the articular cartilage. Correlating pathologic changes on the surface of the patella and clinical symptoms is difficult, and the pain mechanism has not been precisely defined.

Patellofemoral Pain Syndrome—Clinical Features

Patellofemoral pain syndrome is the most common cause of knee pain. Women are more commonly affected than men, and patients typically present in their 20s and 30s. The pain usually begins gradually and is not related to trauma. Unilateral symptoms are more common than bilateral involvement. The knee is more painful with prolonged flexion (e.g., from sitting in a movie theater), and the discomfort typically is accentuated by stair climbing and kneeling. The syndrome occurs in athletes and in older patients who have arthritis affecting the patellofemoral joint. Risk factors for patellofemoral pain syndrome include gluteal weakness, quadriceps weakness, patellar subluxation, prepatellar bursitis, arthritis, meniscal tears, and quadriceps/patellar tendinopathy.

Several physical examination findings may be seen in patients with patellofemoral pain syndrome. Gait abnormalities may be present. The medial and lateral aspects of the patella may be tender to palpation, particularly when the syndrome results from patellar subluxation or dislocation. Recreation of pain while performing a single leg squat on the affected leg may suggest patellofemoral pain syndrome.

Patellofemoral Pain Syndrome—Diagnostic Testing

Patellofemoral pain syndrome is a primarily clinical diagnosis. Standard knee x-rays should be obtained to evaluate the patellofemoral joint space integrity and to assess for osteoarthrosis.

Patellofemoral Pain Syndrome—Management and Disposition

Physical therapy is the cornerstone of management for those with patellofemoral pain syndrome. Literature suggests hip abductor strengthening in addition to traditional quadriceps strengthening improves symptoms.[12] Nonsteroidal antiinflammatory drugs (NSAIDs) may be used early in the course of treatment and can allow the patient to comfortably start a physical therapy program. Several taping techniques and bracing options are available to further assist the patellofemoral pain syndrome patient, although the efficacy of bracing has not been clearly established.[13] Orthopedic follow-up is recommended to facilitate the physical therapy program.

Iliotibial Band Syndrome—Foundations

Overuse can cause inflammation of a bursa underlying the IT band at the lateral femoral epicondyle, resulting in lateral knee pain.

Iliotibial Band Syndrome—Clinical Features

The syndrome is most common in long distance runners and is more likely in severe overpronators. Physical findings include localized tenderness of the lateral femoral epicondyle and IT tightness or pain, elicited by the *Ober test*. To perform the Ober test, the patient lies on his or her unaffected side with the uninjured leg down, flexed to 90 degrees at the hip and knee. The affected hip is abducted, the knee is extended, and then the hip is allowed to return to neutral adduction with gravity. Failure of the hip to adduct fully with gravity or reproduction of pain at the lateral knee indicates IT tightness or inflammation, respectively.

Iliotibial Band Syndrome—Diagnostic Testing

Standard knee x-rays should be done to exclude other causes of lateral knee pain.

Iliotibial Band Syndrome—Management and Disposition

Typical treatment for IT band syndrome should include relative rest, NSAIDs, and physical therapy. Bracing has not been shown to prevent IT band syndrome or help in the recovery process. Steroid injections or surgery may be helpful in refractory cases.

Patellar Tendinopathy—Foundations

Patellar tendinopathy refers to a range of cellular changes to the patellar tendon. These forces can result in microscopic tears. Over time, these microtears can initiate an inflammatory cascade, leading to long-term symptoms.

Patellar Tendinopathy—Clinical Features

Patellar tendinopathy typically results from chronic repetitive physical activity, particularly running and jumping. Patients will typically describe gradual onset pain over the patellar tendon and have tenderness when palpating the tendon. A traumatic mechanism, a palpable

defect over the tendon, or an inability to perform a straight leg raise should raise concern for patellar tendon rupture.

Patellar Tendinopathy—Diagnostic Testing

Standard knee x-rays can be done to evaluate for avulsion fractures or patella alta.

Patellar Tendinopathy—Management and Disposition

As with most overuse injuries, the mainstays of treatment include reducing inflammation, relative rest, and physical therapy in this case focused on eccentric exercises. There is no role for steroid injection in the treatment of patellar tendinopathy. In cases of recalcitrant patellar tendinopathy, surgical débridement may be required.

Plica Syndrome—Foundations

During embryonic development, synovial folds, or plicae, are present within the knee. Although most plicae are absorbed in the neonatal period, a small percentage of people have persistent plicae throughout adulthood. Relatively minor or repetitive knee trauma may result in thickening of this tissue, resulting in an intra-articular band-like structure.

Plica Syndrome—Clinical Presentation

Patients typically complain of pain over the region of the medial femoral condyle. Plicae-associated pain typically increases with repeated activity (especially running and biking) and may also be aggravated by prolonged sitting. Patients often note a snapping or popping sensation as the plica moves across the medial femoral condyle. A small effusion may be seen after significant periods of activity. If the plica continues to increase in size, it may also limit knee motion and lead to knee stiffness. The presence of plicae is difficult to detect clinically as the physical examination is relatively nonspecific. Effusions, medial femoral condyle tenderness, and a false-positive McMurray sign may all be seen on physical examination.

Plica Syndrome—Diagnostic Testing

Plain radiography may be necessary to exclude other causes of knee pain but is of no value in diagnosing plica syndrome. Plicae are often not detected on MRI, and thus nonurgent arthroscopy is the diagnostic study and intervention of choice.

Plica Syndrome—Management and Disposition

ED patients with a suspected plica should be discharged to follow up with orthopedics with weight bearing as tolerated. Physical therapy and NSAIDs may provide some symptomatic relief while awaiting definitive management.

Popliteus Tendinopathy—Foundations

Similar to patellar tendinopathy, popliteus tendinopathy results from cellular changes to the tendon that can cause chronic pain.

Popliteus Tendinopathy—Clinical Presentation

The classic presentation of a patient with popliteus tendinopathy is increasing posterior or posterolateral knee pain following a significant increase in downhill running or hiking. Mechanical symptoms and effusions are uncommon. Tenderness just medial to the lateral head of the gastrocnemius is the hallmark of the physical examination. Because of the close relationship of the popliteus to other soft tissue structures, a definitive diagnosis may be difficult. The *Webb test* may be performed to distinguish popliteus tendinopathy from biceps femoris tendinopathy, lateral meniscal injury and IT band dysfunction. This test is performed with the patient supine and the knee flexed to 90 degrees. The leg is rotated internally, and the patient is asked to resist the examiner's attempt to rotate the leg externally. Reproduction of symptoms suggests the diagnosis.

Popliteus Tendinopathy—Diagnostic Testing

X-rays should be considered to assess for other causes of knee pain but generally are not useful in diagnosing popliteal tendinopathy. As an outpatient, MRI may reveal this diagnosis.

Popliteus Tendinopathy—Management and Disposition

Patients with concern for popliteal tendinopathy should be managed with a period of relative rest, avoidance of hill or incline running, and physical therapy. NSAIDs may be used to decrease the associated inflammation.

Bursitis—Foundations

Bursitis is caused by repeated stress, infection, local trauma, crystal deposition, or systemic inflammatory arthropathy. It is important to differentiate bursitis from a joint effusion.

Bursitis—Clinical Features

Prepatellar bursitis is characterized by swelling of the superficial bursa overlying the lower pole of the patella. Usually, passive motion is fully preserved and the pain is mild. The disorder is often caused by pressure from repetitive kneeling on a firm surface (so-called housemaid's knee). The prepatellar bursa is also a common site of septic bursitis, and a common error is to confuse this entity with a septic knee (involving the tibiofemoral joint).

Anserine bursitis involves pain and tenderness at the proximal medial tibia, a few centimeters inferior to the medial joint line. It usually occurs in obese women in association with osteoarthritis of the knee but also may occur from overuse, especially in runners. It is characterized by localized tenderness and puffiness at the pes anserinus.

Bursitis—Diagnostic Testing

Bursitis is a clinical diagnosis. X-rays may be performed to help better determine if an effusion is intra- or extra-articular. Ultrasound may also be used to evaluate the location of the effusion. The definitive diagnosis of a septic bursa requires aspiration of the fluid in question; this can be done under ultrasound guidance or by using anatomic landmarks. The standard fluid studies should be ordered including protein count, glucose, Gram staining, culture, cell count, and crystal analysis. Additional studies (including gonorrhea and Lyme and tick-borne disease titers) may be added based on clinical suspicion.

Bursitis—Management and Disposition

Isolated septic (bacterial) bursitis without joint involvement requires antibiotic treatment, with operative drainage in refractory cases. Initial ED management includes outpatient antibiotics targeting skin flora with consideration of local resistance patterns and possible methicillin-resistant *Staphylococcus aureus* (MRSA) exposure for a minimum of 10 days with expediated orthopedic follow-up if the patient lacks systemic symptoms and is not immunocompromised. IV antibiotics and admission should be considered if the patient has systemic signs or is immunocompromised. Rarely, patients may fail antibiotic therapy and require operative débridement. Antibiotic choice should focus on skin flora while considering local resistance.

Aseptic (inflammatory) bursitis is treated with drainage, compression, ice, rest, antiinflammatory agents, and consideration of corticosteroid injection. In the ED, steroid injection of the anserine and prepatellar bursae is most common.

ARTHRITIS

Osteoarthritis—Foundations

Osteoarthritis describes degeneration of the articular cartilage, causing narrowing of the joint space and subsequent inflammation. Arthritis can occur at the tibiofemoral joint as well as the patella-femoral joint.

Osteoarthritis—Clinical Features

In the absence of a smooth articular surface, patients complain of pain and stiffness with ROM and activity. Examination may reveal an effusion and joint line tenderness over the affected compartment. Meniscal tears may also cause localized joint line tenderness but are frequently degenerative in nature when superimposed on a background of arthritis.

Osteoarthritis—Diagnostic Testing

Standard weight-bearing AP, lateral, and sunrise views will demonstrate joint space narrowing of the medial compartments, lateral compartments, or patellofemoral space. Osteophytes, subchondral cysts, and loose bodies may also be present.

Osteoarthritis—Management and Disposition

Patients with knee arthritis can be weight bearing as tolerated, but high-impact activities should be minimized. Physical therapy is the mainstay of treatment. NSAIDs and acetaminophen may be provided for pain control. Intra-articular steroid injections may also be used for symptomatic relief but should be used sparingly because evidence suggests they may accelerate arthritis.[14] Surgical treatment is typically limited to joint replacement.

Septic Arthritis—Foundations

Although direct trauma may cause knee joint infection, hematogenous seeding is the most common etiology. Bacterial spread usually affects the vascular synovial membrane and then extends into the joint. Skin flora, particularly *S. aureus,* is the most common causative agent of a traumatic septic joint. Different age groups and conditions may predispose patients to specific organisms. In young, sexually active patients, gonococcal arthritis should be considered.

Septic Arthritis—Clinical Features

Patients with septic arthritis of the knee present with an extremely painful joint that is difficult to elicit full ROM due to pain. The joint is often swollen, red, and warm. Patients often have an accompanying fever but can present with a normal temperature. Extreme pain with passive ROM should prompt the physician to consider this diagnosis even in the absence of erythema or fever.

Septic Arthritis—Diagnostic Testing

X-ray may be useful to rule out an underlying fracture. Most importantly, synovial fluid analysis should be performed. White blood cell count greater than 50,000 and 90% neutrophil predominance may suggest a bacterial source. Fluid should be sent for Gram stain and culture. Patients with early infection or a joint prosthesis may have a low synovial white blood cell count, highlighting the importance of fluid cultures. Orthopedic consultation should be performed if there is clinical suspicion for septic arthritis, regardless of synovial fluid cell count.

Septic Arthritis—Management and Disposition

Patients with septic arthritis should have emergent IV antibiotics initiated in parallel with orthopedic consultation for possible operative washout. Antibiotic selection for nongonococcal septic arthritis should target primarily skin flora. MRSA coverage should be considered. For gonococcal arthritis, IV ceftriaxone should be administered. To prevent septic arthritis in the ED, all open joint injuries should be treated with operative washout and antibiotics. Clinicians should avoid performing arthrocentesis through infected skin, which can seed the joint.

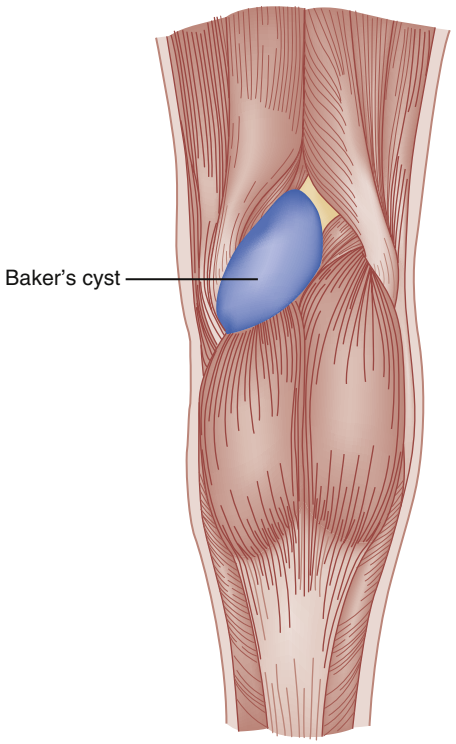

Fig. 48.10 Baker cyst is an extension of the semimembranosus bursa posteriorly. This bursa often is connected with a joint cavity.

BAKER CYST

Baker Cyst—Foundations

A Baker cyst (popliteal cyst) is a herniation of the synovial membrane through the posterior aspect of the capsule of the knee (Fig. 48.10). It results from a knee effusion of any cause.

Baker Cyst—Clinical Features

A mass is palpable in the posteromedial corner of the knee and often produces pressure, pain, and limitation of ROM. Rupture of the bursa, with resultant escape of fluid into the calf, may produce a clinical picture similar to that of DVT or compartment syndrome. Many Baker cysts go unnoticed until rupture, resulting in unilateral lower extremity edema.

Baker Cyst—Diagnostic Testing

A Baker cyst is a diagnosis of exclusion. In the ED, ultrasound should be done to rule out DVT if there is clinical suspicion. Venous duplex studies may identify cyst remnants and help to make the diagnosis as well. Nonemergent MRI can often confirm the diagnosis and help to identify the underlying cause of the cyst.

Baker Cyst—Management and Disposition

Treatment of the cyst focuses on symptomatic therapy (relative rest, compression, and NSAIDs) while also treating the underlying etiology of the cyst. Drainage can be considered on an outpatient basis but is not advised in the ED.

LEG

Foundations

Anatomy, Physiology, Pathophysiology

Anatomically, the leg is comprised of the tibia, fibula, and associated soft tissues, whereas the thigh is composed of the femur and its soft tissues.

Tibia and Fibula

Bearing the full weight of the body, the leg is subject to enormous stress, and *the tibia is the most commonly fractured long bone*. Moreover, the tibia is poorly covered by soft tissue anteriorly, making infection and delayed healing common. This is further compounded by the triangular shaped structure of the tibia, leaving the anteromedial aspect with less soft tissue and thus higher injury rates than other portions.

The distal aspect of the tibia fans out in a bell-bottom fashion to form the fibular notch, providing additional articulations and protection to the distal tibiofibular joint. The medial malleolus projects from the distal medial aspect of the tibia and has a posterior groove for the tibialis posterior tendon. The inferior surface of the distal tibia is covered with articular cartilage and forms the tibial plafond, the upper anterior surface of the ankle joint. The fibula, in contrast to the tibia, is covered by soft tissue except at the ankle, where it is subcutaneous and easily palpable. The fibula is composed of the head with its styloid process, neck, shaft, and lateral malleolus of the ankle. The proximal tibiofibular joint is a small synovial joint between a circular or oval facet on the head of the fibula and a similar facet on the inferior aspect of the lateral tibial condyle. The tibia and fibula are also connected by the superior and inferior tibiofibular ligaments as well as the syndesmotic ligaments. The syndesmosis ligament is a fibrous band that has particular importance at the distal portion of the lower leg, where it is responsible for keeping the tibia and fibula closely approximated to provide a stable ankle mortise.

Vascular Supply

The vascular supply of the lower leg is derived from the popliteal artery, which trifurcates to form three branches—the anterior tibial artery, posterior tibial artery, and peroneal artery. The anterior tibial artery can be assessed at the dorsum of the foot while the posterior tibial artery can be evaluated just posterior to the medial malleolus. The peroneal artery is the third branch of the popliteal to contribute to the vascular supply; however, it is not easily assessed clinically.

Fascial Compartments

The anatomy of the lower leg can be described in terms of four fascial compartments: the anterior, lateral, superficial posterior, and deep posterior compartments. Each compartment has a sensory nerve running through it, an anatomic feature that can be used to help diagnose compartment syndrome. The anterior compartment contains the tibialis anterior, long toe extensor muscles, anterior tibial artery, and deep peroneal nerve, which supplies sensation to the first web space of the foot. The lateral compartment contains two muscles that evert the foot, the peroneus longus and brevis, and the superficial peroneal nerve, which supplies sensation to the dorsum of the foot. The superficial posterior compartment contains the gastrocnemius, plantaris, and soleus muscles and sural nerve, which supplies the lateral side of the foot and distal calf. The deep posterior compartment contains the tibialis posterior muscle, long toe flexor muscles, posterior tibial and peroneal arteries, and tibial nerve, which supplies sensation to the plantar aspect of the foot.

TABLE 48.4 Differential Diagnoses of Leg Injuries

Injury	Differential Diagnostic Considerations
Subcondylar tibial fractures	Tibial plateau fracture, tibial shaft fracture, tibial tubercule fracture
Tibial tubercule fracture	Osgood-Schlatter syndrome, tibial plateau fracture, patellar tendinopathy/rupture
Tibial shaft fracture	Stress fracture, medial tibial stress syndrome (MTSS), tibial tubercule fracture, exertional compartment syndrome
Stress fracture	MTSS, tibial shaft fracture, exertional compartment syndrome, tibial tubercule fracture
MTSS	Stress fracture, tibial shaft fracture, exertional compartment syndrome
Proximal fibular fracture	Tibial plateau fracture, posterolateral corner injury, lateral collateral ligament injury, lateral meniscal injury, Maisonneuve injury
Proximal tibiofibular dislocation	Proximal fibular fracture, tibial plateau fracture, posterolateral corner injury

Leg Injuries Differential Diagnoses

The differential diagnosis for leg pain after a traumatic injury is broad (see Table 48.4). Pain over the tibia or fibula should always raise suspicion for any of a myriad of tibia and fibular fractures described later, depending on history and examination. In patients presenting with isolated proximal lateral leg pain, proximal tibiofibular joint dislocation should also be considered. Insidious-onset diffuse medial tibial pain may be due to MTSS or stress fracture. Focal pain and tenderness are more characteristic of a stress fracture. Sudden onset pain in the posterior lower leg should raise suspicion for gastrocnemius tear, rupture, or plantaris tendon injury. However, the clinician should also consider DVT, a Baker cyst, or even an Achilles tendon rupture (discussed elsewhere). Exercise-induced compartment syndrome, contusion, muscle strain, or tendinitis may also cause lower leg pain.

SPECIFIC LEG INJURIES

Proximal Extra-articular Tibial Fractures

Subcondylar Tibial Fractures—Foundations

Subcondylar tibial fractures are typically transverse or oblique fractures of the proximal tibal metaphysis. They are usually associated with tibial plateau fractures, especially bicondylar fractures.

Subcondylar Tibial Fractures—Clinical Features

The typical mechanism of injury is rotational stress with vertical compression. Patients with subcondylar tibial fractures will often have swelling and tenderness to palpation of this area.

Subcondylar Tibial Fractures—Diagnostic Testing

Standard knee x-rays will usually identify the fracture. If a hemarthrosis is seen on x-ray, the clinician should consider intra-articular extension of the fracture, an associated tibial plateau fracture, or ligamentous disruption. If clinical suspicion is high and x-rays are negative, CT scanning should be considered.

Subcondylar Tibial Fractures—Management and Disposition

Stable extra-articular nondisplaced transverse fractures are treated conservatively with a long leg splint with a sugar tong component.

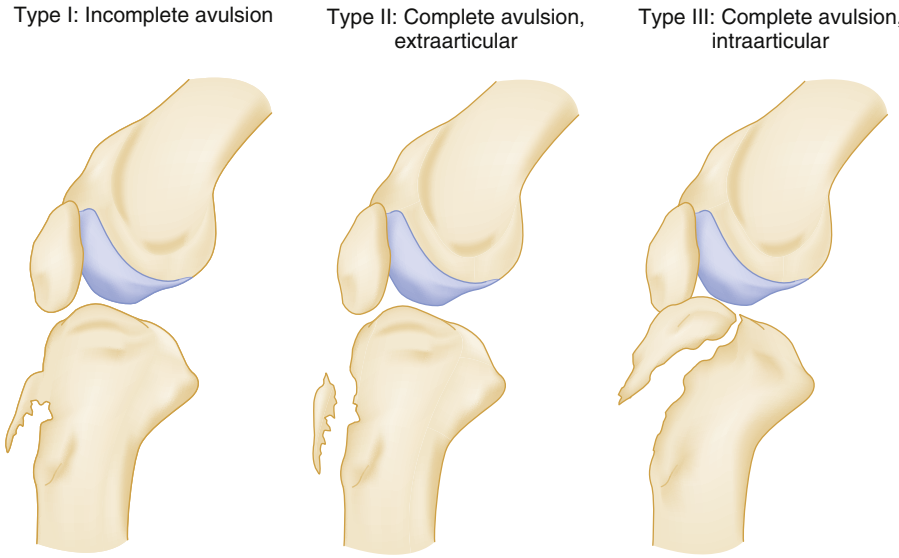

Fig. 48.11 Tibial Tuberosity Fractures.

BOX 48.2 Ogden Classification

Type 1: secondary ossification center fracture (near patellar tendon insertion)
Type 2: fracture extends between the primary and secondary ossification centers
Type 3: fracture extends to the primary center of ossification
Type 4: entire proximal tibial physis fractured
Type 5: sleeve avulsion fracture from the secondary ossification center
Tibial tuberosity fractures are further classified as follows:
Type A: nondisplaced
Type B: displaced

Orthopedic follow-up is recommended for transition to casting once swelling has decreased. Any supracondylar tibial fracture that is intra-articular, comminuted, or displaced has a higher risk for compartment syndrome and requires operative fixation. These patients are typically admitted to allow serial neurovascular examinations and to monitor swelling in the first 24 to 48 hours after injury.

Tibial Tubercle Fractures—Foundations

The tibial tubercle is located at the proximal anterior border of the tibial shaft and is the insertion point of the patellar tendon. The proximal tibial epiphysis and tibial tuberosity develop from two separate ossification centers that coalesce during adolescence. Epiphyseal ossification terminates in late adolescence.

Avulsion fractures of the tibial tubercle are uncommon. They occur predominantly in adolescent boys near the end of growth, when endochondral ossification of the physeal cartilage of the tibial tubercle occurs. Avulsion fractures mainly occur following an indirect injury during strenuous activity. The mechanism of injury has been described as an abrupt flexion of the knee against a tightly contracted quadriceps muscle, which also can cause patellar tendon rupture. The Ogden Classification of tibial tuberosity fractures expands the previously used Watson-Jones classification to better describe the injury pattern (Fig. 48.11; see Box 48.2). This fracture pattern is rarely seen in other age groups as this particular mechanism of injury typically results in patellar tendon rupture in the adult patient.

Tibial Tubercle Fractures—Clinical Features

Physical examination reveals acute tenderness and swelling at the anterior aspect of the knee and proximal tibia. Depending on the type of injury, functional disability may range in severity from extensor lag to complete loss of active extension. Hemarthrosis is evident if there is intra-articular fracture extension across the proximal epiphysis.

Tibial Tubercle Fractures—Diagnostic Testing

Standard knee x-rays should be obtained to evaluate for a tibial tubercle avulsion injury. The lateral view typically shows the avulsion fracture, number of fragments, and degree of displacement. Contralateral knee x-rays may be helpful to assess the patient's stage of ossification and better assess the injury.

Tibial Tubercle Fractures—Management and Disposition

Treatment depends on the degree of displacement and presence of joint involvement. Nondisplaced fractures are treated with a knee immobilizer and urgent orthopedic follow-up for casting. Displaced fractures are usually treated by open reduction and internal fixation. In the ED, orthopedic consultation is advised for these fractures.

Tibial Shaft Fractures—Foundations

The tibia and fibula are tightly bound to each other by the syndesmosis. This strong band of tissue can transmit energy so that the tibia and fibula may be fractured at nonadjacent sites. Tibial shaft fractures can be devastating, with a high rate of infection, delayed union, nonunion, malunion, and associated fibular fractures.

The type of tibial fracture seen varies based on the mechanism of injury. High-energy and direct trauma typically result in transverse fractures, whereas lower-energy, rotational, or compressive forces produce spiral or oblique fractures. Tibial fractures also may occur without trauma. Stress fractures usually occur in the tibial shaft. Pathologic fractures may be caused by metabolic bone disease, osteomalacia, and primary or metastatic neoplasms.

Tibial Shaft Fractures—Clinical Features

Patients with tibial shaft fractures can present with a significant amount of pain, edema, and deformity. Angulation of the foot is commonly seen in rotational injuries. The neurovascular exam should be the focus of the examination, particularly when foot angulation is present. Assessment of the DP and PT pulses should be performed as soon as possible, although

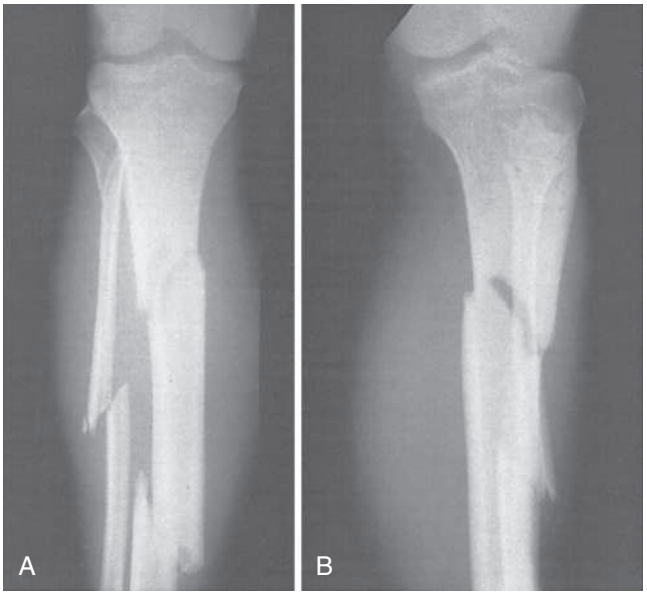

Fig. 48.12 Tibiofibular Fracture. (A) Anteroposterior view. Comminuted fractures of the tibial and fibular shafts are present. Note the obliteration of the normal soft tissue planes secondary to edema or hemorrhage. (B) Lateral view. (From Rosen P, et al. *Diagnostic radiology in emergency medicine.* St Louis: Mosby; 1992:198.)

Fig. 48.13 Maisonneuve Fracture, Anteroposterior View. The rotatory force involved in this injury has caused fractures of the distal tibia and the proximal fibula *(arrows)*. (From Rosen P, et al. *Diagnostic radiology in emergency medicine.* St Louis: Mosby; 1992:197.)

vascular injury is a rare complication. Neurologic injury, by contrast, is common, particularly injury of the peroneal nerve. Motor function of the peroneal nerve is checked by testing active ankle and toe dorsiflexion (deep peroneal nerve) and active foot eversion (superficial peroneal nerve). Sensory function of the peroneal nerve is documented by testing sensation in the first dorsal web space of the foot (deep peroneal nerve distribution) and sensation of the dorsal lateral foot (superficial peroneal nerve distribution). Integrity of the posterior tibial nerve is assessed by checking for the presence or absence of plantar sensation. Compartment syndrome may be a complication of tibial fractures and usually develops within the first 24 to 48 hours.

In general, tibial fractures are slow to heal. A low-energy injury heals in 20 weeks, whereas high-energy injuries typically heal in 30 weeks. Delayed union describes fracture segments that have not united after 24 weeks or that show no radiographic evidence of callus formation for 3 consecutive months. Nonunion describes incomplete fracture healing. Fracture fragments have rounded, well-corticated edges (as compared with the jagged edges seen in the acute phase of injury). A variety of delayed vascular injuries can be seen with tibial fractures, including the development of pseudoaneurysms, arteriovenous fistulas, and DVT. Fat embolism syndrome may develop within the 24 to 48 hours following either the initial injury or operative application of intramedullary rods, nails, screws, or plates. This syndrome typically mimics pulmonary emboli, with sudden onset tachycardia, tachypnea, dyspnea, chest pain, and altered mental status.

Tibial Shaft Fractures—Diagnostic Testing

Standard AP and lateral x-rays of the tibia and fibula can be used to identify these fractures. Standard x-rays of the knee and ankle should be performed to assess the extent of injury. In cases of significant force, x-rays of the femur, hip, and pelvis may also be warranted (Fig. 48.12). Postreduction views should be taken after any manipulation of the extremity and should include the knee and ankle joints so that alignment of the proximal and distal joint surfaces can be determined.

Tibial Shaft Fractures—Management and Disposition

ED management of tibial shaft fractures varies based on the extent of injury. The majority of patients with an acute tibial shaft fracture are admitted for neurovascular monitoring while awaiting definitive operative management. Patients with a closed fracture should be placed in a long leg posterior splint while awaiting emergent orthopedic consultation. Circumferential casts are generally avoided in the acute setting due to the risk of compartment syndrome, although some orthopedists will cast pediatric fractures in the acute phase. In general, after fractures have been immobilized, pain decreases. Persistent pain after splinting should raise suspicion for impending compartment syndrome, nerve compression, or vascular compromise.

If an open fracture is noted on examination, a sterile dressing should be placed over the wound and the protruding bone. Ten days of antistaphylococcal antibiotic coverage (typically cefazolin, 2 g) should be given. Gentamicin (3 to 5 mg/kg daily) may be added for severely contaminated wounds. Penicillin G (2 million units IV q4h) should be added after farm-related injuries, while pseudomonas coverage should be provided for wounds contaminated by fresh or salt water. Gentamicin is also the first choice in penicillin-allergic patients. Tetanus vaccination status should be updated as indicated. A long leg posterior splint should be applied with a sugar tong component while awaiting emergent external fixator placement or operative intervention. Osteomyelitis is more likely with open fracture, significant soft tissue disruption, and delayed time from contamination to definitive surgical management.

Proximal Fibula Fractures—Foundations

The fibula is a non–weight-bearing bone, allowing most fibular fractures to be treated nonoperatively. Most fibular fractures result from a direct blow to the lateral aspect of the lower leg. Varus stress to the knee can also result in fibular head and neck fractures. An important exception is the *Maisonneuve fracture* (Fig. 48.13). This injury involves a medial ankle disruption (deltoid ligament tear or medial malleolar fracture), a complete tear of the syndesmosis, and a proximal fibula fracture. Consequently, the fibula floats freely relative to the tibia,

resulting in an unstable ankle mortise, for which surgical fixation is required. The possibility of this injury indicates the need for examination of the proximal fibula in all medial ankle injuries. A neurovascular examination should be performed on any patient with either a Maisonneuve fracture or an isolated proximal fibular fracture, as the peroneal nerve wraps around the proximal fibula.

Proximal Fibula Fractures—Clinical Features

Patients with isolated fibular shaft fractures typically note localized lateral leg pain that increases with ambulation. Localized swelling and tenderness to palpation can be seen on examination. A neurovascular examination should be performed with a particular focus on common peroneal nerve function. Proximal fibular fractures can be associated with both LCL and posterolateral corner injuries. Anterior tibial artery injury with thrombosis may also occur.

Proximal Fibula Fractures—Diagnostic Testing

If a fibular fracture is suspected, the patient should have standard knee, tibia, fibula, and ankle x-ray series performed.

Proximal Fibula Fractures—Management and Disposition

Isolated fibular shaft fractures are treated symptomatically with ice, analgesia, a stirrup splint, and non–weight bearing. Orthopedics follow-up is advised within 1 to 2 weeks to ensure healing and facilitate referral to physical therapy as needed.

For severely displaced fibular shaft fractures or fractures with associated peroneal nerve deficit (e.g., foot drop), or Maisonneuve fractures, ED orthopedic consultation is indicated. A Maisonneuve fracture results in an unstable ankle, and open reduction and internal fixation are usually required.

Proximal Tibiofibular Joint Dislocations—Foundations

The anterior and posterior tibiofibular ligaments and the joint capsule all contribute to the stability of the joint. This combination of structures makes joint dislocation relatively uncommon. Most proximal tibiofibular dislocations result from high-velocity injuries. When dislocation does occur, anterolateral displacement is most common and is typically seen after a fall onto a flexed, abducted leg. Posteromedial dislocation can be seen after direct force is applied to a flexed knee. A neurovascular examination should be performed in posteromedial proximal tibiofibular dislocations, because there is a high rate of peroneal nerve injury associated with the condition. Superior dislocation is associated with ankle diastasis and typically occurs simultaneously with an ankle fracture. This association highlights the need to examine the joints proximal to and distal to the area of primary injury.

Proximal Tibiofibular Joint Dislocations—Clinical Features

The patient may complain that the knee feels "out of joint" or report a sensation of instability. Physical examination reveals lateral knee pain, tenderness, and swelling over the proximal fibula and tibiofibular joint. In the absence of associated injury, findings on knee examination are otherwise normal, with full ROM and no joint line tenderness or effusion.

Proximal Tibiofibular Joint Dislocations—Diagnostic Testing

Standard knee x-rays may confirm the diagnosis, although CT scanning may be required to identify this injury. On the AP view, the fibular head is displaced laterally, and the interosseous space is widened. Comparison views of the uninjured knee may be necessary to appreciate these subtle findings.

Proximal Tibiofibular Joint Dislocations—Management and Disposition

Closed reduction is the first line treatment for acute proximal tibiofibular dislocations. If the patient seeks treatment acutely, reduction of an anterolateral dislocation can be accomplished in the ED by flexing the knee to 90 degrees, everting the ankle, and applying direct pressure to the head of the fibula. Orthopedic referral and immobilization of the knee are necessary after reduction. If closed reduction fails, the patient may require open reduction, with repair of the torn capsule ligaments and surgical pinning. For recurrent dislocations or injuries that do not respond to initial treatment, resection of the proximal fibula or arthrodesis may be effective. Patients with a delayed diagnosis and those with chronic subluxation of the proximal tibiofibular joint may require operative intervention. Orthopedics should evaluate this patient subgroup in the ED.

Stress Fractures—Foundations

Stress fractures, which occur as a result of excessive repetitive force to normal bone, are distinguished from pathologic fractures, which occur as a result of normal forces acting on abnormal bone (e.g., because of osteoporosis or tumor). Lower extremity stress fractures are more common than upper extremity injuries. The most common sites of stress fracture are the tibia, femur, fibula, navicular, and metatarsal bones. The orientation of the fracture (horizontal, oblique, or longitudinal) varies based on the bone involved and the patient's activities.

Stress Fractures—Clinical Features

Bone pain and tenderness without a history of direct trauma are characteristic for most stress fractures. The most important historical information includes a recent increase in physical activity, training on hard surfaces, and inadequate footwear. Most patients with stress fractures note a dull pain that has increased in intensity over time. Pain is initially noted only with activity but may progress to pain with walking and ultimately to pain at rest. Pinpoint tenderness is the hallmark examination finding in the stress fracture patient. In addition, determine if a patient has a previous history of stress fracture. If a female has a history of recurrent stress fractures, further information regarding menstrual irregularities and nutritional deficiencies should be obtained. ROM and muscle strength are preserved.

Stress Fractures—Diagnostic Testing

Stress fractures may be difficult to diagnose on x-ray. X-rays may not reveal the injury until up to 6 weeks after the onset of symptoms. Some stress fractures remain radiographically occult even after 6 weeks. Radiographic findings vary based on the location of the injury and the duration of symptoms, but may include a perpendicular lucency in the bone cortex, bony sclerosis, or new periosteal bone. MRI can be used to detect the injury within a week of symptom development.

If a stress fracture of the lower extremity is suspected and findings on initial plain radiography are unremarkable, follow-up evaluation within 2 weeks may detect radiographic signs of fracture after a period of inactivity. Evidence of healing (periosteal reaction) in response to treatment is sufficient to confirm the diagnosis.

Stress Fractures—Management and Disposition

Most tibial and fibula stress fractures can be treated nonoperatively. Activity should be decreased for 3 to 6 weeks to allow for healing, and serial radiographs should be obtained as an outpatient. If walking causes pain, splinting and non–weight-bearing status should be implemented. Rare cases of nonunion require surgery.

A small subset of stress fractures (including anterior tibia, navicular, fifth metatarsal, patella, sesamoid, and superior sided femoral neck)

are at high risk of progression to complete fracture and should be made non–weight bearing. They may require operative fixation.

Medial Tibial Stress Syndrome—Foundations

The term *shin splints* refers to anterior tibial pain occurring during or after exercise. Formally known as MTSS, the most common causes are a tibial stress reaction or periostitis. Tibial stress reactions are microfractures caused by stress placed on the tibia and are distinct from gross stress fractures, which predispose the bone to complete fracture.

Medial Tibial Stress Syndrome—Clinical Features

This condition is common among athletes, military recruits, and patients engaging in excessive amounts of running. The risk factors for MTSS are similar to those for stress fractures. MTSS is the result of periostitis or stress reaction and lacks a discrete fracture line. Patients with MTSS typically have more generalized tibial pain than patients with stress fractures.

Medial Tibial Stress Syndrome—Diagnostic Testing

Standard tibial/fibular x-rays are not necessary to make the diagnosis of MTSS but should be performed to rule out fracture.

Medial Tibial Stress Syndrome—Disposition and Management

Rest is a key component in the treatment of MTSS and should be done in conjunction with a review of the patient's training habits and footwear use. Orthopedic follow-up is advised.

Compartment Syndrome

Compartment syndrome is a true orthopedic emergency. Clinicians should have a high index of suspicion for the condition in any patient who has sustained a crush injury or an open fracture. Careful attention should be paid to the neurovascular examination in all patients with a concerning mechanism of injury. Compartment syndrome is caused by increased pressure within a fascial compartment, leading to necrosis of muscle and nerve. Diagnosis and management of compartment syndrome is further discussed in Chapter 47.

Soft Tissue Injuries Involving the Lower Leg

Gastrocnemius and plantaris injury—foundations. The gastrocnemius is composed of two distinct muscle bellies, the medial and lateral heads. The medial head is usually slightly larger and stronger than its lateral counterpart and is frequently injured during athletic activities.

The plantaris is a small muscle that originates at the lateral condyle of the femur and passes beneath the soleus to insert on the Achilles tendon. It is a relatively noncontributory flexor of the knee and plantar flexor of the ankle joint, with little functional significance. Rupture may occur at the myotendinous junction, with or without an associated partial tear of the medial head of the gastrocnemius muscle. A strain of the more proximal plantaris muscle also may occur as an isolated injury or in conjunction with injury to the ACL of the knee.

Gastrocnemius and plantaris injury—clinical features. Patients with gastrocnemius injury typically present to the ED with point tenderness and swelling in the calf. If the gastrocnemius has ruptured, a palpable defect may be appreciated on physical exam. Pain typically increases with passive and active ankle dorsiflexion. Patients with a DVT may present in a similar fashion but typically have more edema associated with the pain and are less likely to have been participating in athletic activities at the onset of symptoms. Patients with a ruptured Baker cyst may also present with generalized lower leg edema and pain about the gastrocnemius. Achilles tendon rupture may also be confused with gastrocnemius injury but can be differentiated by the palpable gap just proximal to the calcaneus and a positive *Thompson test*. Gastrocnemius tear can also present similarly to plantaris tendon rupture.

Patients with a plantaris tendon rupture often present with a pop sensation at the time of injury and may have ecchymosis at the proximal aspect of the lower leg. Tenderness is greatest just lateral to the midline of the posterior calf. Examination will show intact strength but pain with plantar flexion. Patients with Achilles tendon rupture may similarly note hearing "a loud pop" while running or jumping. In contrast, Achilles tendon rupture is associated with lower leg pain that is more distal to the pain associated with plantaris or gastrocnemius injury.

Gastrocnemius and plantaris injury—diagnostic testing. Venous duplex should be performed to rule out DVT and may help to differentiate between these conditions. Soft tissue defects can be seen on standard tibia/fibula x-rays, but this is not the preferred diagnostic modality. MRI is the optimal study for diagnosis because it permits the quantification of tendon retraction, but it is not indicated in the ED.

Gastrocnemius and plantaris injury—management and disposition. A small partial rupture of the medial head of the gastrocnemius can be treated with rest and non–weight bearing for several days. Extensive incomplete or complete gastrocnemius ruptures should be managed with splinting in plantar flexion with urgent orthopedic follow-up.

For plantaris injury, treatment is symptomatic, with a posterior splint in partial equinus position for the first few days if the pain is severe. The patient should be cautioned that significant posterior calf and posterior ankle ecchymosis often appears over the first few days. All patients with gastrocnemius injury or plantaris injury should be given strict precautions regarding the signs and symptoms of compartment syndrome and DVT.

Foreign bodies. Foreign bodies such as plant matter (e.g., thorns), glass, and metallic objects are commonly encountered in the leg. Missed retained foreign bodies in the lower leg can be the cause of cellulitis, abscess, necrotizing fasciitis, and gangrene. Plain films are a necessary part of the initial evaluation but will be unremarkable when the foreign body is radiolucent. Ultrasound may be used to assess for localized infection while helping to identify a foreign body. Ultrasound is more readily available than MRI and is the modality of choice in the ED, particularly if there is the possibility of metal fragments in the wound. If a retained foreign body is suspected, antibiotics should be initiated in the ED. Surgical exploration is sometimes necessary for deeper positioned foreign bodies. Extraction is difficult, and these types of foreign bodies should be removed by a surgeon, often in the operating room.

CHAPTER 48: QUESTIONS AND ANSWERS

1. A 45-year-old woman presents after a high-impact motor vehicle collision with pain in the left knee. She thinks her knee may have gone out of place but isn't sure. The distal neurovascular examination is intact. What is the most appropriate management?

a. Compression wrap and early range of motion exercises
b. Discharge if radiographs are negative with partial weight bearing
c. Knee immobilizer with orthopedic follow-up
d. Measure ankle-brachial index and perform duplex ultrasonography if less than 0.9
e. Orthopedic consultation

Answer: d. This patient had a knee dislocation. Knee dislocation is uncommon but should be considered in the setting of an appropriate injury mechanism because 50% of all knee dislocations are reduced spontaneously before emergency department (ED) arrival. Reduction before ED arrival does not lessen the likelihood of vascular injury, and vascular injury should be considered in patients with severe ligamentous injuries and injuries caused by high-energy mechanisms. Vascular injury to the popliteal artery is the most severe complication and is the major cause of morbidity and limb loss. Management of suspected knee dislocation involves an algorithm designed to be noninvasive but sensitive for arterial injury.

2. A 42-year-old man was at the gym performing squatting exercises. As he was coming to a stand, he had an immediate onset of pain in his right thigh. He presents with an inability to extend his knee. What is the most likely physical finding?

a. High-riding patella
b. Mid-quadriceps muscle tenderness and deformity
c. Popliteal swelling and tenderness
d. Positive Lachman test
e. Suprapatellar tenderness with patella baja

Answer: e. This is a quadriceps tendon rupture. Patients with extensor disruption may have signs and symptoms that include an acute onset of pain, swelling, ecchymoses over the anterior aspect of the knee, a palpable defect in the patella, quadriceps tendon, or patella tendon loss or limited ability for active leg extension; extension lag usually is seen when the last 10 degrees of extension are performed haltingly or with difficulty. With quadriceps rupture, a low-riding patella (patella baja) and inferior retraction may be seen.

3. A college football lineman presents complaining of left knee pain and inability to bear weight. He was on the scrimmage line when the ball was placed in motion and, as he lunged forward, he twisted his leg and heard an audible pop in his knee. He was immediately unable to bear weight. On physical examination, you find the left knee swollen, with a positive Lachman test. What is the most sensitive way to diagnose the injury accurately?

a. Arthroscopy of the knee
b. Computed tomography (CT) scan of the knee
c. History and physical examination
d. Magnetic resonance imaging (MRI) of the knee
e. Plain radiography of the knee

Answer: a. Clinical evaluation is moderately sensitive for anterior cruciate ligament (ACL) tears but, in the acute phase, is often inaccurate because of swelling and splinting. Acutely, only plain films are indicated as long as dislocation is not suspected. Tibial plateau fractures detected on plain film may require CT scanning to determine the need for admission for early operative repair. Arthroscopy is the gold standard for diagnosis of soft tissue injuries of the knee. MRI is useful but may miss small tears and anatomic abnormalities, and a normal study may still lead to arthroscopy if symptoms persist. MRI scanning of the knee is rarely indicated in the emergency setting.

4. A man presents with severe pain of his right lower leg. He was in the ED the previous night for splint placement for a tibial fracture. After removal of the splint, you see a lower leg with mild ecchymosis, healing abrasions, and palpable posterior tibial and dorsalis pedis pulses. He has severe pain on passive movement of his first toe and decreased sensation of the first toe web space. Which of the following should be the next step?

a. Admit for intravenous (IV) antibiotics and pain control.
b. Obtain venous Doppler scans.
c. Resplint the patient.

d. Test the anterior compartment pressures.
e. Test the superficial posterior compartment pressures.

Answer: d. The lower leg is divided into the following compartments by deep partitions of the investing crural fascia—anterior, lateral, superficial posterior, and deep posterior. The anterior compartment contains the tibialis anterior, long toe extensor muscles, anterior tibial artery, and deep peroneal nerve, which supplies sensation to the first web space of the foot.

5. A severe medial ankle sprain with no ankle fracture necessitates evaluation of which of the following?
a. Cervical spine
b. Femoral nerve
c. Lumbar spine
d. Popliteal artery
e. Proximal fibula

Answer: e. An important exception to fibular fractures being stable is a Maisonneuve fracture (see Fig. 48.13). This involves a medial ankle disruption (deltoid ligament tear or medial malleolar fracture), with complete tearing of the syndesmosis joining the tibia and fibula and fracture of the proximal fibula. This results in an unstable ankle mortise because the fibula now floats free relative to the tibia, and surgical fixation is required.

Ankle and Foot Injuries

Nicholas G.W. Rose and Thomas J. Green

KEY CONCEPTS

- The Ottawa Ankle and Foot Rules should be used to evaluate the need for x-rays in ankle and foot injuries.
- CT scans are indicated for negative x-rays of the ankle and foot when a high clinical concern of fracture exists.
- Ankle dislocations with obvious vascular compromise should be reduced promptly, before radiographs are obtained.
- The entire fibula should be examined if a medial malleolar fracture is present to rule out a proximal fibular (*Danis-Weber type C or Maisonneuve*) fracture.
- Osteochondral lesions of the talar dome, nondisplaced fractures of the lateral posterior process of the talus, and fracture of the anterior process of the calcaneus are important to include in the differential diagnoses of presumed ankle sprains.
- Patients discharged with a diagnosis of ankle sprain should be encouraged to seek outpatient follow-up should ankle pain and swelling persist for longer than 2 weeks.
- Patients with Achilles tendon rupture are still capable of weak plantar flexion. Ultrasound may be used to confirm the diagnosis if clinical uncertainty exists.
- A Lisfranc injury should be considered with any fracture or dislocation in the tarsometatarsal region, particularly with fractures of the second metatarsal base. When suspicion for a Lisfranc injury is high, even if plain radiographs and CT scans are negative, immobilization and orthopedic referral are indicated.
- Fifth metatarsal tuberosity (zone 1) fractures should be carefully differentiated from diaphyseal fractures. Orthopedic referral is indicated for zones 2 and 3 fractures.
- Stress fracture should be considered in patients with long-standing foot pain, particularly if symptoms are in the metatarsal region. This may be diagnosed by plain radiography, CT scanning, or radionuclide bone scanning.
- Compartment syndrome may occur in any of the four major compartments of the foot. Diagnosis is made by high clinical suspicion and measurement of the intracompartmental pressures.

ANKLE

FOUNDATIONS

Background and Importance

The ankle and foot are highly evolved structures designed to support the body's weight and facilitate locomotion over varied terrain. Pathology related to ankle and foot injuries is often subtle, and diagnoses may be delayed or missed, particularly in cases of multiple trauma.

The ankle and foot are best approached clinically as a single functional unit. Although they are discussed sequentially in this chapter, mechanisms of injury overlap, and a pathologic condition in one location may accompany an associated pathologic condition in another.

Anatomy

The ankle joint is the articulation of the tibia and fibula with the talus. The dome of the talus fits into the mortise formed by the medial malleolus, horizontal articular surface of the tibia (or plafond, French for "ceiling"), and lateral malleolus. Fundamentally, the stability of the ankle depends on the bony and ligamentous integrity of the mortise. The calcaneus is also important for the motion and stability of the ankle (Figs. 49.1 and 49.2).

The ankle is composed of three primary articulations—the inner surface of the medial malleolus with the medial surface of the talus, the distal tibial plafond with the talar dome, and medial surface of the lateral malleolus with the lateral process of the talus. These three articular surfaces are contiguous, lined with cartilage, and enclosed by a single joint capsule. The distal tibia also articulates with the distal fibula just proximal to the talus, forming the distal tibiofibular joint. Collectively, these articulations are termed the *talocrural joints*.

Three sets of ligaments—the syndesmotic ligament and lateral collateral ligaments (see Fig. 49.1), and medial collateral ligaments (see Fig. 49.2), together which make up the deltoid ligament—support the ankle joint and are essential to its stability.

Tendons course through the ankle in four anatomic groups (Fig. 49.3). The flexor retinaculum tethers the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis muscles behind the medial malleolus. The peroneal retinaculum and tendon sheath tether the peroneus longus and brevis tendons behind the lateral malleolus. The extensor retinaculum tethers the tendons of the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius over the anterior aspect of the ankle. Posteriorly, in the midline, lie the Achilles and plantaris tendons.

Physiology and Pathophysiology

Ankle movements are multifaceted and often involve more than one joint. The ankle joint complex is made up of the talocrural joints and talocalcaneal (subtalar) joints, which allow movements along several axes of motion. Dorsiflexion (ankle flexed so the toes point cephalad) and plantar flexion (ankle extended so the toes point toward the floor) of the ankle joint occur primarily at the talocrural joints. Motions of the ankle joint in conjunction with the midtarsal joints include inversion (sole of the foot points to the midline), eversion (sole of the foot points away from the midline), abduction (external rotation of the foot), and adduction (internal rotation of the foot), which are rotational movements about the longitudinal axis of the tibia.

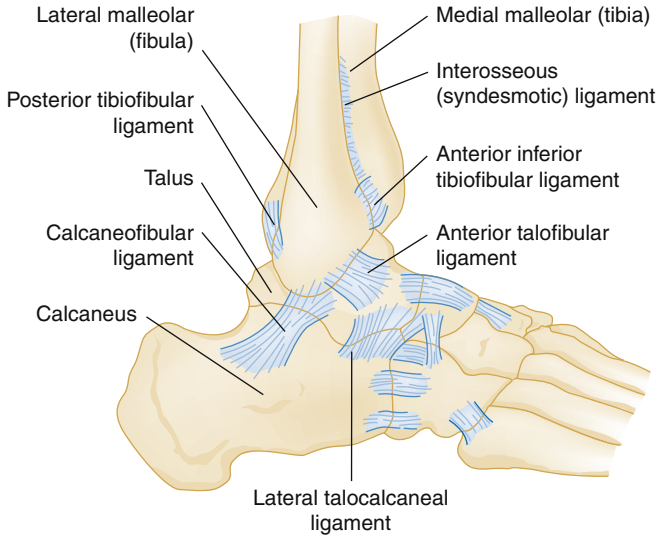

Fig. 49.1 Anatomy of the lateral collateral and syndesmotic ligaments of the ankle.

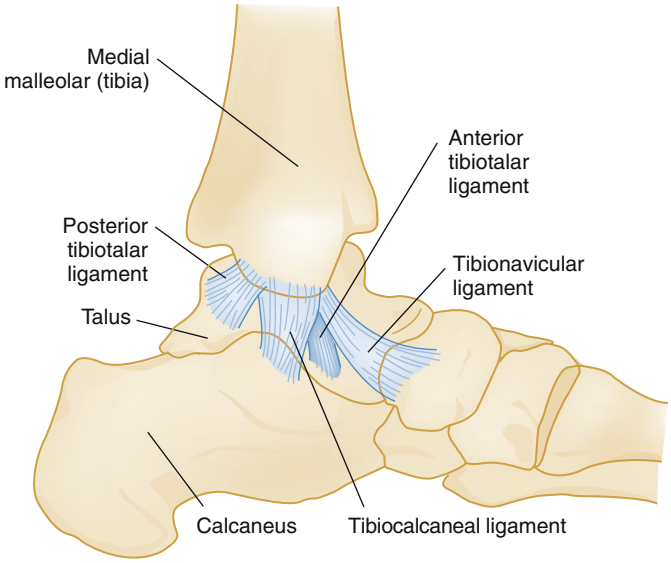

Fig. 49.2 Anatomy of the medial collateral ligaments of the ankle, which collectively constitute the deltoid ligament.

The components providing stability to the ankle are best conceptualized as a ring-like structure surrounding the talus (Fig. 49.4). Disruption of one element of this ring does not, by itself, induce instability. Injury to one ring element, however, should prompt careful scrutiny for a second injury. Any disruption of two or more elements causes ankle instability and can significantly affect joint function.

Fractures occur when a deforming force is sufficient to overcome the structural strength of a bone. A bone under tension fractures along the axis of the deforming force. Alternatively, ligamentous rupture or an avulsion fracture can occur at either end of a stressed ligament or tendon, and the mechanism of injury generally causes predictable fracture patterns (Fig. 49.5).

Clinical Features

Carefully eliciting the mechanism of injury can often provide clues to the injuries sustained. The presence of sudden swelling and severe pain in the ankle region suggests serious ligament disruption, hemarthrosis, or fracture, and rapid progression of symptoms may represent more severe injury. Inability to bear weight immediately after an injury often implies a significant pathologic condition. Patient recollection of a "popping" sound should prompt consideration of ligament, tendon, or retinacular rupture but does not necessarily increase the probability of a fracture. Finally, the inciting event causing the ankle injury should be determined and, when necessary, investigated further.

The physical examination of the ankle starts with an assessment of deformity, ecchymosis, edema, and perfusion, followed by active and passive range of motion. Assessment of point tenderness may help localize and differentiate between ligament, bone, or tendon injuries, particularly when the patient is seen soon after injury. Palpation should include the medial and lateral collateral ligaments, syndesmotic ligament, inferior and posterior edges of the medial and lateral malleoli, entire length of the fibula and tibia, anterior plafond, base of the fifth metatarsal, calcaneus, Achilles tendon, and tendons behind the medial and lateral malleoli. In addition, the medial and lateral dome of the talus is palpable with the ankle in plantar flexion. Stress testing of the ankle joint, discussed later, should not be performed until a fracture has been excluded. An evaluation of weightbearing ability should proceed only if clinical suspicion of a fracture is low, the location of tenderness does not indicate the need for plain radiography, or radiographs have ruled out a fracture.

Clinical findings specific to ankle fractures include ankle swelling, obvious deformity, skin abnormalities including lacerations and tenting and, if presenting in a delayed fashion, fracture blisters. Neurovascular compromise may occur, therefore performance of a neurovascular examination distal to the injury is necessary. If the fracture has occurred due to a fall from a height, the ankle injury can mask other injuries, such as lumbar compression fracture, fractures of the pelvis, tibial plateau, or other axial skeleton injuries. *Maisonneuve fractures* can also cause a neuropraxia to the peroneal nerve. Compartment syndrome is a rare complication following isolated ankle fracture and is usually associated with significant disruptive fracture patterns.

Early operative complications of closed and open ankle fractures include pin site infection, delayed skin necrosis, skin graft rejection, neuropraxia or neurotmesis, and osteomyelitis. Delayed complications of operative and nonoperative treatment include malunion, nonunion, osteopenia, traumatic arthritis, chronic instability, ossification of the interosseous membrane, avascular necrosis, and complex regional pain syndrome.

Differential Diagnoses

There is much overlap in the clinical presentation of skeletal, ligamentous, and tendinous pathologies of the ankle and foot due to the complex anatomy and hence differential diagnoses are broad, especially in subtler presentations (Box 49.1).

Diagnostic Testing

Radiology

The anteroposterior, lateral, and mortise views constitute the standard three-view radiographic series of the ankle. Subtle fractures can be easily overlooked on ankle radiographs, and a standardized approach to radiographic interpretation can reduce the likelihood of missing ankle fractures (Fig. 49.6). The lateral view is useful in identifying an ankle effusion, which appears as a teardrop-shaped density displacing the normal fat adjacent to the anterior or posterior margin of the joint capsule. The presence of an effusion suggests the possibility of a subtle intra-articular injury, such as an osteochondral lesion of the talar dome.

The mortise view, taken with the ankle in 15 to 25 degrees of internal rotation, and the lateral view are the most important for evaluating the congruity of the articular surface between the dome of the talus

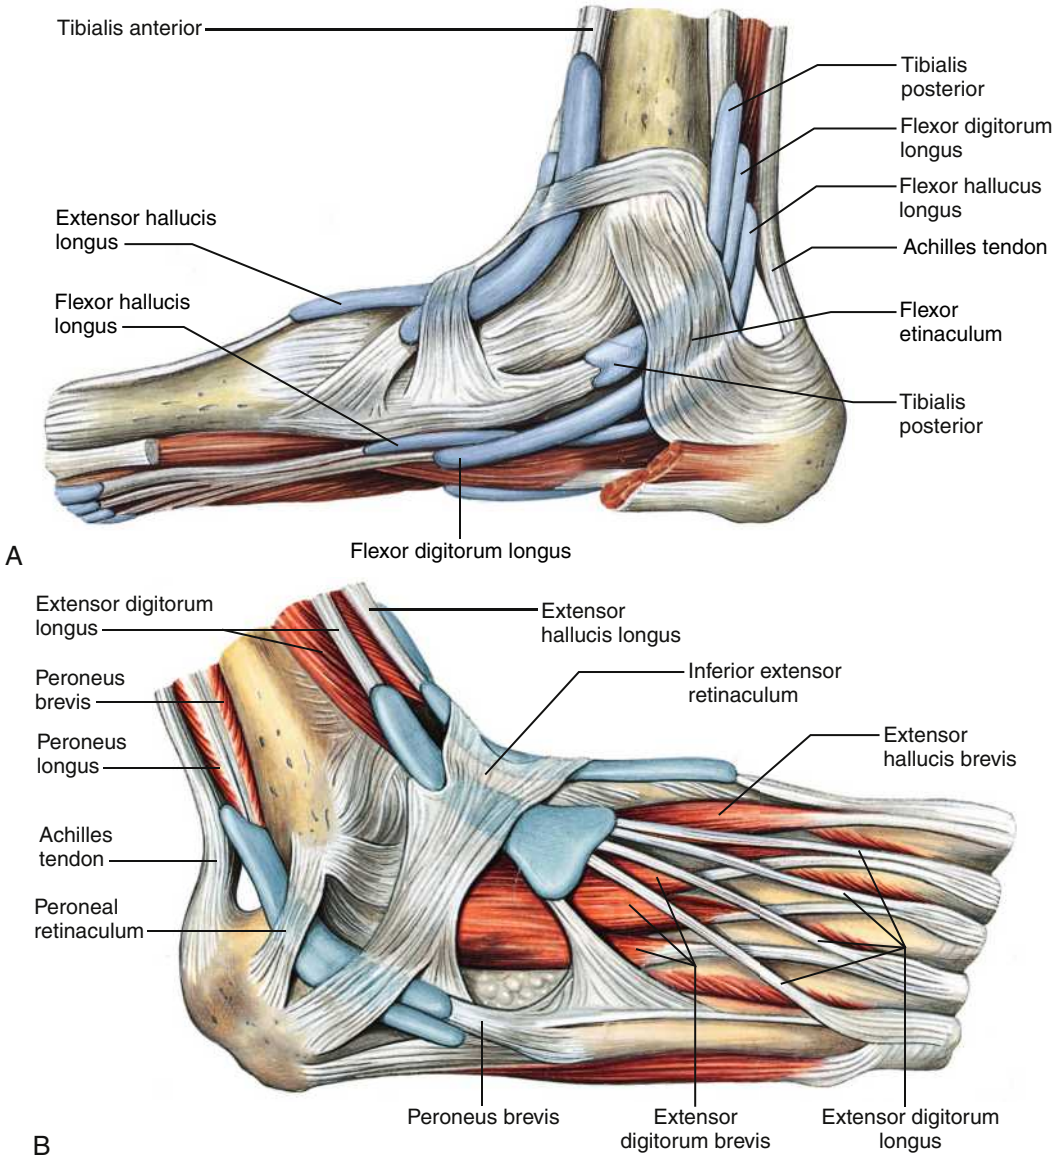

Fig. 49.3 Tendons of the ankle and foot. (A) Medial view. (B) Lateral view. (From Paulsen F, Waschke J. Lower limb. In: Paulsen F, Waschke J, eds. *Sobotta Atlas of Anatomy: General Anatomy and Musculoskeletal System*, ed. 16, vol. 1. Elsevier GmbH; 2018: Fig. 4.115a and b.)

and mortise. In the mortise view, the lines formed between the articular surfaces should be parallel, the joint space should appear uniform throughout the tibiotalar and talofibular components of the joint, and the medial clear space should not exceed 4 mm (see Fig. 49.6 and Fig. 49.7). On the lateral view, any incongruity of the articular space between the talar dome and distal tibia suggests ankle instability, particularly if narrowing of the anterior joint space is present.

Reproducible methods for the radiologic evaluation of syndesmotic diastasis have proven elusive.[1] Plain radiographs are the least reliable method for identifying syndesmotic instability. Rather than rely on standard measurements to evaluate for syndesmotic injury, comparison to the contralateral ankle may be valuable in identifying syndesmotic diastasis. The diagnosis of syndesmotic instability can be difficult in the emergency department (ED) and often relies on advanced imaging, which can be arranged at the time of specialist consultation.

In most cases of isolated blunt ankle trauma evaluated within 48 hours of injury, the Ottawa Ankle Rules (OAR) may be used by clinicians to determine whether ankle or foot radiographs are necessary. The OAR state that an ankle radiographic series is required if there is pain in the malleolar region with any of the following findings:

- Bone tenderness at the posterior edge of the distal 6 cm or tip of the lateral malleolus
- Bone tenderness at the posterior edge of the distal 6 cm or tip of the medial malleolus
- Inability to bear weight (defined as the ability to transfer weight onto each leg regardless of limping) for at least four steps immediately after the injury and at the time of ED evaluation

The OAR further state that a foot radiographic series is required if there is pain in the midfoot region with any of the following findings:

- Bone tenderness at the navicular bone
- Bone tenderness at the base of the fifth metatarsal
- Inability to bear weight for at least four steps immediately after the injury and at the time of ED evaluation

The OAR have a sensitivity approaching 100% for detecting acute malleolar zone ankle fractures and midfoot zone fractures but cannot be applied to subacute or chronic injuries. Although derived in an adult

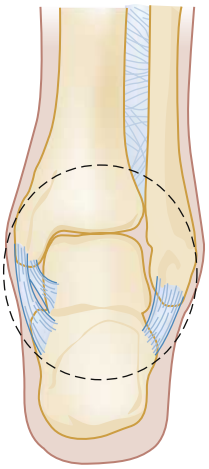

Fig. 49.4 The ring structure surrounding the talus is made up of the tibial plafond, medial malleolus, deltoid ligaments, calcaneus, lateral collateral ligaments, and syndesmotic ligaments. The integrity of this ring determines the stability of the ankle, and the degree of disruption determines the need for operative intervention.

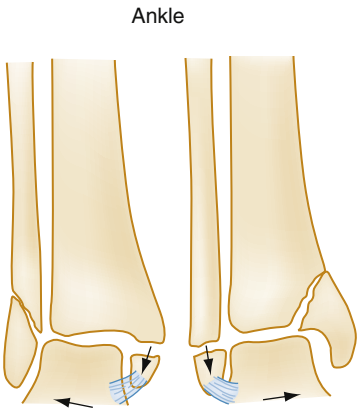

Fig. 49.5 The mechanics of bone failure in rotational tension and types of tension ankle fractures. *Arrows* indicate the direction of distracting forces.

population, the OAR appear to be clinically applicable in pediatric patients older than 5 years. In children younger than 5 years, alternative approaches can be used (see Chapter 170). Nurse initiated application of the OAR has proven to have similar sensitivity and reduce wait times in the ED.[2,3]

The decision rules for foot radiography, although applicable to blunt ankle trauma, apply only to the midfoot zone. The OAR were not designed to be general guidelines for foot radiography and do not apply to the hindfoot or forefoot. Finally, the OAR are not applicable to intoxicated patients or those who are difficult to assess because of head injuries, altered mental status, multiple injuries, or diminished sensation related to neurologic deficits.

Other Imaging Techniques

Although plain radiography is the initial imaging modality of choice for ankle injuries, it can miss subtle ankle fractures, osteochondral lesions, stress fractures, or ligamentous injuries. When unexplained symptoms persist after negative or inconclusive findings on plain radiographs, other imaging modalities or orthopedic consultation may be advisable. In situations where these are unobtainable, the ankle should be immobilized, the patient discharged with instructions to be nonweightbearing, given clear instructions that a fracture may be present despite the lack of conclusive evidence on x-ray, and instructed that repeat x-rays or additional imaging may be required on follow-up examination.

BOX 49.1 Differential Diagnoses for Presumed Ankle Fracture/Dislocation

Ankle sprain
Achilles tendon rupture
Syndesmosis injury ± proximal tibial fracture
Retinaculum rupture
Tendon dislocation
Monoarthropathies (gout/pseudogout/septic arthritis)
Charcot joint
Foot fracture
Pathologic fracture

Computed tomography (CT) imaging provides superior bone images and is an excellent modality to delineate abnormalities not identified or incompletely characterized by other imaging techniques. This is particularly relevant in the foot and ankle, where plain radiographs are complicated by overlying structures and complex articulations. In acute injuries, CT imaging of the foot or ankle is indicated, despite apparently normal radiographs when a fracture is highly suspected.[4] The emergency clinician can perform CT imaging in the ED or as part of outpatient follow-up, with the ankle immobilized and nonweightbearing in the interim. CT scan can detect small fractures, subtle stress fractures, intraarticular fractures, syndesmotic instability, and tendon entrapment or dislocation.[5,6] In certain cases, CT imaging plays an important role in surgical planning.

Radionuclide imaging (bone scanning) can detect soft tissue injuries such as distal syndesmotic disruptions, stress fractures, and osteochondral lesions. Bone scan abnormalities are present once a patient is symptomatic; for example, they typically appear 1 to 2 weeks before radiographic evidence of a stress fracture. Because of its high sensitivity, a negative bone scan effectively rules out the diagnosis. Bone scan abnormalities are nonspecific, however, because infections and tumors also can lead to positive results (see later discussion on stress fracture imaging of the foot). Bone scanning is not useful for follow-up because abnormalities can persist for up to 1 year after recovery. Radionuclide imaging should be ordered on an outpatient basis and has been largely supplanted by CT and magnetic resonance imaging (MRI).

Ultrasound has limited utility in the ED with the exception of the evaluation of tendons, and to some degree, ligamentous structures. Its relative simplicity and rapid availability have led to its increased utility in point-of-care settings in the ED. Ultrasound can easily identify tendinous disruption. The more technically difficult dynamic ultrasound can be used to identify tendinous subluxation or disruption.

MRI, although not typically performed emergently, provides unprecedented clarity in depicting soft tissue structures such as ligaments, tendons, and the syndesmosis, and can also delineate bone marrow changes associated with stress fractures before radiographic abnormalities appear. MRI can be helpful in guiding management decisions and following the patient's response to therapy.

MRI or CT arthrography can be useful in the evaluation of chronic ankle pain to detect loose bodies, ligamentous injuries, cartilaginous abnormalities, or osteochondral lesions. CT plus single-photon emission computed tomography (SPECT), which combines CT and radionuclide scanning, has been shown to increase the diagnostic ability of imaging significantly in osteochondral lesions, stress fractures, impingement syndromes, and osteomyelitis. The decision to perform specialized imaging of this nature is typically made through orthopedic

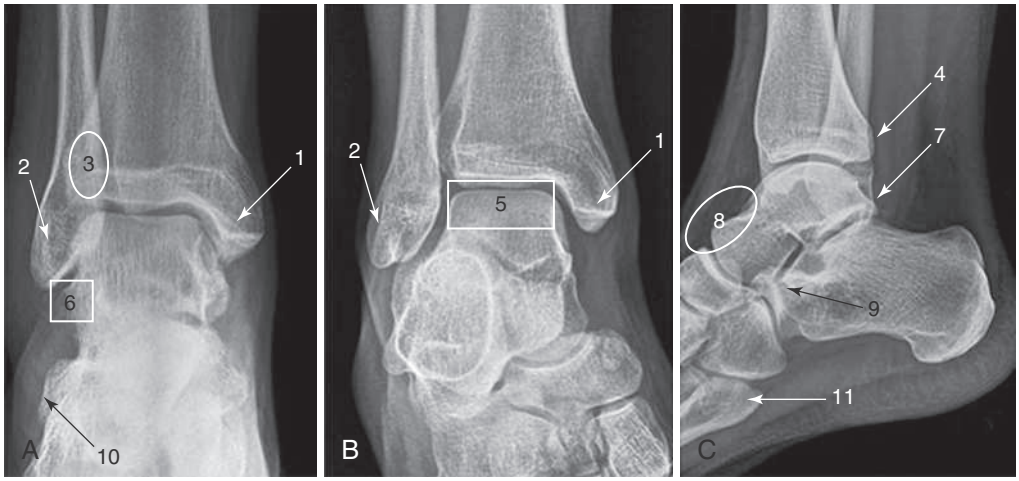

Fig. 49.6 Approach to reviewing ankle radiographs. (A–C) A standard radiographic series of the ankle has three views—an anteroposterior view (A), an internal rotation or mortise view (B), and a lateral view (C). The following 11 locations should be carefully scrutinized because they are areas where fractures frequently occur: medial (1) and lateral (2) malleoli, anterior tibial tubercle (3) and posterior tibial malleolus (4), talar dome (5), lateral talar process (6), tubercles of the posterior talus process (7), dorsal to the talonavicular joint (8), anterior calcaneus process (9), calcaneal insertion of the extensor digitorum brevis (10), and base of the fifth metatarsal bone (11). (From Yu JS, Cody ME. A template approach for detecting fractures in adults sustaining low-energy ankle trauma. *Emerg Radiol.* 2009;16:309.)

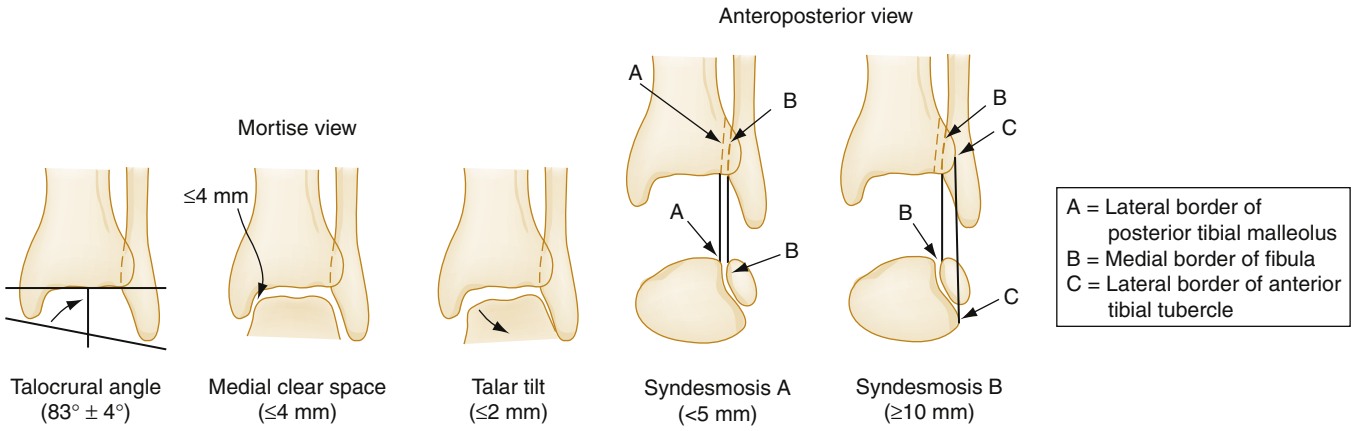

Fig. 49.7 Radiologic criteria for evaluating the stability of the ankle mortise.

or radiologic consultation; such studies are not routinely performed in the ED.

ANKLE FRACTURES AND DISLOCATIONS

General Considerations

The management of ankle fractures consists of identification and classification, emergent reduction of fracture-dislocations that threaten soft tissues or neurovascular status, and specific treatment and disposition. Most important, an evaluation of the stability of the ankle joint affects the decision for conservative versus operative repair.

To date, no ideal system has been developed for the classification of ankle fractures. The *Lauge-Hansen classification* and *Danis-Weber systems* are based on mechanism of injury and fracture location, respectively. The Lauge-Hansen classification was intended to characterize ligamentous injury patterns based on the radiographic appearance of ankle fractures but is complex and has been shown to have limitations in broad applicability. The Danis-Weber system (Fig. 49.8) has predictive value for operative repair in isolated lateral malleolar fractures because the location of the fibular fracture is related to the integrity of the syndesmosis. As such, it is more useful to emergency clinicians than the Lauge-Hansen classification. Both systems have limitations, however, and neither accurately predicts management or clinical outcome in all situations. Further details regarding how and when to apply the Danis-Weber system are provided in the following discussions of specific fractures.

The injured ankle should be promptly immobilized, elevated, and iced to minimize swelling and further soft tissue damage. The presence of gross deformity with neurovascular compromise or skin tenting necessitates prompt intervention. Plain radiography before reduction can be helpful but should not delay reduction in injuries with obvious vascular compromise.

In all cases, appropriate procedural sedation and analgesia techniques are required for reduction. The notion that some reductions are accomplished relatively quickly and easily (from the clinician's perspective) is not an excuse for failing to adequately manage the extreme pain that these orthopedic manipulations may cause for the patient. The fundamental principle of closed reduction is to reverse the deforming

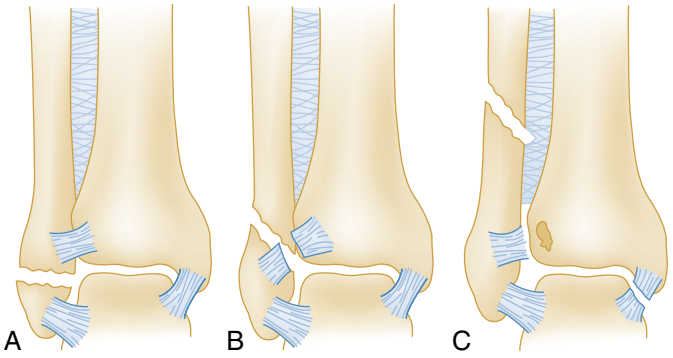

Fig. 49.8 The Danis-Weber classification of ankle fractures focuses on the location of the fibular fracture in relation to the tibiotalar joint and syndesmosis. Weber A fractures involve inversion-adduction forces. Weber B fractures involve abduction forces. Weber C fractures involve eversion-abduction forces. See text for further explanation.

forces. For example, reduction of a fracture-dislocation caused by an adduction injury might require an opposite abduction force. The initial application of a distracting force, sometimes combined with slightly increasing the deformity, is often helpful in achieving reduction. After reduction, neurovascular status should be reassessed, the leg immobilized and elevated, and postreduction radiographs obtained. The overarching goal in the definitive treatment of ankle fractures is to achieve anatomic reduction.

The outcome of ankle fractures depends on the extent of injuries, number of malleoli fractured, ankle stability, and patient age. All displaced or potentially unstable ankle fractures require orthopedic consultation. Traditionally, patients with displaced or unstable ankle fractures were admitted for operative repair, but it has been shown that delayed repair does not affect outcomes, and outpatient management where the emergency clinician immobilizes the patient's fracture, provides strict nonweightbearing instructions, and refers the patient to orthopedics on an urgent basis (within 24–48 hours) is acceptable.[7]

Extraarticular nondisplaced fractures that disrupt only one ring element generally can be treated with casting for 3 to 6 weeks.[8] Depending on the type of ankle fracture, and its stability, some fractures may be made weightbearing as tolerated, whereas others may be nonweightbearing, requiring the use of crutches. The presence of any abnormal measurement on the mortise view (Fig. 49.6) suggests instability and the need for orthopedic consultation, typically within 48 hours. Displaced fractures generally require reduction before immobilization and referral. Avulsion fractures, in which the avulsed fragment is smaller than 3 mm in diameter and minimally displaced, can be treated in a similar manner to an ankle sprain.

Unimalleolar Fractures

Lateral Malleolar Fractures

Lateral malleolar fractures are the most common ankle fracture. Stability of the ankle joint depends on the location of the fracture in relation to the level of the tibiotalar joint, which defines the distal portion of the syndesmotic ligament. The Danis-Weber classification (see Fig. 49.8) is useful and predictive of outcome in these types of unimalleolar fractures. This classification groups fractures into three types—A, B, and C. Subgroups exist but do not assist the emergency clinician in prognosticating the necessity of operative repair and are beyond the scope of this chapter.

Lateral malleolar fractures below the tibiotalar joint (Danis-Weber type A) rarely disrupt other bony or ligamentous structures and, in the absence of injury to medial structures, such fractures are unlikely to affect the dynamic congruity of the ankle joint. Uncomplicated Weber A lateral malleolar fractures may be considered part of the continuum of ligamentous ankle injuries and managed with functional bracing or walking boot and weightbearing as tolerated, with orthopedic follow-up within a week to ensure ongoing union. Concomitant tenderness over the deltoid ligament may suggest a biomechanical disruption of both malleoli, an associated fracture of the medial malleolus, or an associated fracture of the posterior malleolus. This injury warrants orthopedic consultation within 48 hours on an outpatient basis, especially if the medial clear space on the mortise view is widened (see Fig. 49.6). CT imaging can be useful in such situations because it may identify occult medial or posterior malleolar fractures.

Fibular fractures proximal to the tibiotalar joint line (Danis-Weber type C injury; see Fig. 49.8) frequently disrupt the distal tibiotalar syndesmosis and medial structures causing ankle instability. These commonly require orthopedic consultation in the ED, or within 48 hours on an outpatient basis (where the patient is immobilized and made nonweightbearing) for operative intervention.

Treatment of an isolated fibular fracture at the level of the tibiotalar joint (Danis-Weber type B injury; see Fig. 49.8) is controversial. Fifty percent of these injuries are accompanied by an injury to the distal tibiofibular syndesmosis causing ankle joint instability, and therefore may require operative intervention. Historically, Danis-Weber B fractures were all treated operatively, but the tendency more recently is to base the decision to operate on the stability of the joint, rather than purely on a radiologic classification system.[9,10] Tenderness on palpation of the syndesmotic ligament, a positive squeeze test (see soft tissue injury section), or widening of the medial joint space on the mortise x-ray view confirms the need for orthopedic consultation in the ED, or within 48 hours on an urgent outpatient basis (where the patient is immobilized and made nonweightbearing) for consideration of operative repair. Stress x-ray views, which include gravity or manual stressing of the fractured ankle, can identify ligamentous instability and clarify the need for operative intervention but are generally arranged by the orthopedic consultant. If discharged from the ED for urgent outpatient orthopedic follow-up, the patient is placed in a walking boot or noncircumferential splint and made nonweightbearing.

Medial Malleolar Fractures

Medial malleolar fractures are usually the result of eversion or external rotation. These two forces exert tension on the deltoid ligament, causing an avulsion of the tip of the medial malleolus or a rupture of the deltoid ligament. Although they can occur in isolation, medial malleolar fractures are commonly associated with lateral or posterior malleolar disruption. Because of this, identification of a medial malleolar fracture or deltoid ligament injury warrants a careful examination of the entire length of the fibula. Tenderness at any point warrants radiographic evaluation to rule out a proximal fibular fracture, known traditionally as a *Maisonneuve fracture* (Fig. 49.9). Any medial malleolar fracture requires orthopedic referral for assessment of joint and syndesmosis stability for operative syndesmotic stabilization. An isolated nondisplaced medial malleolar fracture can be treated with casting for 6 to 8 weeks, with nonweightbearing and close orthopedic follow-up on an urgent basis, usually within 48 hours. Any displacement or concurrent disruption of the lateral components of the ankle warrants orthopedic consultation in the ED or on an urgent outpatient basis for consideration of operative management. Rarely, stress fractures of the medial malleolus or distal fibula can be seen, particularly in athletes and runners. Plain radiographs may be nondiagnostic, but radionuclide bone scanning, CT imaging, or MRI—the choice is often influenced by local availability—can establish the diagnosis. These injuries can be treated nonoperatively with nonurgent outpatient orthopedic consultation.

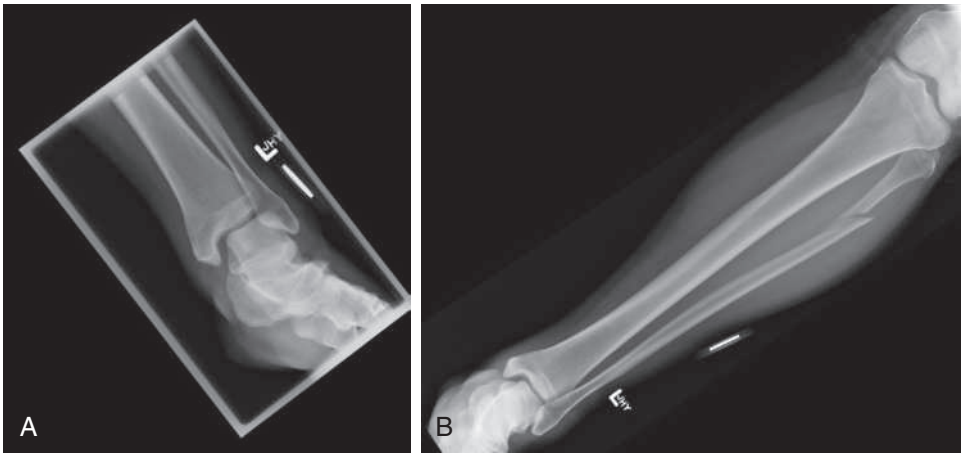

Fig. 49.9 Maisonneuve fracture. (A) Anteroposterior view shows a slight widening of the ankle mortise and the medial clear space. (B) Anteroposterior view shows an oblique fracture at the proximal shaft of the fibula. (Courtesy Dr. Nicholas G.W. Rose.)

Posterior Malleolar Fractures

Isolated fractures of the posterior malleolus are rare and imply an avulsion of the posterior tibiofibular ligament. These injuries can be associated with proximal fibular fractures and medial and lateral collateral ligament sprains. Treatment usually consists of casting for 6 weeks for nondisplaced fractures in which no associated injury or ankle instability is present. CT scanning is generally used to ensure anatomic reduction prior to conservative management. Fractures involving more than 25% of the tibial surface usually require open reduction and internal fixation (ORIF); however, this is an area of controversy, and displaced posterior malleolar fractures require orthopedics consultation within 48 hours on an urgent outpatient basis (where the patient is immobilized and made nonweightbearing).

Bimalleolar Fractures

Bimalleolar fractures involve the disruption of at least two elements of the ankle ring (see Fig. 49.4) and are therefore unstable. These fractures result from adduction or abduction forces, with the latter being more common. Rotational injuries also can cause bimalleolar fractures, as well as trimalleolar fractures, if the posterior malleolus is involved. Associated damage to other soft tissue structures (e.g., the syndesmosis) is common with bimalleolar fractures.

Controversy exists about whether nondisplaced bimalleolar fractures should be treated with surgical or closed reduction, and orthopedic consultation in the ED or within 48 hours on an urgent outpatient basis is warranted. The patient should be made nonweightbearing and placed in a walking boot or posterior splint until specialist follow-up.

Trimalleolar Fractures

Trimalleolar fractures involve fractures of the medial, lateral, and posterior malleoli and almost always require urgent surgical fixation due to their gross instability with orthopedic consultation in the ED.

Open Fractures

Open fractures require emergent orthopedic consult as most benefit from early surgical intervention for débridement and irrigation. After documentation of the neurovascular status and extent of soft tissue trauma, gross contaminants should be removed from the wound, saline-soaked sterile gauze should be applied, and the injured leg should be splinted. Swabbing an open wound for bacterial culture and sensitivity testing is unnecessary. If significant deformity is present, immediate reduction with appropriate analgesia before splinting is indicated. Tetanus immunoprophylaxis should be administered, as appropriate. Because open fractures are invariably contaminated with bacteria, patients with these injuries should receive intravenous (IV) antibiotics within the first hour in the ED. For low-energy injuries with mild to moderate contamination, a first-generation cephalosporin is usually sufficient. Heavily contaminated wounds require the addition of gram-negative bacterial coverage, typically an aminoglycoside. Adding penicillin G or clindamycin (if the patient is penicillin-allergic) as a third antibiotic is recommended for farm- or soil-related crush injuries, in which contamination with *Clostridium perfringens* can be present.

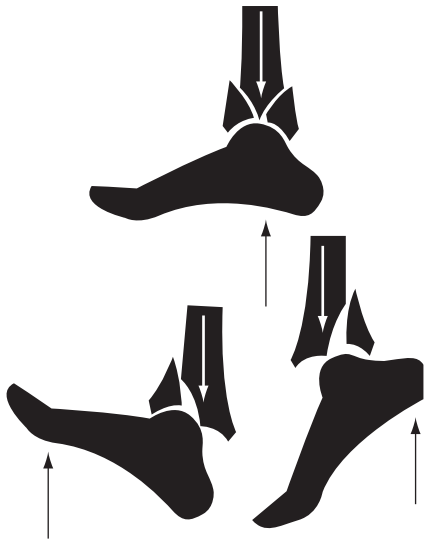

Fig. 49.10 Schematic diagram of the pathophysiology of pilon fractures. The position of the foot at the time of impact determines the fracture pattern.

Pilon Fractures

Clinical Features

Pilon fractures involve the distal tibial metaphysis and usually are the result of high-energy mechanisms with axial loading of the ankle joint, such as falls from a significant height (Fig. 49.10). Destot first coined

the term *hammer fracture* to describe how the head of the talus drives itself into the tibial plafond and causes a pilon fracture. The primary deforming force is one of axial compression, and the position of the foot at the time of injury determines the fracture location and pattern (see Fig. 49.10). Secondary rotational or shear forces may cause increased comminution and fragment displacement with more extensive soft tissue injuries. These injuries often are comminuted and thus associated with significant soft tissue trauma, tendon entrapment or dislocation, devastation of joint architecture, and leg shortening. Due to the high-energy mechanism of injury, patients with pilon fractures frequently have other significant injuries and patient assessments should take into account these mechanisms and include a full evaluation of the neurovascular status of the foot.

One-fourth of pilon fractures are open; associated injuries include fractures of the calcaneus, tibial plateau, fibula, femoral neck, acetabulum, and lumbar vertebrae, as well as trauma to other major systems. Complications of pilon fractures are common, particularly in more severe cases. Early complications include wound infection, skin sloughing, pin site infection, and wound dehiscence. Delayed and late complications include malunion, nonunion, leg shortening, posttraumatic arthritis, avascular necrosis, and protracted pain. Some patients with severe pilon fractures ultimately require arthrodesis of the ankle joint. Careful assessment of the affected bony anatomy and neurovascular status of the foot is necessary in a pilon fracture, and in the case of open fractures, management as outlined previously should occur.

Differential Diagnoses

Differential diagnoses of pilon fractures are relatively limited since the mechanism of injury and clinical presentation makes the diagnosis fairly obvious. However, it is important not to miss other associated injuries or complications such as compartment syndrome, ankle dislocation or other skeletal injuries.

Diagnostic Testing

Plain radiographs are the initial choice of imaging for the diagnosis of pilon fractures and should include the entire tibia and fibula, as well as the ankle. CT imaging is generally required by the orthopedic surgeon for operative planning.

Management

ED treatment involves restoration of the articular surface and fibular length with reduction if necessary, combined with meticulous management of soft tissue injuries. Difficulties in achieving reduction may occur if tendon entrapment has occurred, most often the posterior medial structures. Because surgical management is required, emergent orthopedic consultation is necessary. Pilon fractures with low-grade soft tissue damage are primarily managed with ORIF. In severe pilon fractures with extensive soft tissue damage, however, results are better with a two-stage approach involving initial length restoration and external fixation, followed by anatomic reduction and internal fixation after soft tissue swelling has subsided.

Dislocations

Anatomy, Physiology, and Pathophysiology

Ankle dislocations are described based on the direction of displacement of the talus and foot in relation to the tibia. Dislocation may be upward, posterior, medial, lateral, posteromedial, or anterior. Medial dislocation is the most common. Most dislocations involve associated ankle fractures; rarely, however, dislocations can occur without fracture. The mechanism in all dislocations begins with axial loading of a plantar-flexed foot, which forces the talus anteriorly or posteriorly from the ankle mortise. The eventual position of the dislocation depends on the position of the foot at the time of injury and direction of the displacing force. Ankle dislocations can be closed or open and usually result from significant falls, motor vehicle collisions (MVCs), or high-speed sports. The neurovascular supply to the foot usually is intact but may be compromised in open dislocations.

Clinical Features

The diagnosis is usually obvious due to gross deformity in the ankle joint although determining the orientation of the body of the talus, which must be reduced, can be challenging without imaging. A rapid assessment of neurovascular status is necessary.

Differential Diagnoses

Due to the deformity in the ankle joint that is observed in a traumatic setting, differential diagnoses are limited to evaluation for concurrent fracture at the site of dislocation.

Diagnostic Testing

Plain radiography remains the cornerstone of diagnosis of ankle dislocation and is helpful in clarifying the orientation of the talar body prior to reduction. However, attempts at reduction should not be delayed when vascular compromise or skin tenting is present.

Management

In order to achieve talar reduction, appropriate procedural sedation or an intraarticular hematoma block[11] is used, the patient is placed supine, and the knee is flexed to 90 degrees. Distraction of the foot, followed by a gentle force to reverse the direction of the dislocation, usually accomplishes the reduction. Difficulties in achieving reduction may be caused by entrapped posterior medial tendons. Postreduction reassessment of the neurovascular status, splint immobilization, ankle elevation, and radiography should follow. Open dislocations require the same management as previously discussed for open fractures. The prognosis for an ankle dislocation is generally good, although open fractures are associated with an increased incidence of complications. Isolated ankle dislocations once successfully reduced with documentation of intact neurovascular status, are immobilized and made nonweightbearing. These dislocations can be urgently followed by orthopedics on an outpatient basis within 48 hours.

Ligamentous Injuries

Foundations

Ankle sprains are frequently seen in EDs and are one of the most common injuries in an active patient population. Proper diagnosis and rehabilitation are important because 40% of patients experience dysfunction for up to 6 months post injury. The term *ankle sprain* refers to a multitude of ligamentous and nonligamentous injuries. Even when ligamentous injury is certain, the ideal treatment approach is controversial, and there is significant variation in clinical practice.[12]

Pathophysiology

Most ankle sprains occur from extreme inversion and plantar flexion that produce symptoms on the lateral aspect of the ankle. Usually, the anterior talofibular ligament is injured first, followed by the calcaneofibular ligament if the deforming forces are sufficiently strong (see Fig. 49.1). Approximately two-thirds of ankle sprains are isolated anterior talofibular ligament injuries, whereas 20% involve anterior talofibular and calcaneofibular ligament injuries. In addition, the lateral talocalcaneal ligament may be strained with an inversion injury, leading to avulsion fractures at either end of the attachment sites. Isolated calcaneofibular or posterior talofibular ligament injuries are rare.

TABLE 49.1 Ligamentous Injury Classification According to Functional and Presumed Pathologic Findings

Classification (Grade)	Physical Examination	Pathophysiology	Treatment
1	• Minimal lateral ATFL tenderness • Small effusion or no effusion • Weightbearing immediately or within 24 hr	• Microscopic tearing of ligamentous complex fibers	• PRICE • Weightbearing as tolerated • ROM, proprioceptive, and other functional exercises, as tolerated
2	• Moderate lateral ATFL tenderness and hematoma • Small to moderate effusion • Unable to bear weight for >24 hr	• Complete tear of some ligamentous fibers	• PRICE • Immobilization with air cast • ROM, proprioceptive, and other functional exercises, as tolerated
3	• Significant lateral ATFL tenderness ad hematoma • Large effusion • Unable to bear weight for >24 hr • Positive anterior draw, talar tilt test	• Complete tear of all ligamentous fibers within the ligamentous complex	• PRICE • Immobilization • Delayed ROM, proprioceptive, and other functional exercises, as tolerated • Prolonged rehabilitation phase ± delayed surgery

ATFL, Anterior talofibular ligament; *PRICE*, *p*rotection, *r*est, *i*ce, *c*ompression, *e*levation; *ROM*, range of motion.

Isolated injury of the medially located deltoid ligament occurs in less than 5% of ankle sprains and occurs during an eversion force. Rupture of this ligament usually occurs in conjunction with lateral malleolar fractures, especially when an external rotational force is involved.

Concurrent injury of the anterior talofibular and deltoid ligaments, determined by palpation and other physical signs such as ecchymosis, warrant investigation for instability of the ankle joint due to bimalleolar ligamentous injury

Injuries of the distal tibiofibular syndesmotic ligaments are uncommon in the general population because of the degree of force required but represent 10% to 20% of ankle sprain injuries in competitive athletes, the so-called "high" ankle sprain. Dorsiflexion and external rotation forces are usually responsible for this injury; their presence may significantly prolong the recovery time from concomitant lateral collateral ligament sprains.

Ligamentous injuries are classified into three grades based on functional and presumed pathologic findings, as outlined in Table 49.1. This classification system, although commonly used, fails to characterize ankle injuries involving two or more ligaments and does not address nonligamentous injuries.

Clinical Features

An accurate history of ankle position and injury mechanism is often unavailable. Inversion followed by external rotation of the ankle suggests the potential for deltoid or syndesmotic injury. Forced dorsiflexion with "snapping" may indicate peroneal tendon displacement. On physical examination, the presence of edema, ecchymosis, and point tenderness over the medial or lateral collateral ligaments or syndesmotic ligaments suggests a ligamentous injury. Inability to bear weight in the absence of a fracture suggests the presence of a grade II or III ankle sprain. Deltoid ligament tenderness necessitates palpation of the full length of the fibula to rule out a proximal fibular fracture—type C Danis-Weber or Maisonneuve fracture (see Figs. 49.8 and 49.9). Tenderness should prompt imaging of the entire tibia and fibula.

Differential Diagnoses

Many injuries can masquerade as ankle sprains. Box 49.2 lists conditions to be considered with the differential diagnoses.

BOX 49.2 Differential Diagnoses for Presumed Ankle Sprain or Ankle/Foot Tendon Injuries

Lateral collateral ligament sprain
Peroneal tendon dislocation
Osteochondral lesion of the talar dome
Fracture of the posterior process of the talus
Fracture of the lateral process of the talus
Fracture of the anterior process of the calcaneus
Midtarsal joint injury
Fracture of the base of the fifth metatarsal
Achilles tendon injury

Diagnostic Testing

The fibular compression test, or squeeze test, can be used to diagnose fibular and syndesmotic injuries. To perform this test, the examiner places the fingers over the fibula and the thumb over the tibia at midcalf and squeezes the two bones. Pain anywhere along the length of the fibula suggests a fibular fracture or syndesmotic ligament disruption at that location. Following this, the Achilles tendon should be assessed for rupture.

Stress testing is the application of a deforming force to assess joint motion beyond the physiologic range; its presence suggests ligament disruption or mechanical instability. Common ankle stress tests include the anterior drawer test, inversion stress test, and external rotation test. *The anterior drawer test* primarily assesses the integrity of the anterior talofibular ligament. To perform this test, the patient is seated with the knee in 90 degrees of flexion and the ankle in a neutral position or 10 degrees of plantar flexion, which is best achieved by allowing the foot to rest along the examiner's wrist and distal forearm, as the examiner cups the heel in his or her hand and gently flexes the ankle to the 90-degree position. The examiner then applies slow but firm traction on the heel with that hand and places the other hand on the anterior tibia to prevent the leg from moving anteriorly. Anterior displacement of the talus, the perception of a "clunk," and the induction of a sulcus

anteromedially over the joint indicate partial or complete tear of the anterior talofibular ligament.

The inversion stress test, or "talar tilt test," evaluates the anterior talofibular ligament and calcaneofibular ligament. It is performed by inverting the heel with the knee in 90 degrees of flexion and the ankle in neutral position. Palpation of the head of the talus laterally or a finding of increased laxity compared with the uninjured side suggests partial or complete tear of these ligaments.

The external rotation stress test is indicated when injury to the distal tibiofibular syndesmotic ligaments is suspected. It is performed by externally rotating the foot with the knee in 90 degrees of flexion and the ankle in a neutral position. Pain at the syndesmosis or the sensation of lateral talar motion suggests partial or complete tear of the ligaments.

Stress testing in the ED to identify acute ligamentous disruption is often limited by pain, so to be performed properly, the joint must be anesthetized with local anesthetic. Furthermore, a positive stress test suggesting ligamentous instability rarely alters management in the ED. If needed, this test can be deferred to orthopedic follow-up.

Standard ankle radiographic views exclude fractures and detect ligamentous instability by allowing the measurement of joint spaces (see earlier discussion and Fig. 49.6). Stress radiographs, accomplished by taking radiographs during stress testing of the ankle, including the use of gravity stress testing, generally do not influence the emergency management of ankle sprains and we do not recommend their routine use in the ED.

The presence of avulsion fractures constitutes an important clue to the location of ligamentous injuries. Common locations for avulsion fractures include the bases of the malleoli, lateral process of the talus, lateral aspect of the calcaneus, posterior malleolus, lateral aspect of the distal tibia, and base of the fifth metatarsal.

Management

Most ligament sprains, regardless of severity, heal well and result in a satisfactory outcome. To date, compelling evidence for a significant difference in outcomes between surgical and functional (nonsurgical) treatment is lacking. Most patients with acute sprains of the ankle should start with functional treatment. For the minority who fail to respond, delayed operative repair of ruptured ligaments, sometimes years after the injury, has been shown to yield results equivalent to those with primary repair.

Functional treatment, a form of therapy in which the ankle is not fully immobilized, allowing complete or partial joint function, starts in the ED with PRICE therapy (***p***rotection, ***r***est, ***i***ce, ***c***ompression, and ***e***levation). However, significant variability exists in how this combination is applied, and optimal methods for the rehabilitation of ankle sprains remain unclear.[13] Lace-up ankle splint support is more effective in short-term edema reduction than semirigid ankle support, elastic bandaging, and taping.

For grade I or II injuries, short-term protection with a compression bandage, taping, laced-up support, or commercial brace, with the optional use of crutches for a few days, is appropriate. For patients with first-time ankle sprains, treatment with a lace-up brace combined with elastic wrapping results in an earlier return to function compared with the use of a brace alone, elastic wrap alone, or walking cast.

For severe grade II or grade III injuries, there has been equipoise regarding the merits of immobilization compared with functional rehabilitation using a removable brace, with a paucity of high-quality evidence. We recommend use of a lace-up support or air cast that permits some ankle motion. These patients should also use crutches to avoid weightbearing until they can stand and walk a few steps on the injured ankle without pain. Crutch use varies significantly, ranging from a few days to 2 or 3 weeks. Functional therapy allows for the incorporation of earlier physical therapy rehabilitation and quicker recovery.

Discharge instructions are important in ankle sprains. The expected time for return to activity is generally 2 to 4 weeks, depending on the grade of the injury, with more severe injuries taking longer; however, patients are usually able to weight bear within 7–10 days. Patients who have not returned to a normal activity level beyond this time frame should be reevaluated for talar dome osteochondral lesions, syndesmotic injury, or occult fracture with advanced imaging. Follow-up with the patient's primary care physician or sports medicine specialist is appropriate.

Pain improves with immobilization, but additional analgesia is usually required. Appropriate pain relief can be provided by systemic nonsteroidal antiinflammatory drugs (NSAIDs), in analgesic doses, or with acetaminophen. A short course (2–3 days) of oral opioids is added when pain is severe, although this is generally not required or recommended.

Disposition

Acute ankle ligament sprains rarely require orthopedic consultation in the ED. Primary surgical repair of acute ligament rupture is controversial; possible indications include sprains with displaced osteochondral lesions, complete tears of the anterior talofibular and calcaneofibular ligaments in a young athlete, a ligament sprain associated with a fracture causing instability (e.g., a deltoid ligament rupture with a lateral malleolar fracture), and an acute severe sprain in a patient with a history of recurrent sprains. Failure of nonoperative treatment also constitutes an indication for surgical repair; however, a nonurgent referral on an outpatient basis at the discretion of the orthopedic specialist is an appropriate disposition from the ED.

Small avulsion fractures of the fibula or tibia with minimal or no displacement can be treated in the same manner as an ankle sprain. If the avulsed fragment is larger than 3 mm or significantly displaced, splinting and referral for orthopedic follow-up on a nonurgent outpatient basis within a week is justified.

Tendon Injuries

The tendons of the ankle and foot (see Fig. 49.3) are important for facilitating the complex motions of the foot. In general, chronic causes of tendinopathy are more common than acute injuries and occur with overuse type patterns of injury, although tendon entrapments and dislocation may occur in complex ankle and hindfoot fractures.[6] Nontraumatic causes of tendon injury may present to the ED with sudden worsening or debilitating pain causing an inability to bear weight. Acute nontraumatic injuries tend to occur in the sports settings or with sudden and forced motion, often against an opposing force. Table 49.2 outlines many of the tendinous injuries located around the ankle joint. Some of the more significant tendon injuries are discussed next in further detail.

Differential Diagnoses

Differential diagnoses of ankle tendon injuries is similar to that of ankle sprains and is included in Box 49.2.

Achilles Tendon Rupture

Background and Importance, Physiology, and Pathophysiology. Achilles tendon rupture is most common in middle-aged men, and its causes are multifactorial. This condition is easily misdiagnosed, leading to a delay in therapy, worse prognosis, and increased morbidity, including chronic weakness and loss of function. In the majority of cases, a complete transection of the tendon is present; however, partial tears of the Achilles tendon can occur and may be more prone to misdiagnosis.

TABLE 49.2 Tendon Injuries to the Ankle and Foot

Tendon and Function	Injury and Mechanism	Clinical Presentation	Management
Achilles • Ankle plantar flexion	Chronic tendinopathy > acute injury Tendon rupture • Direct trauma • Sudden or forced ankle hyperdorsiflexion	Rupture • Sudden pain, snap or pop, posterior ankle • Ankle plantar flexion weakness, inability • Palpable defect in Achilles tendon • Positive Thompson test	• Orthopedic referral for conservative vs. operative management • Heel lift with slight plantar flexion while in walking boot, posterior slab
Peroneal longus, brevis • Ankle plantar flexion • Ankle eversion	Chronic tendinopathy > acute injury (rupture vs. dislocation) Tendon rupture • Forced dorsiflexion while forced inversion	• With dislocation, snapping sensation while everting ankle ± dorsiflexion • Sudden pain, swelling, lateral (posterior groove) malleolus • Weakness with eversion	• Orthopedic referral for tendon rupture or dislocation • PRICE, physical therapy for tendinopathy
Tibialis posterior • Ankle plantar flexion • Ankle inversion	Chronic tendinopathy > acute injury Tendon rupture • Forced eversion • Disruption of flexor retinaculum, 2 degrees closed anterior ankle dislocation	• Medial ankle pain • Unopposed peroneal brevis action; exaggerated eversion causing pes planus • Inability to perform single leg heel raise	• Orthopedic referral for tendon rupture • PRICE, physical therapy for tendinopathy
Tibialis anterior • Ankle dorsiflexion	Traumatic laceration > acute rupture > chronic overuse injury	• Anterior mass 2 degrees tendon retraction with laceration • Visible recruitment of EDL, EHL to assist in dorsiflexion causes dorsiflexion of hallux	• Orthopedic referral for tendon rupture • PRICE, physical therapy for tendinopathy
Flexor hallucis longus • Ankle and hallux plantar flexion	Chronic tendinopathy > acute injury	• Pain posteromedial ankle • Pain with ankle and hallux plantar flexion	• Orthopedic referral for tendon rupture • PRICE, physical therapy for tendinopathy
Extensor hallucis longus • Ankle and hallux dorsiflexion	Chronic tendinopathy > acute injury	• Pain anterior ankle • Pain with ankle and hallux dorsiflexion	• Orthopedic referral for tendon rupture • PRICE, physical therapy for tendinopathy

EDL, Extensor digitorum longus; *EHL,* extensor hallucis longus; *PRICE, p*rotection, *r*est, *i*ce, *c*ompression, *e*levation; *ROM*, range of motion.

Clinical Features. Achilles tendon rupture results from direct trauma or indirectly transmitted forces, including sudden unexpected dorsiflexion, forced dorsiflexion of a plantar-flexed foot, and strong push-off of the foot with simultaneous knee extension and calf contraction, as in a runner accelerating from the starting position. Factors predisposing to Achilles tendon rupture include preexisting disease such as rheumatoid arthritis, systemic lupus erythematosus, gout, hyperparathyroidism, chronic renal failure, steroid use or injection, fluoroquinolone antibiotic therapy, and previous Achilles tendon rupture. The vast majority of ruptures, however, occur spontaneously during activity or trauma, without risk factors other than being a middle-aged male.

Diagnostic Testing. The diagnosis of Achilles tendon rupture is primarily clinical. Patients usually describe a sudden onset of pain at the back of the ankle associated with an audible "pop" or "snap." Although the pain can resolve rapidly, weakness in plantar flexion persists. On examination, a visible and palpable tendon defect may be noted 2 to 6 cm proximal to the calcaneal insertion in acute presentations but will be less apparent in delayed presentations because of hematoma or surrounding edema. Even in cases of complete Achilles tendon rupture, weak plantar flexion may still be possible because of the actions of the tibialis posterior, toe flexors, and peroneal muscles. This retained ability for plantar flexion leads to the misdiagnosis of complete ruptures as ankle strains or partial tears in as many as 25% of cases.

The classic maneuver to assess the integrity of the Achilles tendon is the *Thompson test*. This is performed with the patient prone and the knee flexed at 90 degrees or the feet hanging over the end of the stretcher. Alternatively, the patient kneels on a chair with both knees flexed at 90 degrees and the feet hanging over the edge. With an intact Achilles, squeezing the calf muscles in these two positions should cause passive plantar flexion of the foot. Absence of this motion, or a markedly weakened response compared with the uninjured side, suggests complete rupture. Lateral radiographic views of the ankle may suggest rupture by showing opacification of the fatty tissue–filled space anterior to the Achilles tendon (*Kager triangle*) or an irregular contour and thickening of the tendon. Ultrasonography or MRI can demonstrate partial or complete tendon ruptures, but these studies are indicated only when diagnostic uncertainty exists.

Management. A lack of consensus exists between operative and nonoperative management in the treatment of Achilles tendon rupture.[14] Surgical repair is routinely performed in active individuals owing to its lower incidence of rerupture. However, surgery carries higher rates of other complications, such as superficial or deep wound infections, in comparison with nonoperative management. In both types of management, early mobilization improves functional recovery without increasing rerupture rates. Achilles tendon rerupture after initial nonoperative treatment usually necessitates surgical repair. Urgent orthopedic referral of patients with Achilles tendon rupture is necessary to determine the appropriate management. Regardless, on discharge from the ED, for surgical or conservative management, the patient is placed in a walking boot with maximal heel lift, or in a posterior or anterior slab with the foot plantarflexed in a full equinus position.

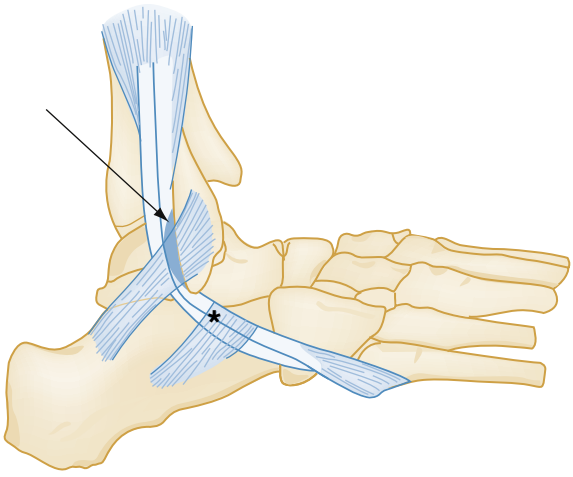

Fig. 49.11 Locations of the superior (*arrow*) and inferior peroneal retinaculum (*star*) in relation to the fibula and peroneal tendons.

Peroneal Tendon Dislocation or Rupture

Foundations and Clinical Features. The peroneal muscles are the primary evertors and pronators of the foot and also participate in plantar flexion. The peroneus longus and brevis tendons use the posterior peroneal sulcus (the fibular groove), located behind and underneath the lateral malleolus, as a pulley for their midfoot insertions. The peroneus brevis tendon inserts onto the tuberosity of the fifth metatarsal, and the peroneus longus tendon courses beneath the cuboid to insert onto the medial cuneiform and base of the first metatarsal. Injuries of the peroneal tendons include chronic overuse tendinopathy, tendon rupture, and tendon dislocation. The superior peroneal retinaculum (Fig. 49.11), a fibrous structure running from the distal fibula to the posterolateral aspect of the calcaneus, maintains the peroneal tendons against the fibular groove and, when ruptured, causes dislocation of the peroneal tendons.

Diagnostic Testing. Plain radiographs of the ankle may show the peroneal "fleck" sign, which can be confused for a simple avulsion fracture off the lateral aspect of the lateral malleolus but represents avulsion and tibial disruption of the superior peroneal retinaculum, considered pathognomonic for a superior peroneal retinaculum tear (Fig. 49.12).

Management. Peroneal tendon rupture, subluxation or dislocation should be clinically (see Table 49.2) or radiologically assessed and the patient referred to orthopedics on an urgent outpatient basis.

Tibialis Posterior Tendon Rupture

Foundations and Clinical Features. The tibialis posterior is primarily responsible for plantar flexion and inversion along the subtalar joint. Its tendon uses the posteroinferior surface of the medial malleolus as a pulley and inserts onto the navicular, medial cuneiforms, and bases of the second through fifth metatarsals. The peroneus brevis opposes the action of the tibialis posterior. With rupture of the tibialis posterior tendon, the peroneus brevis becomes unopposed, and the medial longitudinal arch loses its muscular support, leading to valgus deformity of the hindfoot and a unilateral flatfoot.

The mechanism of traumatic tibialis posterior rupture involves forced eversion. In addition to a unilateral flatfoot, pain and swelling on the medial aspect of the ankle are noted. Tenderness is present over the navicular, and the patient cannot perform a toe raise on the affected side. The patient with a tibialis posterior tendon rupture is also unable to invert the foot when it is in plantar flexion and eversion. With a unilateral flatfoot, an examiner standing behind the patient can see more toes on the lateral aspect of the affected side—a classic sign of tibial posterior rupture.

Fig. 49.12 Mortise x-ray view of the ankle showing a "fleck sign" (*arrow*) which represents an avulsion fracture and thus disruption of the superior peroneal retinaculum complex. (Courtesy Dr. Eric Giza.)

Diagnostic Testing. The diagnosis is generally made on a clinical basis. Plain radiographic films can exclude other bony pathology. Ultrasound can be used to confirm the diagnosis if clinical uncertainty exists.

Management. Urgent outpatient orthopedic consultation within a week is indicated for tibialis posterior tendon ruptures because surgical repair is often required.

Other Tendon Injuries

Injuries to the other tendons of the ankle are relatively rare and are outlined in Table 49.2. The tibialis anterior tendon is the primary dorsiflexor of the foot. It courses under the superior extensor retinaculum anterior to the medial malleolus and inserts onto the navicular, medial cuneiform, and base of the first metatarsal. The flexor hallucis longus tendon is responsible for flexion of the great toe and participates in plantar flexion of the foot. It courses behind the medial malleolus through a fibro-osseous canal and travels along the undersurface of the foot to insert onto the distal phalanx of the great toe. The extensor hallucis longus tendon travels anteriorly through the superior extensor retinaculum and inserts on the dorsal surface of the base of the distal phalanx of the hallux.

FOOT

FOUNDATIONS

Anatomy, Physiology, and Pathophysiology

The foot is composed of 28 bones and 57 articulations (Fig. 49.13), which can be divided into three anatomic and functional regions—the hindfoot (talus and calcaneus), the midfoot (navicular, cuboid, and cuneiforms),

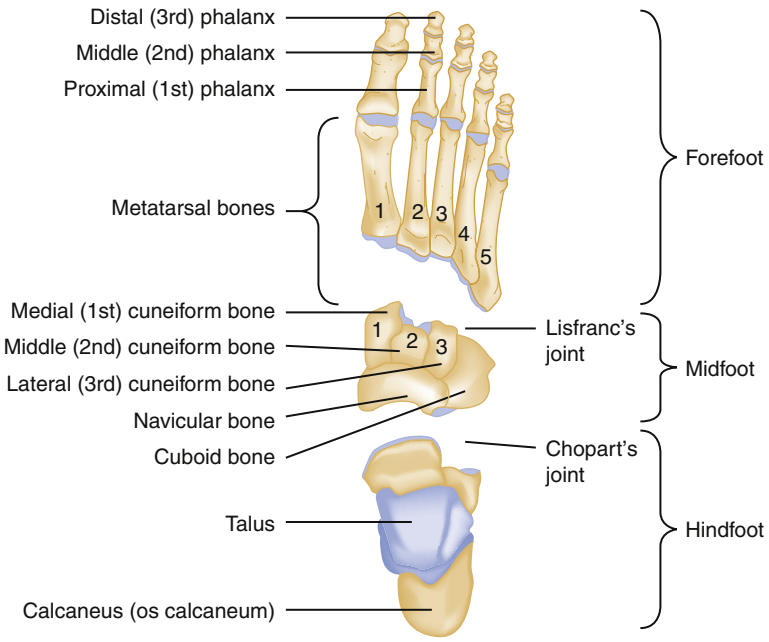

Fig. 49.13 Bones and joints of the foot.

and the forefoot (metatarsals, phalanges, and sesamoids). The midtarsal, or *Chopart joint*, connects the hindfoot to the midfoot. The tarsometatarsal, or *Lisfranc joint*, connects the midfoot and forefoot. The subtalar joint, comprised of three articulations between the talus and calcaneus, is another clinically important joint. Inversion and eversion of the hindfoot occur primarily through the subtalar joint, adduction and abduction of the forefoot through the midtarsal joints, and flexion and extension through the metatarsophalangeal (MTP) and interphalangeal (IP) joints.

The bones of the foot interlock to form a complex system of arches and beams tethered by ligaments and intrinsic muscles. Extrinsic muscles originating in the lower leg are responsible for most of the foot's movements. The course and insertion of these extrinsic muscles are important in their actions and association with specific avulsions and injuries. The arterial supply to the foot is from the anterior and posterior tibial arteries as well as the peroneal artery, a proximal branch of the posterior tibial artery. Motor and sensory innervation comes from branches of the deep and superficial peroneal, posterior tibial, saphenous, and sural nerves.

Clinical Features

In the setting of foot injury, an accurate history, including the mechanism of injury, timing, and duration of symptoms is important. The location of pain, along with a description of its quality, duration, and precipitants, focuses the differential diagnoses. A history of underlying medical conditions, medications, and previous foot problems provides additional key information.

The physical examination of the foot begins, if possible, with observation of gait and proceeds with assessment of the foot in its position of rest, normally one of slight plantar flexion and inversion. Swelling, deformity, ecchymosis, open wounds, color, and temperature should be noted. Precise localization of pain or crepitus, when not precluded by swelling, is valuable and guides further diagnostic testing when indicated. The entire foot should be methodically palpated, paying particular attention to commonly injured areas. Complete assessment includes a detailed neurovascular examination.

In some situations, evaluation of active and passive range of motion is indicated. Subtalar motion is evaluated by holding the lower leg with one hand and the heel with the other. Then, with the foot in a neutral position, the heel is inverted and everted. Normal range is 5 to 20 degrees of eversion and 5 to 40 degrees of inversion although there is substantial individual variability. Midtarsal motion is evaluated by stabilizing the heel while the other hand grasps the forefoot. There should be at least 20 degrees of adduction and 10 degrees of abduction.

Forefoot motion is evaluated by flexing and extending the MTP and IP joints individually. The first MTP joint has a particularly wide passive range of motion, with 45 degrees of flexion and 70 to 90 degrees of extension. Throughout the physical examination, findings can be compared with those of the opposite uninjured foot.

Differential Diagnoses

When formulating the differential diagnoses for injuries to the foot, it is useful to categorize these by anatomic location, mechanism of injury, and chronicity of symptoms. It should be noted that because the foot is an intricate anatomic structure with several interlocking bones and complex ligamentous attachments, it is important to consider a broad differential in the assessment. There is substantial overlap of the differential diagnoses both within, and between anatomic regions. Table 49.3 outlines differential diagnoses by anatomic region.

Diagnostic Testing

A complete plain radiographic evaluation of the foot consists of three standard views. The lateral view gives the best imaging of the hindfoot and soft tissues, whereas the anteroposterior and oblique projections allow assessment of the midfoot and forefoot. Certain specialized plain radiographic views may be considered when clinical concern exists in specific cases. Two commonly utilized "special views" include the Harris, or calcaneus, view when a calcaneus fracture is suspected, or weightbearing images in the case of suspected ligamentous Lisfranc injury. It should be noted that, in many cases, CT imaging has supplanted the utility of these special or focused views.

Accessory ossification centers are found in 30% of the population and may complicate interpretation of plain radiographs. On radiographs, these accessory bones are differentiated from fractures by their smooth corticated surfaces and with comparison radiographs of the

TABLE 49.3 Differential Diagnoses for Acute Traumatic Foot Injuries and Low Energy/Soft Tissue Injuries

Acute Traumatic/High Energy Injuries

Hindfoot		
Talus	Major fractures	Talar head fractures
		Talar neck fractures

	Neuropathies
	Cellulitis
	Neoplasm (sarcoma/soft tissue sarcoma)

opposite foot, although such variants are not inevitably bilateral. The most commonly seen accessory bones are the os trigonum, os tibiale externum (also called an accessory navicular bone), os peroneum, and os vesalianum. Accessory bones themselves can also fracture or cause pain syndromes which should be considered and assessed in the appropriate clinical context.

Plain radiography has limitations in the assessment of foot and ankle injuries. In the foot, overlapping bones and complex articulations can make images difficult to interpret. CT imaging is an invaluable tool for further assessment of many injuries to the foot, in particular to the midfoot, calcaneus, subtalar joint, and tarsometatarsal (Lisfranc) joint complex.

Advanced imaging, including MRI, ultrasound, and bone scanning, are useful for the diagnosis of certain foot injuries. However, these tests are rarely indicated in the emergent evaluation of foot injuries. As in the case of ankle injuries, such tests can be arranged following consultation with orthopedic, sports medicine, or radiology specialists.

MRI has a role in the diagnosis of ligamentous and soft tissue injury but also has value for identifying stress fractures and cartilaginous injury, such as talar dome osteochondral lesions. A common indication for MRI in foot injury would be in the assessment of suspected ligamentous Lisfranc injury, although weightbearing plain radiographs are advocated as an economical alternative when feasible.[15] In the case of stress fractures, MRI has comparable sensitivity and better specificity than bone scanning and has emerged as the imaging modality of choice.

Radionuclide imaging (bone scanning) can be useful for evaluating unexplained foot pain or pain in athletic injuries. CT-SPECT overlays bone scanning with more detailed anatomic information provided by CT imaging to improve localization of lesions. This specialized technique is useful in the diagnostic algorithm for a number of foot disorders, including osteochondral lesions, stress fractures, and osteomyelitis.

Ultrasonography also has utility in diagnosing soft tissue and tendinous injuries. In the foot, the assessment of plantar fascia pain is an example where ultrasound plays an important diagnostic role. Ultrasound has been studied in the assessment of Lisfranc injuries and foot fractures,[16] however, to date, has not been shown to supplant more conventional imaging.

SPECIFIC PATHOLOGIC CONDITIONS

This section covers the major fractures and dislocations seen in the foot, progressing anatomically from the hindfoot through to the forefoot.

Hindfoot Injuries

The hindfoot includes the talus and calcaneus. Injuries to the hindfoot can masquerade as other injuries, including ankle sprains. Attention to the history and physical exam as well as appropriate imaging, when indicated, is critical.

Differential Diagnoses

Differential diagnoses for acute, traumatic injuries to hindfoot structures include fractures to the talus and the calcaneus as well as fractures and ligamentous injuries affecting the midtarsal (or Chopart) joint (see Table 49.3). The calcaneus is the most commonly fractured of the tarsal bones, with fractures generally occurring following falls from height. Fractures to the talus can be differentiated by anatomic region of the talus, and most often occur from falls or forces resulting in dorsiflexion of the foot. In general, fractures to the calcaneus and talus should be considered high-energy fractures, although fractures do occasionally occur with less forceful mechanisms. The talus, in particular, is susceptible to a number of minor, lower-energy fractures such as a lateral process fractures, dorsal lip and talar dome fractures, which may result from mechanisms similar to those seen with ankle sprains. More subtle ligamentous injuries, such as those to the midtarsal (Chopart) joint should be considered in mechanisms of twisting, forced plantar flexion, or forced dorsiflexion.

The hindfoot is also prone to a number of nonacute conditions including stress fractures. A history suggestive of a more insidious pattern of pain should also make one consider other soft tissue pathology such as plantar fasciitis, fat pad syndrome, tarsal tunnel syndrome, Achilles tendinopathy, Achilles enthesitis, or retrocalcaneal bursitis.

Talar Fractures

Anatomy, Physiology, and Pathophysiology. The talus is a complex structure with articular cartilage covering 60% of its surface. It has no muscular attachments and is held in place with ligamentous attachment and by the medial and lateral malleoli. The talus can be divided anatomically into three regions—the head, which articulates with the navicular and calcaneus; the body, which articulates with the tibia, fibula, and calcaneus; and the neck, which connects the head and body. The neck is the only region that is predominantly extraarticular. The anterior width of the talus is greater than the posterior, causing it to be less stable and more prone to dislocation when the foot is plantarflexed.

The blood supply to the talus is from the anterior tibial artery, the posterior tibial artery, and a perforating branch of the peroneal artery. The talar head is supplied by branches of the dorsalis pedis and from the artery of the tarsal sinus. Vessels enter from three sites, all of which can be disrupted by fractures or dislocations, putting the talus at risk of avascular necrosis.

Clinical Features. Talar fractures range from obvious fractures to subtle injuries requiring special imaging for diagnosis. There is generally a history of a twisting injury, fall, or high-energy impact. Both dorsal swelling and tenderness over the talus are characteristic findings. Although ankle motion may be preserved, inversion and eversion of the hindfoot often are painful.

Talar fractures are described according to anatomic location into fractures of the neck, body, and the head. Talar fractures can also be divided into minor or major fractures.

Minor fractures of the talar body include fractures of the lateral and posterior processes, and osteochondral fractures of the talar dome. These fractures do not traverse the central portion of the talar body. Dorsal avulsion fractures of the talar neck and head are also classified as minor fractures.

Major fractures of the head, neck and talar body are fractures that traverse the central portion of the bone. These are often high energy fractures and care must be taken to exclude associated traumatic injuries.

Talar Neck Fractures. Talar neck fractures account for 50% of all talus fractures. With the exception of dorsal avulsion fractures, talar neck fractures are high-energy injuries that most commonly result from extreme dorsiflexion as generated in falls or MVCs. Associated fractures are common, usually an oblique or vertical fracture of the medial malleolus. Other associated injuries include calcaneal fractures and vertebral compression fractures which are common in other high energy, axial load type injury patterns.

Major fractures of the talar neck have a high incidence of complication, the most significant of which is avascular necrosis. Patient outcomes depend on the degree of anatomic reduction attained and preservation of the vascular supply. Other potential complications include skin infection, skin necrosis, posttraumatic arthritis, malunion, delayed union, nonunion, and predisposition to peroneal tendon dislocation.[17]

The *Hawkins classification* grades talar neck fractures by displacement and associated subluxations (Fig. 49.14):

- Type 1 fractures are nondisplaced.
- Type 2 fractures are displaced vertical fractures, with subtalar joint subluxation.
- Type 3 fractures, 50% of which are open, involve a vertical talar neck fracture, with subluxation of the subtalar and tibiotalar joints.
- Type 4 fractures, which are uncommon, involve distraction of the subtalar, tibiotalar, and talonavicular joints.

This classification system guides treatment and correlates with the incidence of osteonecrosis and subtalar arthritis. A recent meta-analysis reported osteonecrosis rates of 10%, 27%, 53%, and 48% for types I through IV respectively. The rate of subtalar arthritis approached 80% in studies with over two years of follow up.[17]

Talar Head Fractures. Talar head fractures make up 10% of all talar fractures. Their mechanism is an axial compressive force applied

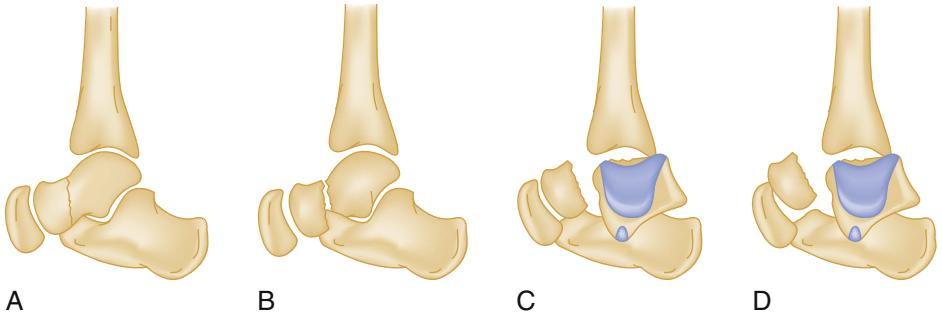

Fig. 49.14 Hawkins classification of talar neck fractures. (A–D) Hawkins tendons. *Shading* indicates the articular surface of the talar dome.

on a plantar-flexed foot and transmitted up through the talonavicular joint. Comminution is common and associated navicular fractures can occur, further disrupting the talonavicular articulation. Avulsion fractures of the dorsal talar head are rare and may extend into the talar body. These are minor fractures that occur from similar mechanisms to ankle sprains.

Talar Body Fractures. Major talar body fractures are uncommon and usually result from falls with axial compression of the talus, between the tibial plafond and calcaneus. These fractures traverse the central portion of the talar body and are typically intraarticular, involving the ankle and subtalar joints.

Minor talar body fractures include fractures of the lateral and posterior processes as well as osteochondral talar dome fractures. Lateral process fractures, sometimes referred to as "*snowboarder fractures*" result from forced dorsiflexion and inversion and have been described in other sports as well as from motor vehicle collisions and other high-energy mechanisms.

Up to 40% of lateral process fractures are missed on initial presentation, with ankle sprain being the most common alternative diagnosis, and hence other differential diagnoses are important to consider (Table 49.3). Posterior process fractures result from forced plantar flexion and present with pain and swelling in the hindfoot. Fractures of the posterior talar process need to be distinguished from an os trigonum, which is a normal accessory bone that can be found in 10% of the population. Osteochondral lesions of the talar dome, which are also considered minor fractures, can cause significant morbidity. These injuries result from the same mechanism as ankle sprains and often present in a delayed fashion as recurrent swelling and pain in the ankle joint.

Diagnostic Testing: Radiology. When talar fractures are clinically suspected, initial imaging should include standard foot and ankle radiographs. This series will usually identify fractures of the talar head, body, and neck (Fig. 49.15). The anterior and oblique ankle projections show talar alignment within the mortise, and the lateral projection shows the talar neck and alignment of the posterior aspect of the subtalar joint. Plain radiographs, however, have been shown to have a sensitivity of only 75%, although most missed fractures are minor. In addition, plain radiographs may underestimate fracture severity, particularly with respect to the degree of articular involvement. CT improves the reliability of classification and provides additional information in 90% of talar fractures. For this reason, a CT scan is recommended in addition to plain radiographs when a fracture is either identified or highly clinically suspected. Minor talar fractures may also be difficult to identify on plain radiographs. CT imaging may be considered when minor talar body fractures are clinically suspected and cannot be identified on carefully assessed plain radiographs.

Management. Talar neck fractures have a significant risk of long-term morbidity and require precise reduction. Type 1 fractures, which are nondisplaced, are the only talar neck fractures amenable

Fig. 49.15 Fracture of the talar neck (*arrow*). (Courtesy Dr. Thomas J. Green.)

to nonoperative treatment, with at least 6 weeks of nonweightbearing in a cast. Close outpatient orthopedic follow-up is required. Hawkins types 2 to 4 fractures, or talar neck fractures with any displacement, are managed surgically although often in a delayed fashion to allow for reduction of swelling. In the case of significantly displaced fractures, particularly if associated with neurovascular or cutaneous compromise, orthopedics should be consulted from the ED and emergent closed reduction should be attempted.

The treatment of talar head and body fractures is controversial and should be made by orthopedic consultants. Displaced fractures and fractures involving a significant degree of the articular surface are managed surgically. Nondisplaced fractures may be managed in a nonweightbearing cast, although some orthopedic surgeons advocate for operative repair due to the large articular surface requiring precise anatomic alignment. In the ED, assuming adequate control of pain and swelling, patients can be made nonweightbearing and immobilized in a well- padded, noncircumferential splint. Urgent, outpatient orthopedic consultation should be arranged for these types of fractures within 48 hours.

In general, minor talar fractures are treated conservatively. Treatment of lateral and posterior process fractures is dependent on the size, displacement, and comminution of the fragments. Displaced or comminuted lateral process fractures require operative fixation because of

their articular involvement. Minor fractures with fragments larger than 5 mm in diameter may require excision. The decisions for operative or conservative management are best made by orthopedic consultation. Depending on the amount of swelling, patients should be made nonweightbearing, and placed in a below-knee cast or posterior splint. Minor dorsal avulsion fractures of the head or neck are managed symptomatically and do not require immobilization.

Disposition. With the exception of minor dorsal avulsion fractures, all talar fractures should be managed by orthopedics. In the case of major fractures, with high-energy mechanisms, careful attention must be paid to rule out associated injuries. Nondisplaced talar neck fractures (type 1) are amenable to outpatient management. Patients in whom pain and swelling has been controlled should be nonweightbearing and immobilized in a padded noncircumferential short leg splint with orthopedic follow-up arranged in 24 to 48 hours. Patients with displaced talar neck fractures (types 2 to 4) should have orthopedic consultation in the ED. In cases where anatomic reduction has been achieved, outpatient follow-up can be arranged by orthopedics after consultation. In many cases, delayed operative repair is preferred.

Patients with talar head and body fractures as well as lateral process fractures require orthopedic consultation. If pain and swelling has been adequately controlled, outpatient referral is reasonable. Patients with these fractures can be splinted for urgent orthopedic evaluation within 48 hours. Minor avulsion fractures of the dorsal talar neck and head can be treated conservatively, similarly to ankle sprains, with weightbearing as tolerated and follow-up with primary care.

Osteochondral Lesions

Foundations. Osteochondral lesions of the talar dome warrant special mention. These talar body injuries are defects of the articular cartilage and often include subchondral bone. Although the incidence varies by study, osteochondral lesions are estimated to occur in 10% to 15% of ankle fractures using CT imaging to identify lesions[18,19] and in up to 40% of displaced fractures undergoing operative repair.[20] Using MRI following acute ankle sprain without fracture, osteochondral lesions were found in 8% of ankles, although older studies have suggested a much higher incidence.

Clinical Features. An osteochondral lesion should be considered in any patient with an acute ligamentous ankle injury with a joint effusion. Most lesions that result from ankle sprains are not diagnosed at the time of injury, but rather present with persistent pain and recurrent effusions (see Box 49.2). Physical findings usually are nonspecific, although tenderness over the posteromedial talus and increasing pain with exertion, weightbearing, or passive plantar flexion may be noted. Standard view radiographs are commonly normal in appearance or show subtle and easily overlooked abnormalities (Fig. 49.16).

Differential Diagnoses. Differential diagnoses of osteochondral lesions include those items outlined in Box 49.2.

Diagnostic Testing. Plain radiography can identify significant osteochondral defects, although CT is useful in identifying occult osteochondral lesions. However, more advanced imaging, most commonly MRI, is often necessary. Advanced imaging such as this can be arranged at the time of outpatient consultation.

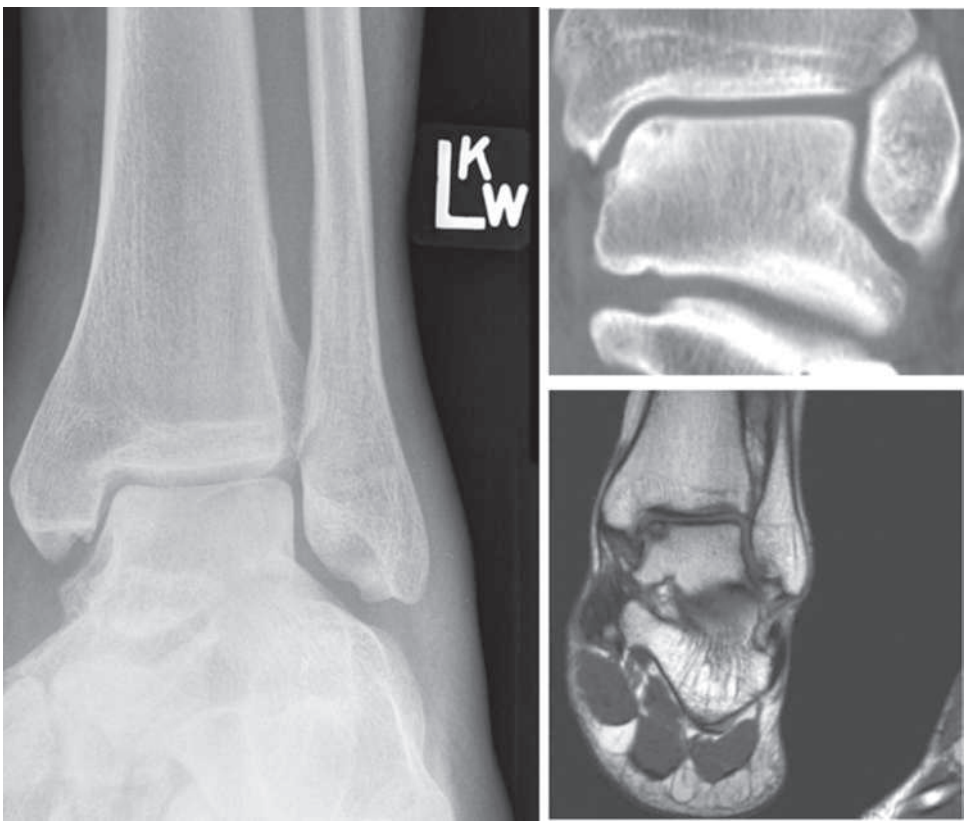

Fig. 49.16 (A) Mortise view of an ankle fails to identify an osteochondral lesion in a patient with recurrent effusions and ongoing pain following a sprain. (B) CT scanning identifies the suspected lesion. (C) Similar lesion in a different patient demonstrates the value of MRI in making the diagnosis. ((A & B) courtesy Dr. Thomas J. Green; (C) Adapted from Frost A, Roach R. Osteochondral injuries of the foot and ankle. *Sports Med Arthrosc Rev*. 2009;17:187.)

Management and Disposition. When an acute osteochondral lesion is confirmed or suspected, patients are best managed with outpatient orthopedic or sports medicine specialist consultation. The exception is with large, displaced fragments for which orthopedics should be consulted emergently.

Low-grade and minimally symptomatic osteochondral lesions are amenable to a trial of conservative therapy in a protective boot. Although there are many management options, higher grade lesions are often managed surgically. Patients with higher grade symptomatic lesions should be made nonweightbearing and can be placed in a splint for comfort.

This discussion underscores the importance of detailed discharge instructions following diagnosis of an ankle sprain. Patients with persistent swelling and pain or inability to return to function beyond the expected 2 to 4 weeks should be advised to seek follow-up with a primary care physician.

Subtalar Dislocations

Pathophysiology. Subtalar dislocation, also called peritalar dislocation, is the simultaneous disruption of the talocalcaneal and talonavicular joints, without disruption of the tibiotalar joint. This occurs when the talonavicular and talocalcaneal ligaments rupture while the stronger calcaneonavicular ligament remains intact. Subtalar dislocations are rare and are classified by the direction that the foot takes in relation to the talus. Medial dislocations are most common, with lateral, anterior or posterior occurring rarely. Ten percent of subtalar dislocations are open and associated fractures are present in 50% of cases. Isolated dislocation of the calcaneus is an exceptionally rare event distinct from subtalar dislocation; it involves disruption of the talocalcaneal and calcaneocuboid articulations.

Clinical Features. Obvious deformity is typically present, often with skin tension on the side opposite the direction of dislocation. Neurovascular status should be carefully assessed, although it is rarely compromised. Although serious complications, such as AVN, are uncommon in cases of closed subtalar dislocation, most patients have long-term limitation of subtalar motion, a sequela that can affect their gait.

Diagnostic Testing. Although standard foot radiographic views are diagnostic, properly positioning the patient for them may be difficult. The single most helpful radiograph is an anteroposterior view of the foot, which will demonstrate the talonavicular dislocation. Subtalar dislocations are frequently associated with fractures that may be difficult to detect on plain radiographs. Following reduction of the deformity, CT scanning should be considered.

Management. Subtalar dislocations require emergent reduction. Most closed subtalar dislocations can be treated with closed reduction with procedural sedation in the ED, although some patients require general anesthesia. Closed reduction is performed by flexing the knee and applying longitudinal traction to the foot with initial accentuation, followed by reversal of the deformity, using eversion for medial dislocations and inversion for lateral dislocations. Sometimes, direct pressure over the head of the talus aids in reduction. In some cases, buttonholing of the talus through the extensor retinaculum, entrapment in the peroneal tendons, or associated fractures can make closed reduction virtually impossible. After reduction, immobilization in a below-knee cast for 4 to 6 weeks is indicated. Orthopedics may elect to manage grossly unstable injuries that have been reduced with Kirschner (K) wire fixation.

Disposition. Emergent orthopedic consultation is indicated for subtalar dislocations.

Pantalar Dislocation

Pantalar or total talar dislocation is a rare and devastating injury requiring emergent orthopedic consultation in the ED. These injuries are the result of extreme forces that cause simultaneous disruption of the subtalar, tibiotalar, and talonavicular joints. Most are open fractures and infection and AVN are common complications.[20a]

Calcaneal Fractures

Anatomy and Pathophysiology. *The calcaneus is the largest and most commonly fractured tarsal bone*. It articulates superiorly with the talus (forming the subtalar joint) and anterolaterally with the cuboid.

Calcaneus fractures most often occur as a result of a fall from a height and from traffic accidents.[21,22] They are often high-energy injuries and frequently occur in association with other injuries, most importantly with vertebral fractures in up to 8% of cases.[22] Up to 5% of calcaneus fractures are open.[23] Calcaneus fractures can have serious short- and long-term sequelae. Compartment syndrome, historically thought to complicate up to 20% of fractures, has recently been identified in 5% of fractures. Unfortunately, the diagnosis of compartment syndrome is often made late, after development of sequelae, likely because the pain of the fracture itself masks early signs of compartment syndrome.[23] The degree of comminution is most predictive of risk of compartment syndrome. Other common complications include infection, chronic heel pain, posttraumatic arthritis, and hindfoot deformity. The inability to return to work or wear normal shoes are also common complications. Calcaneus fractures are classified as intraarticular, which involve the subtalar joint, or extraarticular.

Intraarticular Calcaneal Fractures. These are more serious and more common, accounting for up to 75% of calcaneal fractures. Classification systems used to describe intraarticular fractures are complex and more relevant to orthopedic consultants for guiding treatment planning and for prognosis. The commonly used classification systems have suffered poor interobserver reliability, although CT scanning has improved reliability.

Extraarticular Calcaneal Fractures. These include fractures of the anterior process, *sustentaculum tali*, lateral and medial calcaneal processes, peroneal tubercle, and tuberosity and extraarticular fractures of the calcaneal body. Isolated calcaneal tuberosity fractures are rare and occur as a result of avulsion by the Achilles tendons. However, these fractures deserve particular attention because displacement can compromise the skin overlying the Achilles tendon.

Clinical Features. Physical examination reveals pain, swelling, and tenderness over the heel. Weightbearing on the hindfoot is usually impossible. Ecchymosis may extend over the entire sole, and the heel may appear deformed, shortened, widened, or tilted. Particular attention should be given to the assessment for compartment syndrome, as well as to tension in overlying skin.

Differential Diagnoses. Please refer to Table 49.3 for differential diagnoses of extraarticular calcaneal fractures.

Diagnostic Testing. In the case of a suspected calcaneus fracture, initial radiographic imaging should include a foot series with the addition of an axial calcaneal view, also known as a *Harris view*. The anteroposterior view shows the calcaneocuboid joint and anterosuperior calcaneus, whereas the lateral view shows the posterior facet and can demonstrate compression of the calcaneal body. The Harris view is an additional axial projection of the calcaneal tuberosity, subtalar, and sustentaculotalar joints (Fig. 49.17).

The lateral X-ray allows for two important assessments: determination of involvement of the subtalar joint and evaluation of the degree of depression of the posterior facet by calculation of the *Boehler angle* (Fig. 49.18). Assessment of the Boehler angle can help identify

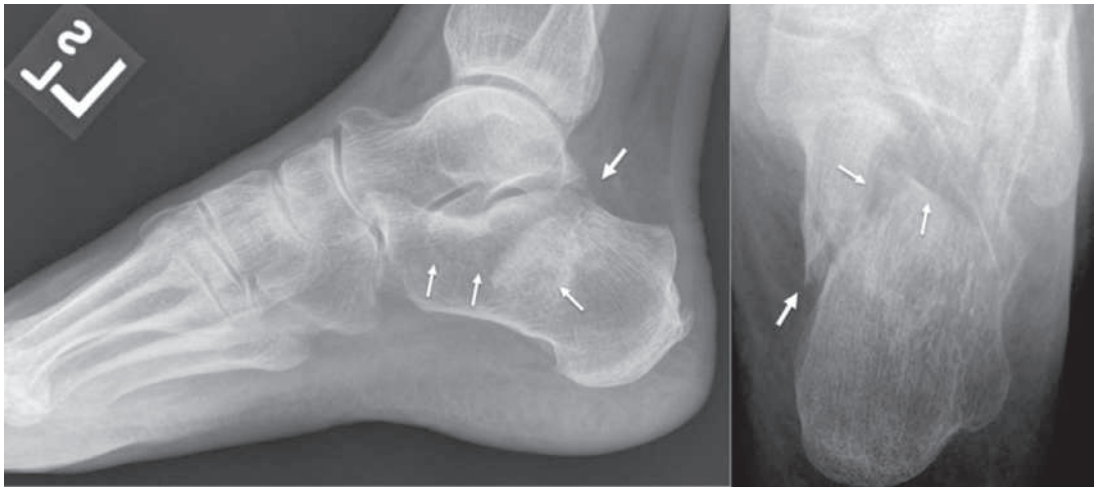

Fig. 49.17 (A) Lateral view of a comminuted fracture of the body of the calcaneus (*arrows*). (B) Axial or Harris view of the same fracture. (Courtesy Dr. Thomas J. Green.)

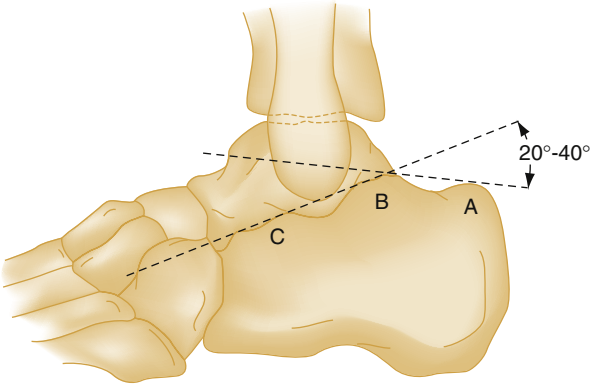

Fig. 49.18 Boehler angle is obtained by measuring the angle formed by two lines, one between the posterior tuberosity (A) and apex of the posterior facet (B) and the other between the apex of the posterior facet (B) and apex of the anterior process (C). Although several ranges for this measurement have been cited, an angle of 20 to 40 degrees gives the best diagnostic performance for fracture detection. An angle of less than 20 degrees suggests a compression fracture; comparison measurement of the uninjured side is helpful in questionable cases.

compression that may not be obvious, and is also prognostic of long-term functional outcome.[24]

Findings on plain radiographs can be subtle. CT imaging should be performed when fracture is highly suspected but is not identified on initial assessment. CT imaging also provides valuable information for classification, prognosis, and treatment planning. When an intra-articular fracture is identified on plain film, a CT scan should be performed.

Management. Emergency evaluation includes careful assessment for associated injuries, particularly vertebral fractures. Adequate pain control, splinting in a well-padded, compressive, noncircumferential splint, and careful clinical assessment for compartment syndrome are the mainstays of emergency care for calcaneus fractures. The decision to manage intraarticular or displaced calcaneal fractures operatively or conservatively must be made in consultation with an orthopedic surgeon and is frequently made on a case-by-case basis. In general, research does not support intervention for the majority of intraarticular fractures.[22,25,26] When operative repair is indicated for closed fractures, it is often best performed on a delayed basis, after resolution of swelling. In general, the goal of operative management is to reestablish both joint congruity and the Boehler angle by elevating depressed fractures. Operative repair is also indicated for open fractures, as well as those with neurovascular, skin, and soft tissue compromise. Emergent orthopedic consultation is indicated for patients in which compartment syndrome is a consideration.

Extraarticular fractures are most commonly treated nonoperatively. The emergency management of these fractures should include immobilization in a well-padded splint.

Calcaneal tuberosity, also known as tongue-type fractures, deserve special mention. These fractures, which may be intraarticular, are the result of avulsion at the Achilles insertion. Displacement may compromise overlying skin. In such cases, emergent orthopedic consultation is indicated. Nondisplaced tuberosity fractures may be placed in a nonweightbearing cast with the foot in slight plantar flexion.

Disposition. All patients with intraarticular calcaneal fractures, or fractures that compromise overlying skin or soft tissue, warrant orthopedic consultation in the ED. Compartment syndrome has been described as a complication to lower severity calcaneal fractures and as such orthopedics may decide to observe the patient for a period of time.[23] Conversely, in cases where pain and swelling is controlled and the risk of compartment syndrome is deemed unlikely, orthopedics may elect to discharge the patient for outpatient follow-up. In this case, the patient should be immobilized in a well-padded splint, made nonweightbearing, and given specific instructions on indications to return.

In general, nondisplaced extraarticular fractures have lower morbidity and benefit from symptomatic or conservative therapy. Outpatient orthopedic follow-up in the next 48 hours should be arranged, patients should be made nonweightbearing, and can be discharged with a compressive soft dressing or splint.

Midtarsal Joint Injuries

Foundations and Clinical Features. The midtarsal joint (*Chopart joint*) is comprised of the talonavicular and calcaneocuboid joints. Injury in this area is uncommon, occurring four times less frequently than injuries to the Lisfranc joint.[27] Falls, including those on stairs, and sports injuries are the most frequent causes of midtarsal joint injury.[27] Midtarsal joint injuries usually result from forced dorsiflexion and often are associated with other fractures. Pain, swelling, inability to bear weight, and tenderness over the midtarsal joint are usual findings. The possibility of a midtarsal joint injury should be

considered with any isolated midfoot fracture, particularly those of the navicular tuberosity. Complications of midtarsal (Chopart joint) injuries are common and include persistent pain, arthritis, and long-term disability.

Differential Diagnoses. Refer to Table 49.3 for a list of differential diagnoses of midtarsal joint injuries.

Diagnostic Testing. Although standard radiographs are often abnormal, the diagnosis frequently is overlooked or delayed, with symptoms ascribed to an ankle sprain (see Box 49.2). CT imaging is useful in identifying occult fractures around the midtarsal joint. In some cases, advanced imaging such as MRI may be helpful, although this can be arranged at the time of orthopedic follow-up.

Management and Disposition. Nondisplaced injuries may heal with casting, but operative fixation is often required. Orthopedic consultation in the outpatient setting is important when midtarsal injuries are identified or even when clinically suspected. Patients should be made nonweightbearing and follow-up arranged.

Nontraumatic Hindfoot Pain

Clinical Features

Hindfoot pain is a common complaint that more often is the result of overuse rather than trauma. History should elicit prior injury, with attention paid to patterns of activity and overuse, as well as a review of relevant medical history and whether pain is acute or chronic in onset. The plantar fascia is a tough layer of the sole that is functionally significant during foot strike and the early stance phase of walking. Plantar fasciitis typically presents with difficulty ambulating and pain with activity. Pain is classically felt on first weightbearing either in the morning or after prolonged sitting. Tenderness is noted at the calcaneal insertion.

Plantar fascial rupture is a tear of the origin of the plantar fascia at the calcaneus. This injury usually occurs during the push-off phase of gait. Swelling may be noted, and typically pain is elicited by passive dorsiflexion of the hallux.

Differential Diagnoses

See Table 49.3. Bone pain in the hindfoot necessitates consideration of calcaneal or talar stress fractures. A calcaneal stress fracture may be suspected when pain is elicited on squeezing the calcaneus mediolaterally.

With subcalcaneal heel pain, plantar fasciitis is the most common diagnosis. Differential diagnoses also include calcaneal fat pad atrophy, acute rupture of the plantar fascia, lateral plantar nerve compression, and tarsal tunnel syndrome.

Many tendons course through the hindfoot, particularly anteromedially, and tendinitis can occur (see Fig. 49.3 and Table 49.2). Other tendon pathologic conditions (e.g., ruptures, dislocations, retinacular injuries) should be considered because they can result in significant functional disability.

Diagnostic Testing

Plain radiographs are of limited diagnostic value for hindfoot pain although are usually necessary to rule out other bony pathology. Although MRI is the most useful diagnostic tool in the context of nontraumatic hindfoot pain, ultrasound (plantar fasciitis) and CT-SPECT (stress fractures) also have diagnostic utility. However, for many of these subacute nontraumatic hindfoot injuries, the diagnosis is clinical and the decision for advanced imaging may be at the discretion of the orthopedic consultant.

Management

Although there are several options for treatment of plantar fasciitis, the mainstays of management include activity and footwear modification, stretching, NSAIDs, and physiotherapy. Primary care follow-up is sufficient.

Treatment of plantar fascia rupture is generally nonsurgical, often with a period of cast immobilization for symptomatic relief. These patients generally benefit from referral to orthopedics or sports medicine on a nonurgent basis for guidance.

Midfoot Injuries

The midfoot (navicular, cuboid and cuneiforms) is an inherently stable region of the foot and is infrequently injured. Fractures and relationships of the midfoot tarsals are difficult to visualize on standard radiographic views. A compounding factor is that pain associated with midfoot injuries may be ill-defined and poorly localized. Although isolated fractures of the midfoot tarsals occur, associated injuries, including metatarsal fractures, subluxations, and spontaneously reduced tarsometatarsal dislocations, may be present.

Differential Diagnoses

The differential diagnoses of acute traumatic injuries of the midfoot includes fractures to the navicular, cuneiform bones, and the cuboid, as well as injuries to the Lisfranc joint (see Table 49.3). When considering the differential diagnoses, mechanism of injury is essential to narrow down the list of considerations. Specifically, one should consider whether the injury occurred from a high- or lower-energy trauma. This is particularly the case when Lisfranc injury is clinically suspected.

Midfoot bones, the navicular bone in particular, are prone to stress fractures, which should be considered in cases of insidious onset of pain. Soft tissue structures including the plantar fascia also traverse the midfoot and may be a cause of more chronic or nontraumatic pain.

Navicular Fractures

Anatomy. The navicular forms the supporting structure for the medial arch of the foot and bears most of the load within the tarsal complex during weightbearing. The navicular tuberosity is an insertion point for the tibialis posterior tendon. Because of the navicular's extensive articular surface, its blood supply enters only through a small waist of cortex, leaving the middle third relatively avascular and therefore at risk for avascular necrosis.

Pathophysiology. Navicular fractures are classified as dorsal avulsion fractures, tuberosity fractures, and body fractures. Fractures of the body are classified according to direction of the fracture line and disruption of surrounding joints, but classification to this detail is beyond the scope of this chapter. Stress fractures do occur in the navicular and although uncommon, carry a high risk of morbidity often related to misdiagnosis and subsequent fracture with nonunion.

Clinical Features. Navicular fractures cause localized tenderness over the dorsal and medial aspects of the midfoot. The navicular tuberosity is palpated anterior to the *sustentaculum tali*, a shelf of bone on the medial ankle approximately 2.5 cm below the tip of the medial malleolus. In the case of tuberosity fractures, pain may be exacerbated by passive eversion or active inversion of the foot. Navicular tuberosity fractures can be complicated by nonunion. Avascular necrosis and arthritis are potential late sequelae, particularly in displaced body fractures.

Differential Diagnoses. See Table 49.3. The *os tibiale externum* is an accessory bone present in approximately 10% of the population and it is not uncommon to confuse this with an acute fracture.

Diagnostic Testing: Radiology. Although standard foot radiographs usually identify navicular fractures, advanced imaging with CT may be necessary. This is particularly the case for patients with high-energy or complex foot injuries, for which the sensitivity of plain radiography is poor.

Management. Nondisplaced dorsal avulsion fractures can be treated symptomatically. Displaced dorsal avulsion fractures, or those involving more than 25% of the talonavicular joint surface may be

treated surgically. Navicular body and tuberosity fractures should be treated with the guidance of orthopedics. These fractures can have long-term complications and functional limitation. Nondisplaced fractures are amenable to treatment in a weightbearing cast, whereas displaced tuberosity and body fractures are managed surgically.

Disposition. The majority of navicular fractures are suitable for outpatient orthopedic referral. Nondisplaced dorsal avulsion fractures involving less than 25% of the articular surface are treated symptomatically with a compressive dressing. Nondisplaced body and tuberosity fractures should be splinted in a nonweightbearing splint, cast or boot with outpatient orthopedic follow-up within a week. Displaced tuberosity and body fractures as well as displaced or intraarticular avulsion fractures may be surgically managed. Assuming adequate pain control, these patients may be placed in a nonweightbearing splint and have orthopedic consultation arranged within 24 to 48 hours.

Cuboid Fractures

Cuboid fractures usually occur with other midfoot fractures, including Lisfranc injuries. Fractures are generally the result of avulsion or crush injury. The latter, known as a "*nutcracker fracture*," results from compression of the cuboid between the bases of the fourth and fifth metatarsals and calcaneus. These injuries may have associated with fractures of the posterior malleolus.

The cuboid is best evaluated by the oblique view of a standard foot radiographic series which demonstrates the calcaneocuboid and cuboid-metatarsal relationship. The possibility of Lisfranc injury should be considered with any cuboid fracture. Treatment of isolated injuries ranges from casting for minor nondisplaced fractures to operative fixation. Nondisplaced cuboid fractures are suitable for urgent outpatient orthopedic follow-up. A compressive dressing and splint are reasonable in the interim prior to consultation. Cuboid fractures associated with more significant injury or other fractures should have orthopedic consultation in the ED. Extraarticular cuboid fractures can be complicated by disruption of the peroneus longus tendon at the level of the peroneal groove.

Cuneiform Fractures

Fractures of the cuneiforms are extremely uncommon and usually result from direct trauma. As with cuboid fractures, the patient should be assessed carefully for the presence of a Lisfranc injury. Treatment usually is by casting; however, displaced fractures require orthopedic assessment.

Dislocations of the Navicular, Cuboid, and Cuneiforms

Isolated dislocations of each of the midfoot bones have been described. These uncommon injuries often require open reduction. Emergent orthopedic consultation is required for these injuries.

Lisfranc (Tarsometatarsal) Fractures and Dislocations

Anatomy. Lisfranc injuries refer to any fracture, dislocation, or ligamentous injury at the tarsometatarsal joint (*Lisfranc joint*). In concert, the tarsometatarsal joints act to allow supination and pronation of the forefoot. The Lisfranc joint is composed of the articulations of the bases of the first three metatarsals with their respective cuneiforms and bases of the fourth and fifth metatarsals with the cuboid. The stability of the Lisfranc joint is provided by the bony architecture and associated ligaments. The metatarsal bases form an arch, with the second metatarsal acting as the keystone. The Lisfranc ligament itself joins the medial cuneiform with the base of the second metatarsal and provides crucial structural support. Strong transverse intermetatarsal ligaments join the bases of the second through fifth metatarsals. The joint is further supported by dorsal and plantar ligaments, plantar fascia, and insertions of the tibialis anterior and peroneus longus tendons at the first metatarsal base (Fig. 49.19).

Physiology and Pathophysiology. Lisfranc injuries carry a significant risk of long-term disability resulting from arthritis, instability, foot deformity, and chronic pain. They arise from three mechanisms: rotational forces of the midfoot, axial loads of the foot, and crush injuries. Injuries to the Lisfranc joint complex can be thought of as high-energy injuries, such as occurring in MVCs, or low-energy injuries, such as those occurring in sports activities. Historically, these injuries were often described in equestrian riders who got their foot caught in the stirrup when falling from a horse.

High-energy injury usually results in fractures or fracture-dislocations, whereas low-energy injuries can result in isolated ligamentous injuries. Historically, low-energy mechanisms were thought to account for the minority of injuries but more recent evidence suggests that over 50% of injuries result from low-energy mechanisms.[27,28] Low-energy injuries are more likely to be primarily ligamentous, while high-energy injuries are much more likely to have associated foot, as well as non-foot, fractures.[29]

The most intuitive classification describes the direction of the dislocation in the horizontal plane (Fig. 49.19). In type A, or homolateral, injuries, all the metatarsals are displaced in one direction. In type B, or isolated, injuries, one or more metatarsals are displaced. In type C, or divergent, injuries, the metatarsals are splayed outward in the medial and lateral directions. Dorsal displacement is also commonly present in displaced Lisfranc injuries, whereas plantar displacement is uncommon because of the joint's bone architecture and strength of the plantar ligaments and fascia.

Low-energy Lisfranc injuries have been previously classified as stage 1 injuries, which are nondisplaced with low-grade strain, stage 2 injuries, in which a 2- to 5-mm diastasis exists between the first cuneiform and base of the second metatarsal, and stage 3 injuries, in which more than 5 mm of diastasis exists and there is loss of metatarsal arch height. Because of ligamentous attachments, Lisfranc injuries are frequently associated with metatarsal fractures, usually of the second metatarsal base. Fractures of the cuboid, cuneiforms, and navicular also are common, occurring in more than one-third of cases.

Clinical Features. The diagnosis of Lisfranc injury can be a challenge, particularly in the case of low-energy, isolated ligamentous injuries. Clinical and radiographic findings may be subtle, and the true extent of the pathologic condition can easily be missed or misdiagnosed. Seemingly trivial fractures, if viewed in isolation, may fail to reflect the extent of ligamentous disruption. Some have estimated the diagnosis is missed on initial presentation in up to 30% of cases, particularly for low-energy mechanisms.[29]

The clinical presentation varies with the extent of injury and displacement. Pain in the midfoot and inability to bear weight, particularly on the toes, are usual features. Typically, there is tenderness along the affected tarsometatarsal joints and pain with passive abduction and pronation of the forefoot, sometimes with pathologic mobility. Paresthesias are occasionally present, and examination may reveal edema and ecchymosis. The dorsalis pedis pulse can be absent, or evidence of vascular compromise of the forefoot may be present. It should be kept in mind that low-energy injuries may present with more subtle findings, such as chronic pain and limitation in activity. Lisfranc injuries may be complicated by vascular injury because a critical branch of the dorsalis pedis artery dives between the first and second metatarsals to form the plantar arch. Trauma to this vessel can cause significant hemorrhage and, uncommonly, vascular compromise.

Differential Diagnoses. See Table 49.3 for differential diagnoses of Lisfranc (tarsometatarsal) fractures and dislocations.

Diagnostic Testing: Radiology. Standard radiographic views of the foot are the initial investigation of choice for suspected Lisfranc injuries. However, plain radiographic findings can be subtle or even absent (Fig. 49.20). Abnormal radiographic findings are outlined

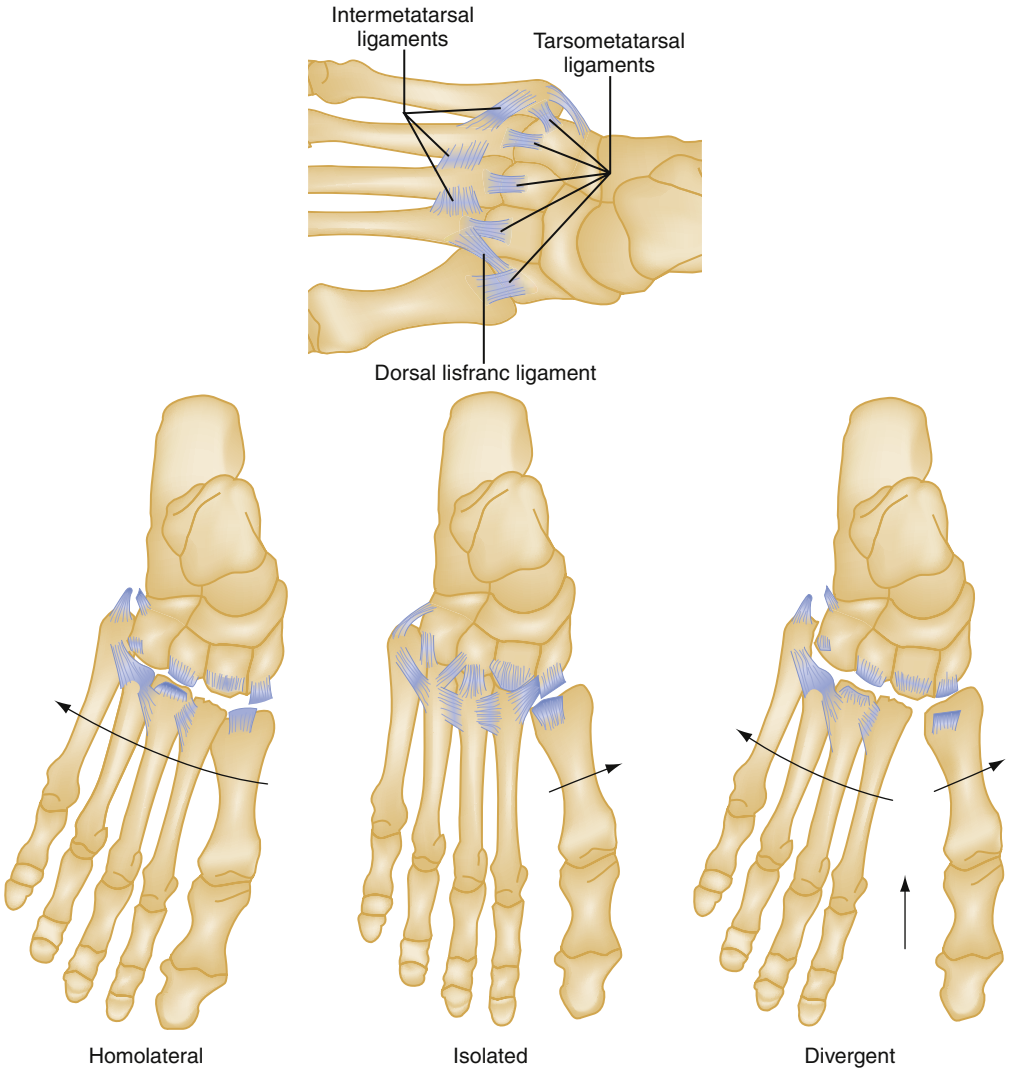

Fig. 49.19 Ligamentous anatomy of the Lisfranc joint and classification of Lisfranc injuries by direction of displacement of metatarsals with respect to the midfoot. Direction of displacement is indicated by arrows.

in Box 49.3.[30] In a recent retrospective study on nonweightbearing radiographs, the presence of an avulsion fracture ("*fleck sign*"), diastasis of greater than 2 mm between the medial cuneiform and base of the 2nd metatarsal, and diastasis of greater than 2 mm between the medial cuneiform and the middle cuneiform, were strong predictors of instability.[31]

When plain radiographs are normal, and Lisfranc injury is suspected, there are a number of alternative imaging options. Weightbearing films improve diagnostic accuracy for ligamentous injury.[30] Unfortunately, weightbearing radiographs are often impossible to obtain in the acutely injured foot, thus their utility in the ED is limited.

CT imaging detects subtle, or nondisplaced, fractures and avulsions that may be missed by plain films, but also fails to detect many isolated ligamentous injuries.[16] MRI is the most sensitive and specific for ligamentous injury, and there is a strong correlation with intraoperative instability, but the ability of MRI to detect subtle instability is unclear.[16] Ultrasound is a cost-effective and useful technique for many emergency medicine applications and can be used to evaluate the dorsal Lisfranc ligament,[32,33] however, the utility of ultrasound to diagnose instability is unproven.[16] Stress fluoroscopy is a technique that may be used in follow-up assessment, or under anesthesia by orthopedics, and may be a more definitive assessment of ligamentous injury.

BOX 49.3 Radiographic Findings Consistent with Lisfranc Injuries

Anteroposterior View

Fleck sign—bony fragment between medial cuneiform and second metatarsal
Lateral displacement of second metatarsal with respect to middle cuneiform
>2 mm widening between medial cuneiform and second metatarsal
>1 mm widening between first and second metatarsals or medial and middle cuneiforms and metatarsals

Lateral View

Dorsal subluxation of the metatarsals at the tarsometatarsal joint
Talometatarsal angle >15°
Reduced plantar distance between medial cuneiform and fifth metatarsal

Adapted from: Kennelly H, Klaassen K, Heitman D et al. Utility of weight-bearing radiographs compared to computed tomography scan for the diagnosis of subtle Lisfranc injuries in the emergency setting. *Emerg Med Australas*. 2019;31:741.

Fig. 49.20 (A) Anteroposterior radiograph showing a Lisfranc injury with fractures of the bases of the second through fourth metatarsals, including a fragment suspicious for an avulsion from the Lisfranc ligament at the second metatarsal base. (B) Lateral radiograph showing a step-off at the tarsometatarsal joints (*arrow*). (C) Computed tomography scan of the same patient showing increased detail, including lateral displacement of the first metatarsal relative to the first cuneiform (*arrow*). (From: Gupta RT, Wadhwa RP, Learch TJ, Herwick SM. Lisfranc injury: imaging findings for this important but often-missed diagnosis. *Curr Probl Diagn Radiol.* 2008;37:115.)

The American College of Radiology in their appropriateness criteria for acute trauma to the foot suggest the following approach.[15] Initial assessment of the Lisfranc joint should include standard three-view radiography. Weightbearing radiographs do provide additional diagnostic benefit and should be added, if possible. If weightbearing images are not possible, CT scanning or MRI may be considered on a case-by-case basis. In the case of a patient with normal plain radiographs, who cannot bear weight, the choice if advanced diagnostics and clinical assessment can be made at the time of consultation by the orthopedic specialist.

Management. High-energy Lisfranc injuries or ligamentous injuries with displacement, either on standard radiographs or stress imaging, are usually treated surgically. Following repair, patients are kept in a nonweightbearing cast for up to 12 weeks. Low-energy ligamentous injury without displacement can be treated with immobilization in a below-knee cast for 6 weeks. There is a significant rate of failure of nonoperative management of nondisplaced, ligamentous injuries. These patients may go on to have operative repair.[34]

Disposition. All proven or suspected Lisfranc injuries should be managed with orthopedic consultation. Delayed treatment or misdiagnosis can result in significant complications and poor functional outcome. When radiographic assessment in the ED is nondiagnostic, clinical suspicion of Lisfranc injury warrants further investigation and referral to an orthopedic surgeon.

Patients with high-energy or displaced Lisfranc injury are managed surgically. Orthopedic consultation, either in the ED or outpatient in 24 to 48 hours, is appropriate. Such patients can be immobilized in a well-padded lower leg splint and should be nonweightbearing. Patients with significant pain, swelling, or those with signs of compartment syndrome, require emergent orthopedic assessment.

Patients with nondisplaced but suspected ligamentous Lisfranc injury should have urgent outpatient orthopedic consultation within 48 hours arranged. These patients should be placed in a well-padded splint and should be nonweightbearing.

Nontraumatic Midfoot Pain

Isolated midfoot pain is less common than forefoot or hindfoot pain. Midfoot stress fractures, although uncommon, usually involve the navicular. Other causes of midfoot pain include symptomatic accessory bones, particularly the accessory navicular, os tibiale externum, and os peroneum.

Forefoot Injuries

Traumatic forefoot conditions are underdiagnosed and often consist of more than one fracture or dislocation occurring simultaneously. As occurs elsewhere in the foot, forefoot trauma may lead to prolonged disability and dysfunction.

Differential Diagnoses

The differential diagnoses for acute forefoot injuries include fractures of the metatarsal bones, phalanges and sesamoid bones in the forefoot (see Table 49.3). Dislocations of the interphalangeal and metatarsophalangeal joints should also be considered. The mechanism of injury is important to include when considering a broad differential. For example, an inversion injury may result in a ligamentous sprain, or in an acute avulsion fracture. The metatarsal bones are prone to stress fractures, in particular the base of the fifth metatarsal, the so called "*Jones and pseudo-Jones*" fractures. When pain is isolated to joints in the forefoot, common causes include inflammatory conditions such as gout, osteoarthritis, and a septic joint. When a more progressive or insidious history of pain is elicited, consideration of soft tissue pathology such as Morton neuroma and other causes of metatarsalgia should be considered.

Diagnostic Testing

Plain radiographs are generally adequate in diagnosing fractures to the forefoot. One potential exception may be when there is consideration of Lisfranc injury with metatarsal base fractures. In that circumstance, CT scanning provides an added diagnostic modality.

Metatarsal Fractures

Foundations. Metatarsal fractures are common and account for one-third of foot fractures. Management depends both on the specific location of the fracture, and on the metatarsals involved; first, middle (metatarsals two, three, four), and fifth. In assessing metatarsal fractures, it is important to consider and rule out associated injuries, particularly Lisfranc injury when there are fractures of the base of the first to fourth metatarsals.

Fractures of the First Metatarsal. The first metatarsal is the largest and strongest of the metatarsal bones and is rarely fractured. Injury to the first metatarsal occurs from both direct, and indirect trauma as well as from crush injuries. Patients will present with pain and swelling over the medial side of the foot along with pain or inability to bear weight. Axially loading the first phalanx will illicit pain. First metatarsal fractures are typically identified by a standard plain radiograph series of the foot.

Because of the forces acting through the first metatarsal, and its essential role in ambulation, maintenance of length and anatomic alignment is important. All first metatarsal fractures should be followed by orthopedics urgently within 48 hours. Nondisplaced fractures are treated with a nonweightbearing cast for up to 6 weeks. Displacement, shortening or comminution are indications for surgical repair, which can be arranged after outpatient orthopedics consultation in 24 to 48 hours. In the ED, care must be taken to rule out associated injuries, specifically Lisfranc injury. Assuming pain is adequately controlled, patients should be placed in a nonweightbearing cast or splint and outpatient orthopedic follow up should be arranged.

Fractures of the Middle Metatarsals (Two to Four). Middle metatarsal fractures often result from crush injuries but can occur from indirect trauma such as in twisting injuries. These metatarsals are also prone to stress fractures.

Clinical Features. Patients will present with pain, tenderness, and swelling in the midfoot and usually inability to bear weight.

Differential Diagnoses. See Table 49.3 for a list of differential diagnoses of metatarsal fractures.

Diagnostic Testing. Plain radiographs are generally adequate for diagnosis of acute fractures. CT imaging may better delineate the diagnosis, particularly in cases of fractures to middle metatarsal bases where Lisfranc injury is a concern.

Management and Disposition. The middle metatarsals are inherently stable with extensive soft tissue support from adjacent metatarsals. Nondisplaced fractures may be treated with weightbearing as tolerated usually in stiff soled footwear. If limited by pain, an initial period of nonweightbearing with application of a compressive dressing in the ED is a reasonable approach. Displacement, particularly in the sagittal plane, affects normal foot loading and can result in persistent pain. Fractures with greater than 3 mm of displacement, or greater than 10 degrees of angulation require reduction, which may be attempted using traction of the affected phalanx. Following reduction, patients with displaced fractures should be nonweightbearing and splinted.

Patients with nondisplaced or reduced middle metatarsal fractures can be referred to orthopedics for follow-up in 1 to 2 weeks. Patients with multiple fractures, or with persistently displaced fractures should be referred to orthopedics within 48 hours for consideration of operative repair.

Fractures of the Fifth Metatarsal. *The fifth metatarsal is the most commonly fractured metatarsal.* Fractures of the fifth metatarsal are divided anatomically into fractures of the base and fractures of the shaft and head. Fractures of the base are further divided into three types, based on anatomic zones. Zone 1 fractures are avulsion fractures of the tuberosity, zone 2 fractures or "*Jones fractures*" involve the metaphyseal diaphyseal junction, at the level of the intermetatarsal articulation of the fourth and fifth metatarsals. Zone 3 fractures occur in the proximal 1.5 cm of the diaphysis and are most commonly stress fractures (Fig. 49.21).

Fifth Metatarsal Shaft Fractures. Fractures of the shaft of the 5th metatarsal are often referred to as "*dancers' fractures.*" These injuries result from an inversion injury when the foot is in plantar flexion, as seen in dancers when up on demi-pointe. Fractures of the fifth metatarsal shaft present with localized tenderness and pain or inability to bear weight. These generally heal well and are treated nonoperatively with weightbearing as tolerated. The use of a walker boot or rigid support, although not strictly necessary, may be required in the initial phase due to pain. Routine follow-up with orthopedics is reasonable although these fractures could be safely managed in a primary care setting.

Fifth Metatarsal Base Fractures. Fractures in zone 1 of the fifth metatarsal base occur from avulsion of the tuberosity by the lateral band of the plantar aponeurosis. These fractures are extremely common and are the result of sudden inversion on a plantar flexed foot. They are usually extraarticular, although they may extend into the cubometatarsal joint. Often, these injuries masquerade as ankle sprains (see Box 49.2), making the fifth metatarsal base an important area to palpate following any twisting injury.

Differential Diagnoses. See Box 49.2 and Table 49.3 for a list of differential diagnoses of fifth metatarsal fractures.

Diagnostic Testing. Plain radiographs are generally adequate for diagnosis of acute fractures of the fifth metatarsal.

Management and Disposition. Historically, tuberosity fractures involving more than 30% of the articular surface or with more than 2 mm of displacement were managed operatively. Current evidence, however, suggests that all zone 1 fractures, regardless of articular involvement, can be managed symptomatically and functionally.[35,36] Often an elastic bandage and supportive footwear are adequate. If required due to pain, a short period in a walking boot is reasonable. These fractures can be managed in a primary care setting.

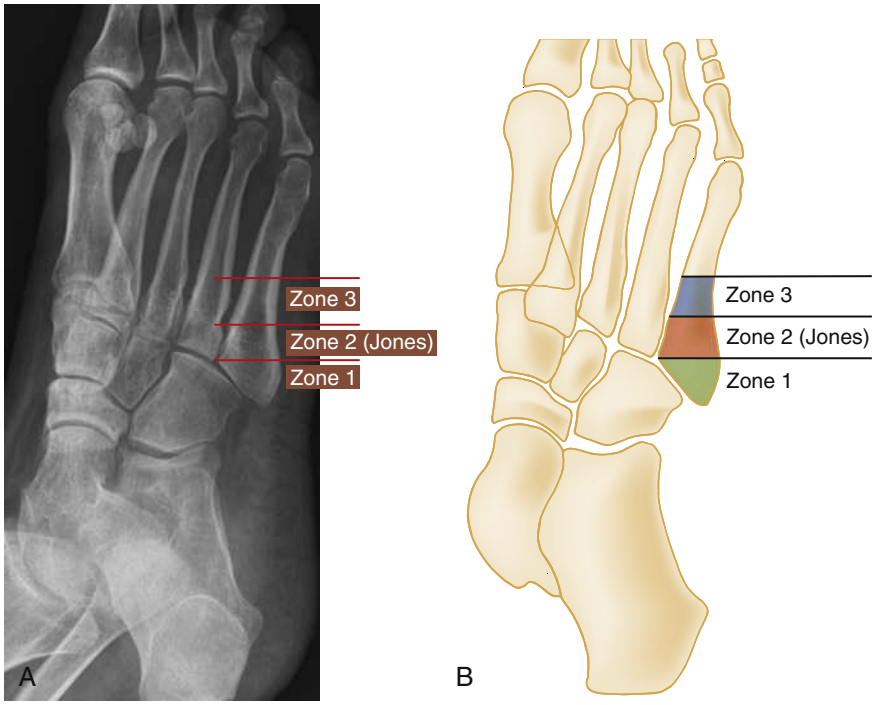

Fig. 49.21 Classification of fractures of the base of the fifth metatarsal. Zone 1 is a tuberosity avulsion fracture. Zone 2 (Jones fracture) occur through the fourth and fifth intermetatarsal articulation. Zone 3 fractures are distal to the articulation.

Zone 2 is a watershed area of blood supply and therefore fractures here are at a higher risk of nonunion. Historically, these fractures have been treated with prolonged immobilization, however, recent evidence questions this dogma, advocating for functional treatment with weightbearing as tolerated. In several studies the rate of symptomatic nonunion has been low, and the need for operative intervention approaches only 1%.[37,38] These studies show safe and effective nonoperative treatment at substantially lower health care cost.[37-39] Early operative intervention is still considered for certain populations, including athletes.[40] As management decisions are made on a case-by-case basis, routine referral to orthopedics is recommended for fractures in zone 2. In the ED, patients can be treated symptomatically in a compressive bandage and supportive footwear. In some cases, pain will necessitate provision of a walking boot, or even a period of nonweightbearing.

Fractures in Zone 3 are most commonly stress fractures resulting from repetitive trauma in a cavovarus (or high arched) foot. These fractures have a high rate of nonunion and may require prolonged immobilization and in some cases, operative management. In the ED, treatment of zone 3 fractures can be guided by symptoms. If there is pain upon weightbearing, patients should be made nonweightbearing and may benefit from the use of a walker boot. These fractures should be managed with the guidance of orthopedics or sports medicine specialists with routine referral in 2 weeks.

Phalangeal Fractures

Foundations. *Phalangeal fractures are the most common forefoot fracture.* The proximal phalanges are more commonly fractured than middle or distal phalanges and the proximal phalanx of the fifth toe is the most commonly injured of all. Fractures of the hallux often are displaced, whereas those of the lesser phalanges are often comminuted but are less commonly displaced.

Clinical Features. Although phalangeal fractures generally are considered minor injuries, they can lead to disabling sequelae. Patients present with acute pain and swelling of the affected toe, often with difficulty ambulating or wearing shoes. Examination will reveal tenderness and crepitus. A subungual hematoma is often present if the distal phalanx is involved, and open fractures are common. Complications of phalangeal fractures are uncommon. With intraarticular phalangeal fractures, particularly those involving the hallux, arthritis may be a late sequela. Symptomatic angular malunion and osseous deformity can occur with phalangeal fractures, and exostectomy is sometimes required.

Differential Diagnoses. See Table 49.3 listing differential diagnoses for phalangeal fractures.

Diagnostic Testing. As with metatarsal fractures, carefully assessed standard radiographic views are sufficient to demonstrate phalangeal fractures. Careful inspection will help to rule out associated dislocations.

Management. Most phalangeal fractures are easily managed and heal well. Large (greater than 50% of the nail bed) and symptomatic subungual hematomas should be trephinated and, on rare occasions, nail bed repair may be required. Nondisplaced lesser phalangeal fractures should be stabilized by dynamic buddy taping, with placement of gauze between the splinted toes to prevent skin maceration. Patients are advised to expect pain for 2 to 3 weeks until the fracture is stabilized by callus. Use of a stiff shoe is often beneficial.

If significant displacement or angulation is present, reduction should be performed with manual traction after digital anesthesia. Moderate persistent angulation or displacement is acceptable if the clinical appearance and function of the toe remain satisfactory. Rarely, operative fixation of lesser phalangeal fractures is indicated, particularly in cases with severe rotatory deformity or open fractures requiring débridement.

Nondisplaced phalangeal fractures involving the hallux are treated by buddy taping with a walking cast worn for 2 to 3 weeks if the toe is painful. Displaced hallux fractures require reduction. If the reduction is inadequate or unstable, operative fixation may be indicated. Unless

completely nondisplaced, most intraarticular fractures involving the hallux are treated with operative fixation.

Disposition. In general, primary care follow-up is appropriate for phalangeal fractures. If displacement persists or causes cosmetic or functional concern, nonurgent outpatient orthopedic referral is advised. Poorly reduced, or intraarticular hallux fractures should be splinted for urgent outpatient orthopedic follow-up within a week.

Sesamoid Fractures

The sesamoids are two flat oval bones found in the tendon of the flexor hallucis brevis, under the head of the first metatarsal and, rarely, under the second to fifth metatarsal heads. Sesamoid fractures are uncommon, usually resulting from direct trauma or hyperextension of the great toe, although they have been described in association with MTP joint dislocations. Stress fractures of the sesamoids also occur. A fracture should be differentiated from a bipartite sesamoid, which occurs in up to one-third of the population and also is more common on the medial aspect. Most sesamoid fractures heal without complication with symptomatic treatment only. A walker boot or below-knee cast may help function, although typically a supportive shoe is sufficient, possibly with a shaped pad to alleviate direct pressure. Orthopedic consultation is suggested only for patients with nonunion or chronic pain. This can be arranged by the primary care physician.

Metatarsophalangeal Dislocations

Foundations and Pathophysiology. MTP joint dislocations can occur in any joint and in any direction. First MTP joint dislocations require large forces and usually result from MVCs. These injuries, which are frequently open, are usually dorsal dislocations of the distal component caused by hyperextension of the MTP joint. Associated sesamoid fractures may be present. Complex dislocations, in which the sesamoids or local tendons prevent closed reduction, can occur. The most common MTP dislocation is a lateral dislocation of the fifth MTP joint.

Clinical Features. First MTP joint dislocations usually are obvious because the toe is angled upward, with dorsal and proximal displacement of the proximal phalanx. Rarely, the sesamoids are palpable dorsal to the metatarsal, indicating a complex dislocation. Dislocations of the lesser toes may be more subtle in presentation, and comparison with the uninjured foot may be helpful. Complications are rare after MTP dislocation but arthritis and reduced range of motion, particularly of the hallux, do occur. Dislocations for which the diagnosis is delayed for more than 3 weeks often are not amenable to closed reduction and may require metatarsal head excision.

Differential Diagnoses. See Table 49.3 describing differential diagnoses of metatarsophalangeal dislocations.

Diagnostic Testing: Radiology. Dislocations of the MTP joint are well-visualized on standard radiographic views of the foot. Radiographs should be scrutinized for signs of complex dislocation, such as the sesamoids lying between the articular surfaces or dorsal to the metatarsal head.

Management. Most MTP joint dislocations, particularly of the lesser toes, are easily reduced with longitudinal traction. Analgesia or local anesthesia may be required. Dorsal dislocations of the first MTP joint can be more challenging and may require initial accentuation of the deformity, in addition to longitudinal traction, for reduction. Joint stability should be assessed, and repeat radiographs obtained after reduction of an MTP joint dislocation. Joints that are stable after reduction can be treated with buddy taping and benefit from use of a hard soled, supportive shoe.

Disposition. Most MTP joint dislocations can be managed without orthopedic consultation. If crepitus or obvious instability is present, or postreduction radiographs show joint incongruity or an intraarticular fracture, outpatient orthopedic consultation should be obtained for possible fixation. First MTP joint dislocations that are open, are complex or do not easily reduce require emergent orthopedic consultation.

Interphalangeal Joint Dislocations

IP joint dislocations are much less common than MTP joint dislocations and are often overlooked. Most IP joint dislocations occur in the great toe and are a result of axial loading. IP joint dislocations usually involve dorsal displacement of the distal component. Reduction is performed with longitudinal traction after digital block anesthesia. If the dislocation involves the great toe, a walking cast with a toe plate for 3 weeks is indicated after reduction. Lesser toes require only buddy taping. As with the MTP joint, complex dislocations involving the first IP joint can occur, and orthopedic consultation in the ED for open reduction may be necessary. In rare cases, lesser toe IP closed reduction is not possible and open reduction is required.

Nontraumatic Forefoot Pain

Clinical Features. The forefoot is the site for a myriad of painful problems. Bunions, painful bursae, blisters, corns, calluses, hammertoes, and ingrown toenails all are diagnostically obvious but can pose therapeutic challenges. Many are the result of poor footwear or a biomechanical problem with the foot. These often respond to appropriate padding and avoidance of precipitants although in certain specific cases surgical intervention may help.

Metatarsalgia is an often used, loosely defined term referring to pain in the region of the metatarsal heads. This is a common presenting complaint, with many potential causes relating to biomechanics of the forefoot. Metatarsal stress fractures should be considered in the differential diagnoses for any unexplained forefoot pain. Flexor or extensor tendinitis also can produce metatarsal area pain. Arthritis, sesamoiditis, or a sesamoid stress fracture should be considered when pain occurs in the plantar area of the hallux. The term *turf toe* refers to MTP joint inflammation of the hallux resulting from repeated hyperextension. It usually responds to symptomatic measures but can be a debilitating injury in some athletes.

An important cause of unilateral metatarsalgia is a perineural fibrosis of the intermetatarsal plantar digital nerve, more commonly known as *Morton neuroma*. This neuropathy usually involves the second-third or third-fourth intermetatarsal space, causing lancinating pain with weightbearing that can radiate to the toes and may be associated with paresthesia. Pain is reproduced when structures of the affected interspace are pinched or when the metatarsal heads are compressed together. Hence, pain may occur with tight-fitting footwear. Crepitus or a nodule may be palpable.

Freiberg disease is an osteochondrosis of the metatarsal head, usually involving the second metatarsal, and is another cause of pain in this area. Ingrown toenails are a common affliction that can occur in any toe, usually the hallux. Often, the abnormality is perpetuated by short nail trimming, which affords the opportunity for a spicule of nail to grow under the nail fold.

Differential Diagnoses. Refer to Table 49.3 for differential diagnoses of nontraumatic forefoot pain.

Diagnostic Testing. Although the vast majority of nontraumatic forefoot pain is diagnosed clinically, plain radiography may be useful to rule out bony pathology. MRI may be helpful to clarify diagnostic challenges for entities such as Morton neuroma, tendinitis, stress fractures, and turf toe.

Management. Most diagnoses of nontraumatic forefoot pain may be managed on a nonurgent basis by a podiatrist or primary care physician. Morton neuroma treatment ranges from footwear

modification and physiotherapy to steroid injections and surgery for chronic and severe cases.

Ingrown toenails may be treated by allowing the nail to grow out and providing local care usually will lead to resolution, although chronic or recurring ingrowth necessitates partial or complete excision of the nail and germinal ablation. Antibiotics are indicated if infection is present.

SPECIAL CONSIDERATIONS

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is a chronic pain condition in which pain is disproportionate in severity and duration to the expected course. CRPS is divided into types I and II, in which type II is associated with a nerve lesion, whereas type I is not. The International Association for Study of Pain (IASP) diagnostic criteria, also known as *the Budapest criteria*, were updated in 2010. These criteria require pain disproportionate to the inciting event, and without any alternative diagnosis. Signs and symptoms are categorized in four categories: sensory, vasomotor, sudomotor/edema, and motor/trophic. The diagnosis requires the report of one symptom in three out of four categories and manifestation of one sign in two of the four categories at the time of evaluation. Typically, pain is described as diffuse burning, aching, or searing in nature, together with evidence of vasomotor instability. The incidence of CRPS following foot and ankle injury has varied in the literature. CRPS has been reported in 5% of patients following foot and ankle surgery and in only 0.3% of patients with foot and ankle fractures.[41] Complex regional pain syndrome should always be considered in the differential diagnoses for chronic foot pain after trauma even after a relatively innocuous injury. The management of CRPS is multifaceted, often guided by a pain specialist. Although important to consider, the definitive diagnosis of CRPS is unlikely to be made in the ED. Emergent conditions on the differential include compartment syndrome, cellulitis, DVT, peripheral vascular disease, and ischemia. Other considerations on the differential include peripheral neuropathy, erythromelalgia, neoplastic diseases, and conversion and factitious disorders.

Stress Fractures

Foundations and Pathophysiology

Stress fractures can occur anywhere in the appendicular skeleton but are particularly common in the lower extremity. They can occur as a result of extrinsic factors (e.g., training volume, footwear, training surface) and intrinsic factors (e.g., metabolic state, fitness, muscle endurance, anatomic alignment). The syndrome of relative energy deficiency in sport, historically termed the *female athlete triad*, is a condition of disordered eating, menstrual disturbances, and low bone mineral density and is known to be associated with stress fractures.[42]

It is useful to categorize stress fractures as being high risk and low risk based on the rate of complications, including delayed union, nonunion, and persistent functional limitation. High-risk stress fractures often occur in bones with a vulnerable vascular supply. In the lower extremity, these stress fractures include the femoral neck, anterior tibia, medial malleolus, navicular, proximal fifth metatarsal, and sesamoid bones.

Clinical Features

Most stress fractures produce localized aching pain of insidious onset over several weeks. Initially, symptoms occur after athletic activities, but later they limit such activities. Often, a predisposing factor, such as a training regimen change, is present. Physical examination may reveal swelling, point tenderness, or percussion tenderness. However, in most patients, these findings are absent, and the diagnosis is suspected by history alone. A dietary history (e.g., restrictive diets or those low in vitamin D and calcium) may contribute as well. In addition, a menstrual history should be obtained in female patients because amenorrhea associated with overtraining is a marker of the syndrome of relative energy deficiency in sport.

Differential Diagnoses

See Table 49.3 for differential diagnoses of stress fractures.

Diagnostic Testing

Initial plain radiographs are commonly read as normal because bone reaction in stress fractures depends on the length of time from symptom onset. Radiographic abnormalities in the metaphysis can take up to 4 weeks to develop, and those in the diaphysis can take 6 weeks. Although plain radiographs have low sensitivity for stress fractures, their specificity is high. The three important findings are periosteal new bone formation, endosteal thickening, and a radiolucent line.

Because only 50% of patients develop plain radiographic abnormalities, the diagnosis of a stress fracture can be easily missed. Traditionally, plain radionuclide bone scanning was the imaging modality of choice for stress fractures. Bone scans are nonspecific but extremely sensitive, usually showing abnormal uptake within 24 hours of injury. More advanced imaging techniques such as CT-SPECT and MRI have gained value in diagnosing stress fractures.

Management

Low-risk foot and ankle stress fractures often resolve in 4 to 6 weeks with limitation of impact activities as guided by pain; most patients can remain weightbearing and do not require immobilization unless symptoms are severe. High-risk stress fractures, including the anterior tibia, medial malleolus, navicular, base of fifth metatarsal, and sesamoids, require treatment with immobilization and nonweightbearing under the guidance of a sports medicine or orthopedic surgery specialist as these are frequently are managed surgically, particularly stress fractures of the anterior tibia.

Disposition

Patients with confirmed low-risk stress fractures can be managed by primary care and can be weightbearing as tolerated, with activity modification. If required by symptoms, these patients may be placed in a short walker boot for comfort. Athletic stress fractures are overuse injuries that necessitate evaluation of training habits, equipment, and techniques. Patients with clinically suspected but unconfirmed stress fractures can be referred to sports medicine or orthopedic specialists to arrange further diagnostics, as indicated. All patients with high-risk stress fractures should be made nonweightbearing and immobilized, with arrangements made for outpatient orthopedic or sports medicine consultation within 2 weeks.

Tendon Injuries

Acute tendon ruptures in the foot, apart from the Achilles and posterior tibial tendons, are rare. Although isolated ruptures of the flexor hallucis longus and anterior tibial tendons have been described, most tendon transections are the result of lacerations (see Table 49.2).

Orthopedic or plastic surgery consultation is indicated for any patient known or suspected to have a tendon injury in the foot. It is clear that flexor and extensor hallucis longus tendons should be repaired primarily; however, the need to repair other tendons is controversial. In general, an attempt should be made to repair any tendon transection, because apparently minor injuries can lead to complications, such as *claw deformity*. Tendon injuries associated with innocuous lacerations

are easily missed if not carefully sought. Splinting for 2 to 6 weeks is required after tendon repair.

Compartment Syndrome of the Foot and Ankle

Foundations

Compartment syndrome is defined as an increase in pressure within a confined osseofascial space that impedes neurovascular function, resulting in tissue damage; it is discussed in detail in Chapter 41. Compartment syndrome related to ankle fractures may involve either the compartments of the lower limb (anterior, lateral, superficial posterior, deep posterior) or the compartments of the foot, which by convention are defined by four compartments (medial, central, lateral, and interosseous). However, as many as nine compartments have been identified in the foot. As elsewhere, compartment syndrome in the foot constitutes a surgical emergency.

Compartment syndrome in the lower limb secondary to ankle fractures is rare and is most often associated with significant force and hence disruptive fracture patterns.

Pedal compartment syndrome is most commonly caused by high-energy injuries, such as crush injuries, Lisfranc fractures, calcaneus fractures, and midfoot or forefoot trauma. Pedal compartment syndrome after an ankle sprain has also been reported. Damage is related to the duration and magnitude of compartment pressure increase and the arteriovenous gradient. Compartment syndrome can develop anywhere from 2 hours to 6 days after a traumatic injury, although the peak incidence is at 15 to 30 hours.

Clinical Features

Compartment syndrome typically causes pain out of proportion to that expected for the injury and is not decreased by immobilization. Physical examination may reveal tense swelling and sensory deficits. Pain is exacerbated by any movement (active or passive) that stretches the muscles of the involved compartment. Peripheral pulses and capillary refill usually are initially normal in compartment syndrome and thus offer no reassurance when present. The presence of an open wound does not guarantee that all compartments are decompressed. It should be noted that compartment syndrome is often missed in its early stages, perhaps masked by the pain of the acute injury. In calcaneus injury, for example, although compartment syndrome is known to complicate 4% of fractures, one-third of patients had the diagnosis missed on initial assessment.[23]

Differential Diagnoses

See Table 49.3 for differential diagnoses of compartment syndrome of the foot and ankle.

Diagnostic Testing: Special Procedures

Definitive diagnosis of compartment syndrome is by measurement of intracompartmental pressure. Pressure greater than 30 mm Hg is generally considered an indication for emergent decompression but compartment syndrome can occur at lower pressures in hypotensive patients. Because needle localization of foot compartments is challenging, and because of its importance in surgical decision making, measurement of pedal compartment pressures is optimally performed by the orthopedic specialist.

Management and Disposition

Early identification and prevention of further tissue damage are important considerations in any patient in which compartment syndrome is considered. Circumferential bandages and casts should be avoided during early management of foot and ankle injuries where swelling is expected. In diagnosed or suspected cases of compartment syndrome, the limb should be positioned at the level of the heart. Elevation beyond this is contraindicated because resultant decreased arterial flow narrows the arteriovenous pressure gradient. When compartment syndrome is identified or suspected, emergent orthopedic consultation is indicated for consideration of decompressive fasciotomy.

CHAPTER 49: QUESTIONS AND ANSWERS

1. A middle-aged farmer presents after an accident with a plow with a crushed open distal tibia fracture. What is the appropriate antibiotic choice?
   - **a.** Cefazolin
   - **b.** Cefazolin and gentamycin
   - **c.** Cefazolin, gentamycin, and penicillin G
   - **d.** Ciprofloxacin
   - **e.** Pen VK and cephalexin

Answer: C. Because the patient has a probable soil contaminant in his open fracture, he will need the addition of penicillin G to cover *Clostridium perfringens*. For low-energy injuries with mild to moderate contamination, a broad-spectrum cephalosporin is usually sufficient. Heavily contaminated wounds require the addition of gram-negative bacterial coverage, typically with an aminoglycoside. Adding penicillin G as a third antibiotic is necessary for farm- or soil-related crush injuries.

2. A 30-year-old woman complains of pain in the ankle and difficulty walking after attempting a jump shot while playing basketball. Her past medical history includes a recent urinary tract infection, for which she is taking ciprofloxacin. On physical examination, her ankle joint is not swollen, there is a palpable defect 4 cm proximal to the posterior ankle, and she has weakened plantar flexion. Which of the following is true concerning her condition?
   - **a.** The Boehler angle should be less than 20 degrees.
   - **b.** In a seated position, squeezing the calf causes foot dorsiflexion.
   - **c.** It requires a stress radiograph view.
   - **d.** On the radiograph, there may be an opacification at the Kager triangle.
   - **e.** Talofibular ligament laxity is present.

Answer: D. The patient has a ruptured Achilles tendon. On examination, a visible and palpable tendon defect 2 to 6 cm proximal to the calcaneal insertion may be present. In some cases of complete Achilles tendon rupture, weak plantar flexion may still be present because of the actions of the tibialis posterior, toe flexors, and peroneal muscles. When the Achilles tendon is intact, squeezing the calf muscles should cause passive plantar flexion of the foot (Thompson test). Lateral radiographs of the ankle may confirm rupture by showing opacification of the triangular fatty tissue–filled space anterior to the Achilles tendon (Kager triangle) or an irregular contour and thickening of the tendon.

3. A 24-year-old patient presents with pain in the left lateral ankle after a twisting injury. On physical examination, you find no point tenderness on the medial or lateral distal 6 cm of the malleoli, no proximal fibular tenderness, and no navicular tenderness. Which of the following physical findings would necessitate radiographs being taken in the emergency department?
   - **a.** Inability to ambulate to the car
   - **b.** Laxity on anterior drawer testing
   - **c.** Moderate swelling with ecchymosis
   - **d.** Tenderness at the base of the fifth metatarsal
   - **e.** Tenderness over the deltoid ligament

Answer: D. The Ottawa Ankle Rules advise ankle radiographs when any of the following are present: tenderness at the posterior edge of the distal 6 cm or tip of the lateral malleolus, tenderness at the posterior edge of the distal 6 cm or tip of the medial malleolus, or inability to bear weight for at least four steps immediately after the injury and at the time of evaluation. Foot radiographs in the setting of blunt ankle trauma are advised when any of the following are present: tenderness over the navicular, tenderness at the base of the fifth metatarsal, or inability to bear weight for at least four steps immediately after the injury and at the time of evaluation.

4. A 40-year-old female falls down some stairs and her ankle is forced into sudden dorsiflexion and eversion. She reports pain over the lateral aspect of the ankle and reports a "snapping" sensation with active ankle eversion, otherwise the rest of the examination is unremarkable. The plain radiograph of the ankle is negative with the exception of what appears to be a large avulsed fragment over the lateral malleolar region. The optimal management of this patient is:
   - **a.** Reassuring the patient that this is an avulsion fracture and make her weightbearing as tolerated.
   - **b.** Order a CT scan to evaluate the origin of the avulsed fragment.
   - **c.** Orthopedic evaluation in the emergency department.
   - **d.** Outpatient dynamic ultrasound and referral to orthopedics.
   - **e.** Splinting, nonweightbearing, and outpatient referral to orthopedics.

Answer: D. The patient's mechanism of injury, symptoms, and x-ray findings are consistent with a rupture of the superior peroneal retinaculum with peroneal tendon dislocation. If the diagnosis is in doubt, dynamic ultrasound can be used to evaluate the peroneal tendon because it will show dislocation of the tendon when the foot is dorsiflexed and everted. Rupture of the superior peroneal retinaculum invariably requires operative repair.

5. A 32-year-old male presents after a fall in which his foot was forced into dorsiflexion. He has severe pain and swelling on his dorsal foot just anterior to the ankle. In the ED, he is diagnosed with a nondisplaced talar neck fracture (Hawkins type 1). His pain is controlled, and he has no associated injuries. What is the disposition for this patient?
   - **a.** Place in a walking boot or a cast, weightbearing as tolerated, and follow up with orthopedics in 1 to 2 weeks.
   - **b.** Orthopedics consult in the emergency department is required and the patient should be admitted.
   - **c.** Immobilize in a padded, noncircumferential splint and arrange outpatient orthopedics within 48 hours.
   - **d.** Immobilize in a cast and nonweightbearing for 6 weeks, with outpatient orthopedics follow-up in 1 to 2 weeks.

Answer: C. Hawkins type 1 fractures are nondisplaced. These fractures are treated conservatively and are the only talar neck fractures that are appropriate for outpatient orthopedic follow-up. Follow-up, however, should be urgent in 24 to 48 hours, and the patient should certainly be immobilized in a well-padded and noncircumferential splint. Depending on local practice, orthopedic consultation in the ED is reasonable.

6. A 44-year-old male presents after a fall from a ladder in which he landed on his right foot. He has severe pain in his heel and is diagnosed with an intraarticular calcaneus fracture on plain x-rays. Which of the following is incorrect in the emergency management of this patient?
   - **a.** Assessment for other traumatic injuries, particularly spinal injury.
   - **b.** Once pain and swelling are controlled, the patient may be immobilized in a padded splint with orthopedic follow-up arranged for 48 hours.
   - **c.** The patient should get a CT scan of the foot, if available, in the emergency department.
   - **d.** Orthopedic surgery should be consulted to assess the patient in the emergency department.
   - **e.** Place the patient in a well-padded splint with the foot elevated.

Answer: B. Patients with intraarticular calcaneus fractures should have an orthopedics consultation in the ED. Treatment may be conservative, but even when operative repair is chosen, the repair may be done electively at a time when the swelling has decreased. It is important to

CHAPTER 49: QUESTIONS AND ANSWERS—cont'd

assess these patients for other associated injuries and for patients to be placed in a well-padded splint with the foot elevated to the level of the heart, to decrease swelling. CT imaging aids in classification and decisions about management.

7. A 22-year-old male football player presents with midfoot pain and difficulty weightbearing after being tackled in a college game. You are concerned about a Lisfranc injury, but his plain radiographs appear normal. What is the recommended next step in his management?
   - **a.** MRI in the emergency department
   - **b.** Attempt weightbearing x-rays or a CT scan, to assess for ligamentous disruption.
   - **c.** Immobilize in a nonweightbearing splint and refer for follow-up with orthopedic surgery.
   - **d.** Ultrasound to assess for disruption of the Lisfranc ligament
   - **e.** Orthopedics consultation for stress fluoroscopy

Answer: B. Diagnosing low-energy, ligamentous Lisfranc injuries is a challenge. The American College of Radiology guidelines recommend an attempt at weightbearing stress views to look for diastasis of greater than 2 mm between base of the first and second metatarsals, or a difference greater than 1 mm between the base of the first and second metatarsals comparing both feet. If weightbearing x-rays are not possible, a CT scan is recommended. If clinical concern persists, more advanced imaging with MRI or fluoroscopic stress views may be necessary, but these can be arranged at the time of specialist follow-up. Ultrasound has not yet demonstrated utility.

8. A 28-year-old female suffers a twisting injury to her foot during a fall. She is tender at the base of her fifth metatarsal. Plain radiographs reveal an acute, nondisplaced fracture at the level of the intermetatarsal articulation. Which of the following management options is incorrect?
   - **a.** She can be treated functionally in a supportive shoe and can bear weight as tolerated. Orthopedic follow-up should be arranged.
   - **b.** This type of injury may be managed surgically. She should be referred for orthopedic assessment as an outpatient.
   - **c.** She should be placed in a weightbearing cast or walker boot for 3 months with outpatient follow-up.
   - **d.** She can be provided with a walker boot but instructed to remove it when able. Orthopedic follow-up should be arranged.
   - **e.** She can be treated functionally in a supportive shoe if necessary. No follow-up is needed

Answer: E. This is a zone 2 fracture. The treatment of these fractures is evolving and varies according to patient factors. In high-level athletes, primary surgical management may be of benefit. Historically, these injuries were thought to have a high rate of nonunion and prolonged immobilization has been the standard approach in the average patient. More recent data, however, suggest that the rate of symptomatic nonunion is actually quite low, and there is evidence that treating these patients functionally in supportive footwear, perhaps with initial use of a protective boot, is efficacious and more economical. However, as there remains a risk of nonunion, orthopedic follow-up is recommended for these injuries. Fractures in zone 1 are the only base of fifth fractures that do not require orthopedic follow-up.

Wound Management Principles

Barry C. Simon and H. Gene Hern Jr.

KEY CONCEPTS

- Risk factors for wound infection include crush mechanism; long (>5 cm) deep penetrating wounds; high-velocity missiles; diabetes; and contamination with saliva, feces, soil, or other foreign matter.
- Soaking wounds in povidone-iodine (Betadine) is toxic to healthy tissue. Prepare the skin with a chlorhexidine-alcohol solution.
- The most effective intervention to decrease wound bacterial counts and infection is thorough cleansing, with use of saline or tap water irrigation at approximately 8 psi. Attaching an 18-gauge needle to a 30-mL syringe creates an irrigant force of 7 or 8 psi.
- Bupivacaine is the preferred local anesthetic agent for the care of most wounds. In adults, the maximal reported safe dose is approximately 2 to 2.5 mg/kg without epinephrine and 3 to 3.5 mg/kg with epinephrine.
- The discomfort associated with the injection of bupivacaine into wounds can be reduced by warming the anesthetic and by adding sodium bicarbonate (0.1 mL of sodium bicarbonate to 10 mL of bupivacaine).
- High-risk wounds should not be sutured primarily but may be repaired in 4 or 5 days (i.e., delayed primary closure).
- Tissue adhesives offer several advantages compared to the suturing of simple wounds. However, the use of adhesives is not recommended for lacerations longer than 4 cm, for high-tension wounds, or in areas subject to frequent repetitive movements, such as joints and hands.
- Skin tears in elders are best treated with Steri-Strips, augmented with topical skin adhesives when tension exists.
- Antibiotics are indicated for through-and-through intraoral lacerations, cat bites, some dog and human bites, puncture injuries to the foot in high-risk individuals, open fractures, and wounds involving exposed tendons or joints.
- Tetanus immunization should be provided soon after injury but can be given days or weeks later as the incubation period for tetanus is 7 to 21 days (range, 3 to 56 days).
- Tdap is recommended for patients 65 years old or older requiring tetanus prophylaxis.

FOUNDATIONS

Background and Importance

The goals of emergency wound treatment are to restore function, repair tissue integrity with strength and optimal cosmetic appearance, and minimize risk of **infection**. Risk of infection depends on the location, mechanism, host factors, and wound care. The risk for a clean facial wound produced by incision is less than 1%, whereas a dirty crush injury to the lower extremity may have more than a 20% risk. Wound infection generally results in delayed healing, decreased strength, and a poor cosmetic result. These facts highlight the need for high-quality wound care. Understanding the biology of wound healing and the technical aspects of wound treatment facilitates emergency management of these patients.

Emergency clinicians must be aware of the medicolegal risk associated with soft tissue injuries. Including injuries to the hand, wound-related complaints are the fourth most common cause of malpractice claims against emergency clinicians with missed **foreign body**, wound infection, and missed tendon or nerve injury as the most common complications leading to claims.

Anatomy, Physiology, and Pathophysiology

An understanding of skin anatomy leads to better appreciation of wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion, ensures thermoregulation, and helps to regulate water content and register sensory stimuli.

The skin and fascia vary in thickness from 1 to 4 mm, depending on the part of the body. The epidermis, the outermost layer, is several cell layers thick. The most important parts of the epidermis are the stratum germinativum (basal layer), where new cells originate, and the stratum corneum, the outermost cell layer that gives the skin its cosmetic appearance. The layer of skin directly beneath the epidermis is the dermis. It is a thicker, connective tissue layer and primarily responsible for ultimate wound healing. Removing debris and devitalized tissue from the dermis is key for optimal healing and minimal scar formation. The dermis also functions to anchor sutures placed percutaneously or subcutaneously.

The superficial fascia lies directly beneath the dermis and encloses the subcutaneous fat. This space must be irrigated and debrided to decrease the risk of infection. The deep fascia lies beneath the fat and is a strong, off-white sheath that covers and protects the underlying muscles and helps prevent superficial infection from spreading to deeper tissues. The deep fascia must be closed to maintain its protective and functional roles.

Normal wound healing is a well-choreographed sequence of biologic events.[1] (1) These include coagulation, inflammation, collagen metabolism, wound contraction, and epithelialization. Maintaining

the balance of these events is crucial for normal healing. Delaying any of the stages may result in a weak closure and dehiscence. Prolonging segments of the process may affect the ultimate scar appearance.

Soon after tissue integrity is altered, the process of coagulation begins. Platelets release factors that initiate and enhance a response from inflammatory cells. Capillary permeability increases to allow white blood cells to migrate into the wound. Neutrophils and monocytes act as scavengers to rid the wound of debris and bacteria. Monocytes transform into macrophages, which seem to have a major role in subsequent healing phenomena. In addition to providing wound defense, macrophages release chemotactic substances, signaling other monocytes to stimulate fibroblast replication and trigger neovascularization.

Collagen is the principal structural protein of most body tissues. Normal tissue repair depends on collagen synthesis, deposition, and cross-linking. Fibroblasts synthesize and deposit collagen compounds 48 hours after injury. Immature collagen is highly disorganized and has a gel-like consistency.

After a series of enzymatic processes, characteristic fibrils are produced followed by intermolecular cross-links that bolster their strength. The entire process depends on tissue lactate and ascorbic acid and is directly related to tissue arterial carbon dioxide partial pressure. In the absence of vitamin C, prolyl and lysyl hydroxylase do not activate, and oxygen is not transferred to proline or lysine. Under-hydroxylated collagen is produced, and characteristic collagen fibers are unable to form. As a result, wound healing is poor, and capillaries are fragile. Without oxygen to hydroxylate proline and lysine, a local condition resembling scurvy occurs.

Under normal conditions, collagen synthesis peaks by day 7, coincident with rapid increases in tensile strength. The healing wound has the greatest mass at 3 weeks but remodels itself during the next 6 to 12 months. However, the wound achieves less than 15% to 20% of its ultimate strength by 3 weeks and only 60% by 4 months.

Wound contraction is the movement of whole-thickness skin toward the center of the skin defect. Immediately after injury, the wound edges retract and increase the size of the defect. Normal skin tension along the lines of minimal tension produces this retraction (Figs. 50.1 and 50.2). Wounds perpendicular to these lines are under greater tension and result in a larger scar.

During the next 3 or 4 days, the wound size shrinks as its edges move toward the center. This phenomenon is independent of epithelialization, and the presence of collagen is not necessary for it to occur. This process is considered beneficial to healing and should not be confused with contracture that results from scar shortening.

Contracture becomes more apparent when the normal healing process is prolonged often producing a disfiguring hypertrophic scar. Optimizing the duration of the inflammatory phase and minimizing wound tension help to produce a more "appealing" scar.

Epithelialization is a process whereby epithelial cells migrate across the wound. Mitosis appears at the wound edge near the basal cell layer within hours of injury. Eschar or other debris impedes this process. Epithelialization proceeds most efficiently when a wound is properly cleansed, debrided, and kept moist and protected.

In a surgically repaired laceration, epithelialization bridges the defect by 48 hours. The new tissue proceeds to thicken and grow downward, beginning to resemble the layered structural characteristics of uninjured epidermis within 5 days. Simultaneously, keratin formation loosens the overlying scab.

Various forces (lines of tension) exist as a result of skin elasticity from collagen fibers. These static forces may vary more than fivefold with the respective area of body skin surface, but the static tension of a given area of skin remains constant. These static forces are shown clinically by the gaping of wounds after incision. The magnitude of static skin tension is directly related to ultimate scar width.

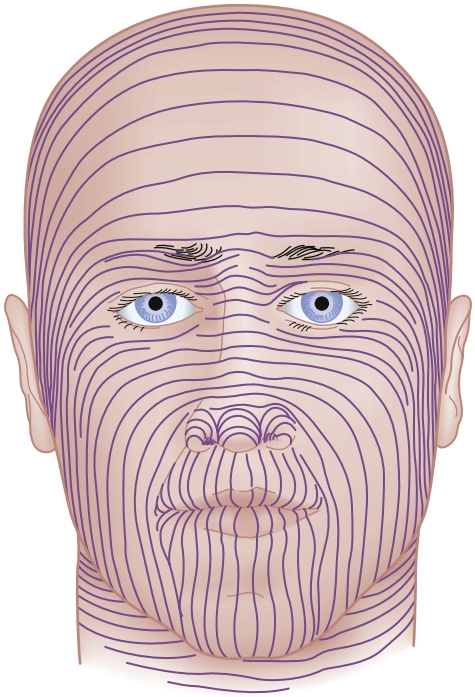

Fig. 50.1 Skin Tension Lines of the Face. Incisions or lacerations parallel to these lines are less likely to create widened scars than those that are perpendicular to these lines. (Adapted from Simon R, Brenner B. *Procedures and Techniques in Emergency Medicine*. Baltimore: Williams & Wilkins; 1982; as published in Trott A. *Wounds and Lacerations: Emergency Care and Closure*. 2nd ed. St Louis: Mosby; 1997.)

Uneven, jagged wounds have greater surface area than do linear lacerations. The skin tension distributed over a greater area is less per unit length of tissue. Meticulous reapproximation of the jagged edges results in a more appealing scar. Sharp debridement, converting a jagged wound to a linear laceration, is often unwise because it may result in too much tissue loss and produce a wider, more visible scar. Skin forces produced by muscular contraction and movements of flexion and extension influence healing and scar size. These dynamic forces are greatest where skin elasticity is necessary for function. Lacerations parallel to skin folds, lines of expression, and joints do not impair function or produce unattractive scars. Wounds that traverse the skin lines heal with conspicuous scars and may impair function. Knowledge of these lines and forces is necessary for optimal wound repair. In addition, the patient should be educated about wound healing and scarring potential.

CLINICAL FEATURES

History

A detailed history should be obtained as part of routine wound evaluation. Serious complications can result when basic information is not obtained. Wound care decisions may be changed if the patient has significant peripheral vascular disease, is immunocompromised, or has a high risk of a retained foreign body. Essential historical information includes past medical history, mechanism and setting of injury, and **tetanus** status.

Risk factors for wound morbidity include prolonged time since injury; crush mechanism; long (>5 cm) and deep wounds; patient age; high-velocity missiles; location on lower extremities; and contamination with saliva, feces, soil, or other foreign matter (Box 50.1).

Three hours after acute trauma, bacteria proliferate to a level that may result in infection. Standard wound care guidelines for routine

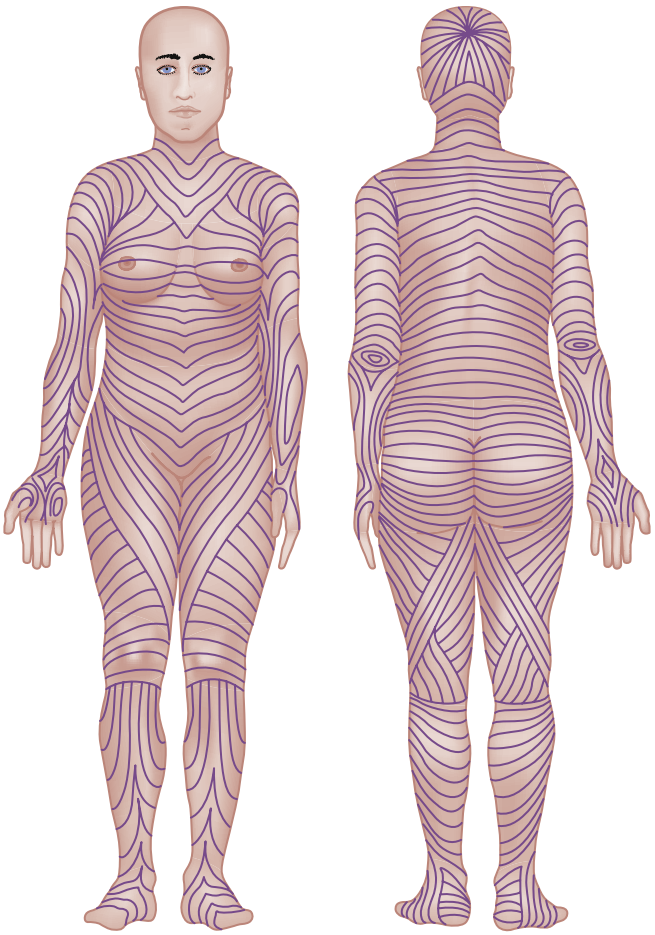

Fig. 50.2 Skin Tension Lines of the Body Surface. (Adapted from Simon R, Brenner B. *Procedures and Techniques in Emergency Medicine*. Baltimore: Williams & Wilkins; 1982; as published in Trott A. *Wounds and Lacerations: Emergency Care and Closure*. 2nd ed. St Louis: Mosby; 1997.)

wound care recommend closure within 8 to 12 hours of injury yet more recent data suggest that timing is less important than the other risk factors. All risk factors must be considered to optimize wound care, and flexibility is required. Lacerations produced by fine cutting forces resist infection better than crush injuries. Reduction of blood flow to wound edges in the latter may increase the infective concentration of bacteria by a hundredfold. High-velocity missile injuries produce damage remote from the missile tract. The extent of injury may not be apparent for several days. Clean, finely cut lacerations on the face may be safely closed in some patients 24 or more hours after injury, whereas blunt lacerations to the leg or thigh may be treated with delayed primary closure as early as 4 to 6 hours after injury. For sutured wounds, location has the strongest association with infection. Lacerations repaired on the leg and thigh may have an infection rate greater than 20%, those on the torso and other extremities greater than 10%, and those on the face and scalp less than 4%.

Optimal physical assessment of wounds requires patience, diligence, and an organized approach. Wound closure decisions involve an individualized approach for each laceration and patient. In addition to the history, host-specific data will influence management decisions: (1) immunocompetence of the host, (2) physical characteristics of the host (e.g., peripheral vascular disease), and (3) structural defects that invite bacterial seeding (e.g., damaged or prosthetic heart valves).

BOX 50.1 Risk Factors for Wound Infection

1. Location: Leg and thigh, then arms, then feet, then chest, then back, then face, then scalp
2. Contamination with devitalized tissue, foreign matter, saliva, or stool
3. Blunt (crush) mechanism
4. Presence of subcutaneous sutures
5. Type of repair: Risk greatest with sutures > staples > tape
6. Anesthesia with epinephrine
7. High-velocity missile injuries
8. Diabetes

Physical Examination

Physical examination errors are minimized with optimal visualization and anesthesia. When the injury occurs on an extremity, use of a sphygmomanometer may help to ensure a bloodless field. The blood pressure cuff is placed proximal to the injury, and the extremity is elevated above the heart for at least 1 minute. Exsanguinating the extremity may be hastened by wrapping the limb tightly with an elastic bandage, beginning distally and ending at the base of the cuff. The sphygmomanometer is inflated to a pressure greater than the systolic pressure of the patient. Although this process is uncomfortable at first, the cuff can safely remain inflated for 2 hours. Peripheral nerve blocks are often used if inflation is anticipated to be longer than several minutes.

Adequate anesthesia is required for a thorough wound examination. Subcutaneous tissues quickly reapproximate after injury, giving the appearance of a shallow wound. In addition, significant subcutaneous swelling lends to this appearance and renders examination of the laceration more difficult, as in wounds of the scalp and face. Careful probing and examination are needed to avoid missing damage to structures deep to the skin and subcutaneous tissue. This warning is more crucial for wounds on the distal aspects of upper and lower extremities. Finger lacerations are rarely gaping, but crucial structures (e.g., tendons, nerves, and vessels) are often damaged. The examiner must carefully pry the wound margins apart, ensure a blood-free field, and examine the tissues as the digit or extremity is placed through range of motion. The injured section of tendon may have been in a different state of tension and in a more proximal or distal location at the time of injury. Wounds that cannot be explored adequately and wounds with probable trauma to underlying tissues or with foreign matter require additional studies. A laceration can be extended if visualization of wound depth and extent is challenging.

Sterile gloves may not be a necessary part of wound closure. Although data are limited, one study found that the use of sterile gloves does not change infection rates. However, clean nonsterile gloves may be worn during wound assessment and closure to offer some protection for both the patient and the provider.

No single method can guarantee the identification and removal of all foreign matter from wounds. The key is to document all efforts and to explain to the patient the possibility of a foreign body. Physical examination with wound exploration will discover about 78% of foreign bodies; plain radiography will detect glass foreign bodies in about 75% of cases, metal in 99%, but wood in only 7%. Good documentation and follow-up can protect the patient as well as the health care provider.

DIFFERENTIAL DIAGNOSES

While a list of differential diagnoses is not required since the presence of soft tissue wound is self-evident, a differential list of causes is helpful as the mechanism can affect management decisions about closure technique, antibiosis and follow-up. Careful history-taking and visual

inspection are typically all that are required to differentiate high energy wounds from low energy injuries, determine whether contamination risk is high (e.g., cat bites) or low (e.g., laceration from a clean knife), or if foreign material is likely to be present.

DIAGNOSTIC TESTING

Standard radiography will not detect all foreign matter. The radiodensity of an object depends on the relative density of the matter and the adjacent tissue. Pieces of glass more than 1 mm thick are visible when appropriate views are ordered. Many organic substances, such as wood, are not visible on plain films, but specifically requested soft tissue views may increase the yield. A radiolucent shadow may be seen on close inspection because the foreign substance displaces tissue in its path. A computed tomography (CT) scan is excellent for identifying all foreign substances but is expensive and results in exposure to radiation. Ultrasonography is a good technique, but the small size of many foreign bodies and pockets of air, edema, pus, and some calcifications may produce confusing echoes, limiting its clinical usefulness. When simpler, standard methods fail to locate a foreign body that is likely or definitely present, we recommend that ultrasonography or a CT scan be performed.

MANAGEMENT

Anesthesia

After an appropriate neurovascular examination is documented, the involved tissue is anesthetized. Careful physical examination and thorough cleansing, irrigation, and debridement require that the patient be free of pain. Regional anesthesia may be preferable for wounds innervated by one superficial nerve. Injections along the wound margins produce swelling and further distortion of landmarks. With a regional block, more than one laceration may be repaired in the same nerve distribution without additional anesthesia. Lacerations on the face, hands, fingers, feet, and toes and in the mouth are often well suited for regional anesthesia.

Anesthetic Agents

Lidocaine and bupivacaine are the most common agents used for local and regional anesthesia. Both are safe and fast acting. For lidocaine, onset of action following direct infiltration occurs within seconds, and the effects last 20 to 60 minutes. When lidocaine is administered as a regional nerve block, onset occurs in 4 to 6 minutes and the effects generally last 75 minutes, although the block may remain effective for up to 120 minutes. A 1% lidocaine solution contains 10 mg/mL. It is safe to use 3 to 5 mg/kg, not exceeding 300 mg at a single injection. More volume can be added safely every 30 minutes. When epinephrine is added, the resulting vasoconstriction prolongs the effect for 2 to 6 hours, and the safe dose increases to 5 to 7 mg/kg. However, the addition of epinephrine has been shown to delay healing and lower resistance to infection. Lidocaine with epinephrine should be avoided in wounds with a high risk of infection and when tissue viability is of concern. Traditionally, epinephrine was not used in the fingers and toes because of the risk of vasoconstriction in small arterioles resulting in digital ischemia. However, literature from case studies in hand surgery suggests that with careful screening, epinephrine can be safely used in digital blocks. Digital artery vasospasm, accidentally induced by local injection of epinephrine, can be reversed successfully with a local injection of 0.5 to 2 mg of subcutaneous phentolamine or application of topical nitroglycerin.

Bupivacaine provides anesthesia that is equal to that of lidocaine. Onset of action is slightly slower than that of lidocaine, but the duration of anesthesia is four to eight times longer. These benefits suggest that bupivacaine is the preferred local **anesthetic** agent for the care of most wounds. In adults, the maximal reported safe dose is approximately 2 to 2.5 mg/kg without epinephrine and 3 to 3.5 mg/kg with epinephrine. The dose can be repeated every 3 hours, not exceeding a total of more than 400 mg in a 24-hour period. The maximal intraoral dose is 90 mg.

Local injection of lidocaine is best performed with a 27-gauge needle and slower injections are less painful. The rate of injection through a 30-gauge needle is too slow, and the thin needle is fragile and difficult to control. A 25-gauge needle is acceptable, but the more rapid injection can result in greater patient discomfort. The needle should be introduced through the cut margin to minimize the pain of the injection. Concerns of spreading bacteria into the adjacent uninvolved tissue and increasing the frequency and severity of wound infections are unfounded. Bicarbonate will buffer lidocaine and reduce the pain of injection. The shelf life of the lidocaine-bicarbonate mixture decreases, but it remains effective for 1 week at room temperature and for 2 weeks if refrigerated. Adding sodium bicarbonate in a 1:10 volume ratio to lidocaine (1 mL bicarbonate and 10 mL lidocaine) decreases the pain of injection without compromising the quality of anesthesia. A much smaller dose of bicarbonate is added to bupivacaine because the alkalinization results in precipitation. A 1:100 volume ratio (0.1 mL of bicarbonate and 10 mL of bupivacaine) has been found to be effective. Warming the anesthetic solution is also an effective means of decreasing the pain of injection.

Topical anesthesia can act synergistically with injectable agents. Studies show that a combination of lidocaine (4%), epinephrine (0.1%), and tetracaine (0.5%) (LET) can function effectively on skin lacerations, especially on the face and scalp. LET may be administered by soaking a cotton ball with 3 mL of the combined solution and applying it to the wound for 20 minutes. A gel formulation is available and may be preferred because it's easier to control and has less run-off which can inadvertently contact mucous membranes. The duration of action is 45 to 60 minutes following the removal of the gel from the wound. Toxicity is rare when the dose administered is less than 3 mL and mucous membranes are avoided. Potential toxic effects of lidocaine and tetracaine are related to the cardiovascular and central nervous systems. Cardiovascular effects may include dysrhythmias, decreased myocardial contractility, and cardiac arrest. Central nervous system toxicity may include headache, irritability, restlessness, blurred vision, and seizures. Topical anesthetics reduce repair time, preserve landmarks, and improve patient (and family) satisfaction. If additional anesthesia is required, the pain of the subsequent injection is lessened by the topical anesthesia.

Although LET has been found to be very safe, weight-based dosing has been recommended for children weighing less than 17 kg. Administering a maximum of 0.175 mL/kg of LET will prevent the application of more than 5 mg/kg of lidocaine. No cases of methemoglobinemia have been reported, but given the small risk associated with tetracaine extra caution is advised in neonates.

Tetracaine, adrenaline (epinephrine), and cocaine (TAC) was the original topical anesthetic solution. This combination is as effective as LET on the face and scalp and more effective elsewhere on the body, but the higher risk of complications and the complexities tied to handling cocaine limit its utility. Dripping 1% lidocaine into mucosal lacerations was demonstrated to be effective in one small case series, an interesting painless alternative that deserves further investigation.[2]

Eutectic mixture of local anesthetics (EMLA) is a cream used to produce anesthesia of wounds and intact skin. The active ingredients are lidocaine (2.5%) and prilocaine (2.5%). The micron-sized particles of the cream are designed to penetrate the skin and lessen the pain of needle penetration. Studies have demonstrated efficacy in venipuncture, immunization administration, lumbar puncture, and laceration

repair. Peak effect is seen at 1 hour and continues for 30 to 60 minutes after removal of the cream.

Allergy

Allergy to local anesthetics is uncommon. Two distinct groups of "caine" anesthetics exist. The esters include procaine, tetracaine, and benzocaine. The second group, including lidocaine and bupivacaine, belong to the amide family. Allergy to the esters is uncommon. True allergy to agents in the amide family is rare.

The subject of allergy is further complicated because multi-dose vials contain the preservative methylparaben, an ester structurally related to anesthetics in the ester family. Allergic reactions to lidocaine or bupivacaine may be a reaction to this preservative. Single-dose, preservative-free vials of lidocaine and bupivacaine should be standard stock in every emergency department (ED).

When allergy to a local anesthetic is known or strongly suspected, alternatives are available. No cross-reactivity occurs between the amide and ester families, so an agent from a different group may be chosen. If clarification is required, a test dose of 0.1 mL may be administered intradermally before proceeding. The patient is then observed for 30 minutes before proceeding. As with any allergy testing, the emergency clinician should be prepared to treat all complications. Injectable diphenhydramine (1%) has also been shown to provide effective local anesthesia.

Skin Preparation

Disinfection of the skin (not the wound itself) may be accomplished with several different agents. The ideal agent is fast acting and has a broad spectrum of antimicrobial activity and a long shelf life. Povidone-iodine (Betadine) and chlorhexidine (Hibiclens) have all three characteristics. Although excellent as skin disinfectants, both products are toxic to wound defenses and may increase the incidence of wound infection. Avoid spilling these substances into the wound. Povidone-iodine is effective against gram-positive and gram-negative bacteria, fungi, and viruses. Chlorhexidine is less effective against gram-negative bacteria and its efficacy against viruses is unknown. Eye exposure to these agents can be detrimental. Chlorhexidine has been shown experimentally and in case reports to produce serious permanent corneal opacification. Current data suggest that chlorhexidine-alcohol preparations are safe and more effective at limiting infection compared with povidone-iodine solutions.

Body, facial, and head hair is usually removed to clean and examine a wound, although this is not necessary to reduce the risk of wound infection. Hair removal makes it easier for the patient to keep the area clean and ultimately facilitates accurate suture placement and subsequent removal. Exceptions include parts of the body where hairlines provide important landmarks for the accurate reapproximation of tissue margins, most notably the eyebrow. Eyebrow hair should not be shaved since regrowth may be inconsistent or absent.

Surgical studies show that hair removal with a razor is three to nine times more likely to result in a wound infection than clipping the hair. The razor damages the infundibulum of the hair follicle and provides access for bacterial invasion and infection. For wounds at high risk of infection, clipping may be done with electric shears or scissors. Another option is application of a petroleum-based product to the hair adjacent to the wound margins, allowing the provider to keep the hair away from the surgical field.

Wound Preparation

Debridement

Debridement is the removal of foreign matter and devitalized tissue from the wound. With respect to ultimate wound healing and risk of infection, debridement remains the most important step in wound care. Devitalized wound tissue delays healing and significantly increases the risk of infection. The benefits of debridement, however, are weighed against the consequences of producing a larger tissue defect. Higher tension in the resultant closure may result in a wider scar. Skin edges that are clearly devitalized are debrided before wound closure. On the trunk, where there is little concern for specialized tissue, wide excision and debridement are feasible. On the face and hands, where as much tissue as possible must be saved, the process is more difficult. Meticulous sharp excision of small fragments of nonviable tissue is performed only by experienced clinicians. When the viability of large areas of skin or muscle is a significant concern, the wound should be prepared for delayed primary closure.

Wound Cleansing

An ideal wound cleanser has broad antimicrobial activity with a rapid onset. It is nontoxic to the tissue and does not reduce tissue resistance to infection, delay healing, or decrease the tensile strength of the healing wound. Many antiseptic solutions have been used clinically yet, despite multiple studies, there is still debate regarding which agent comes closest to possessing these qualities. Povidone-iodine in various concentrations, saline, and, more recently, tap water have received the most attention.

Evidence suggests that a 0.9% normal saline solution or tap water are effective irrigants when used with high-pressure syringe irrigation. While saline has been the traditional wound-**irrigating** fluid of choice, tap water has consistently shown equivalent rates of infection and cosmetic outcomes. Tap water irrigation allows a large volume of irrigation rapidly and inexpensively and is especially suited to upper extremity and scalp injuries.

Free iodine, although possessing broad, rapid antimicrobial activity, is too tissue toxic to have therapeutic value in the open wound. Iodophor is a complex of iodine with a carrier to increase its solubility and decrease the availability of free iodine. The most widely used iodophor is povidone-iodine, in which the carrier molecule is povidone (formerly polyvinylpyrrolidone). It is available in a 10% solution, which is 1% free iodine. It is well documented that even a 5% povidone-iodine solution is toxic to polymorphonuclear neutrophil leukocyte activity and may increase the infection rate. A 1% solution is safe and effective with little or no toxicity. Detergent-containing cleansers, such as povidone-iodine scrub, may be excellent for skin preparation but are toxic to tissue defenses and should never be allowed to contaminate open wounds.

Although many different irrigation solutions may be beneficial, the key to cleansing is high-pressure irrigation rather than the type of solution used. Tap water is the preferred wound irrigation solution, because it is safe, effective, requires no preparation, and is less expensive than other options.[3] Distilled water is preferred to tap water for nasal irrigation.

Irrigation

The quality of mechanical cleansing is one of the most important determinants of wound prognosis. The most effective form of wound cleansing is high-pressure irrigation. Irrigating with pressures greater than 7 pounds per square inch (psi) significantly decreases bacterial counts and the incidence of infection. Several commercial devices are available; however, one can be made by attaching an 18-gauge needle to a 30-mL syringe which will yield a force of 7 or 8 psi. High pressures of 50 to 70 psi may be obtained with a commercial water pick. These pressures may cause some tissue damage, but the beneficial effect of reduced bacterial load and debris outweighs this risk. Simply soaking the wound in an antiseptic solution is not beneficial and may be harmful. Scrubbing the wound with a sponge with large-pore cells inflicts tissue trauma and impairs the ability to resist infection. Using a sponge

with a fine pore cell size will decrease tissue damage. Adding a surfactant further minimizes mechanical trauma. Flooding the wound under low pressure via a bulb syringe or gravity alone does not reduce the incidence of infection, regardless of the agent used.

At least one study has shown little benefit to any irrigation in facial and scalp lacerations. This study prospectively compared outcomes of almost 2000 immunocompetent patients. Infection rates and cosmetic outcomes were similar in the irrigation and non-irrigation groups. We recommend irrigation only for scalp wounds more than 5 cm long and those with other high-risk features.

Wound Closure

Decision-Making

The first determination required is whether the wound should be treated open or closed. Each wound, patient, and clinical circumstance must be handled individually. Most wounds have a low risk of infection and can safely be closed primarily. A small study from Europe failed to show a difference in infection risk for wounds sutured greater than 6 hours after injury compared with those sutured in less than 6 hours. At the other end of the spectrum, some wounds must never be closed at the time of the initial ED visit. A large stellate laceration to the foot produced by blunt force and contaminated with dirt and grease must be cleaned and left open to be closed later. Human and animal bites to the hand are additional examples of wounds that should not be closed primarily given the high rate of infection. Physician judgment is often the best method for deciding when it is safe to close a wound. In one study in which hand wounds were described as dirty, 22% became infected. When the injury was documented to be clean, the incidence of infection was 7.1%.

Three wound closure options are available. The wound may be (1) closed primarily in traditional fashion, (2) closed in 4 or 5 days (delayed primary closure), or (3) left open and allowed to heal on its own. A safe alternative to traditional primary closure, delayed primary closure does not change overall healing time and the risk of infection is greatly decreased if proper technique is used. When a wound is slated for delayed primary closure, it is prepared, debrided, and irrigated in the same manner as for immediate closure. Initially, the wound is packed with sterile gauze to prevent it from closing on its own. If the wound is on an extremity, the injury is splinted and dressed, and appropriate wound care instructions are provided. The patient returns for a wound check and packing change in 24 hours and is instructed to follow up in another 72 hours for definitive repair, with wound closure undertaken 96 to 120 hours after injury. No studies offer guidelines for prophylactic antibiotic use when delayed primary closure is the treatment option. Extrapolation from other wound studies strongly suggests that **antibiotics** offer no benefit.

Individuals who do not seek medical care after an injury select the option of leaving a wound open to heal on its own. Most patients who visit an ED with a laceration undergo some form of wound closure. Yet one study that examined unsutured hand lacerations less than 2 cm long found that there was no significant difference in cosmetic appearance or time to resumption of activities of daily living after 3 months.

Closing a wound loosely is not a good choice although it is often discussed as an option in the treatment of contaminated wounds. This choice should rarely be considered. The loosely closed wound approximates the tissue margins enough to allow the wound to seal itself completely within 48 hours. The infection risk when this method is used is the same as when the wound is closed traditionally.

Wound Tension

The goal of wound closure is optimal anatomic and functional reapproximation of tissue with minimal risk of complications. Wounds with high static and dynamic tension that require meticulous closure cannot be closed with tape or staples. Delicate approximation of wound edges under tension can be accomplished only with suture.

Several techniques may be used to reduce wound tension. Deep sutures placed in subcutaneous tissue help bring the wound margins closer together. In this manner, forces on the skin are reduced and potential dead space can be closed. Avoid suturing adipose tissue because it may become necrotic, increasing the likelihood of infection. The number of dermal sutures depends on the characteristics of the wound. In general, the number should be kept to a minimum, because suture material acts as foreign matter in the wound and can increase the risk of infection. Subcutaneous sutures are rarely placed in the hand or foot because of the major structures that reside near the surface. Another method of ameliorating static tension from cut edges of the wound is to undermine at the lacerated margin. Undermining helps free the dermis from its deeper attachments, allowing the skin edges to be approximated with less force. It is crucial to preserve the blood supply to the wound margins and not increase dead space in the process.

Suture Technique

Careful surgical technique is important to optimize wound repair. Pickups, hemostats, and pointed or "rat tooth" forceps should not be used, especially on wound margins. Blind clamping in a wound can damage a nerve, artery, or tendon. Wound margins should be everted and the sutures tied just tightly enough to allow the edges to approximate lightly. The edges can be everted by ensuring that the needle enters and exits perpendicular to the skin. Wounds with opposing margins of different thickness can be difficult to close. If this difference is not considered and corrected, the ultimate scar has uneven margins that cast a shadow on the skin and is unsightly. In closing these wounds, the needle is pulled through the cut margin of one side before entering the opposite edge. This method gives the emergency clinician the best opportunity to take an equivalent amount of tissue on both sides of the wound. Viable edges of a jagged wound must be meticulously reapproximated. The greater surface area and the ultimate contraction of the wound preserves the jagged edges, resulting in a more "natural" scar.

Most lacerations are closed with running or interrupted percutaneous suture. The running technique is appropriate for linear lacerations under minimal tension when there is a low risk of infection. This technique is more rapid, requires less suture material, and yields equivalent cosmetic results. Curvilinear or jagged wounds are best closed with interrupted sutures to distribute tension properly. The tensile strength of interrupted sutures may be superior and wound edges subjected to higher levels of tension should be closed with this technique.

Simple sutures. Wound closure with simple interrupted sutures is the most common method of laceration repair in the ED and the majority of wounds can be closed with this technique. Simple interrupted sutures yield excellent cosmesis and a low infection rate.

Procedure. The needle is placed to one side of the laceration margin and enters the skin at approximately 90 degrees. To pass the needle through the tissue, the clinician supinates his or her wrist and guides the needle deep but parallel to the skin surface. Wrist supination is extended as the needle exits the skin on the opposite side perpendicular to the surface. The distance between the laceration margin and the entrance and exit sites of the needle needs to be equal to avoid asymmetric skin puckering. Proper technique produces wound edges that are slightly everted and are lightly touching. The art of the process takes into consideration swelling while being careful not to secure the suture too tightly, because necrosis of the wound margin tissue can seriously compromise healing.

Intradermal (buried) sutures. Placing cutaneous sutures in wounds under tension can lead to ischemia of the wound margin and an

unsightly scar. Proper placement of absorbable buried intradermal sutures helps to approximate dermal margins and reduce wound edge tension. Buried sutures should not be used in contaminated wounds because they increase the risk of wound infection. Sutures through adipose tissue also increase infection and do not relieve skin tension.

Procedure.. Placement of buried sutures differs from traditional suturing because of the need to bury the knot deep to the skin. Failure to do this can interfere with dermal healing and can leave a small lump under the surface of the skin. The needle is introduced deep in the wound in the subcutaneous tissue and emerges from the dermis below the skin surface. The needle is reintroduced in the dermis on the opposite wound margin and emerges from the subcutaneous tissue at the same level on the opposite side. The knot is secured and remains buried deep below the skin surface.

Scalp laceration repair. In contrast to small lacerations elsewhere on the body, most scalp lacerations require repair because of the propensity to bleed profusely. The dense connective tissue beneath the skin tends to hold vessels open and delay hemostasis. Frontal scalp lacerations just beyond the hairline should be considered cosmetically significant wounds, especially in men. Although the scalp laceration currently may be well hidden by hair, most men experience some balding. Explore the laceration thoroughly to look for a defect in the galea, an injury that requires repair with deep sutures. Staples may be ideal for the skin closure of simple linear scalp lacerations. Hair is less of a problem in placing staples; staples can be placed much more quickly than traditional sutures, are easier to see, can be removed 1 to 3 days earlier than traditional sutures, and yield cosmetically similar results (Fig. 50.3). Staples may produce artifact on CT scans, but useful information may still be obtained if CT is necessary. Staples may move during magnetic resonance imaging (MRI) and should not be placed if this imaging modality is being considered. Lightweight stapling devices are available. Most devices come preloaded with five or more staples and are easy to use. Hair apposition may also be an option for many scalp wounds. The technique involves grabbing a bundle of hair on both sides of the wound and then twisting the hair bundles with a hemostat. A small dab of cyanoacrylate glue is applied to the twisted hair to prevent unraveling. Patient satisfaction is high with this approach.

Traditional sutures are used to repair most scalp lacerations, usually with standard nylon suture. Absorbable chromic gut can be used in children and in adults who may not return for suture removal.

Procedure. Anesthesia with epinephrine is recommended to help control bleeding. Hair removal is necessary only if the hair makes closure difficult. A defect in the galea is closed first with 3-0 or 4-0 absorbable suture. Failure to repair the galea can lead to cosmetic deformity related to frontalis muscle function. Linear superficial scalp lacerations that do not require deep sutures can be closed with staples or with monofilament nylon sutures applied with a simple interrupted

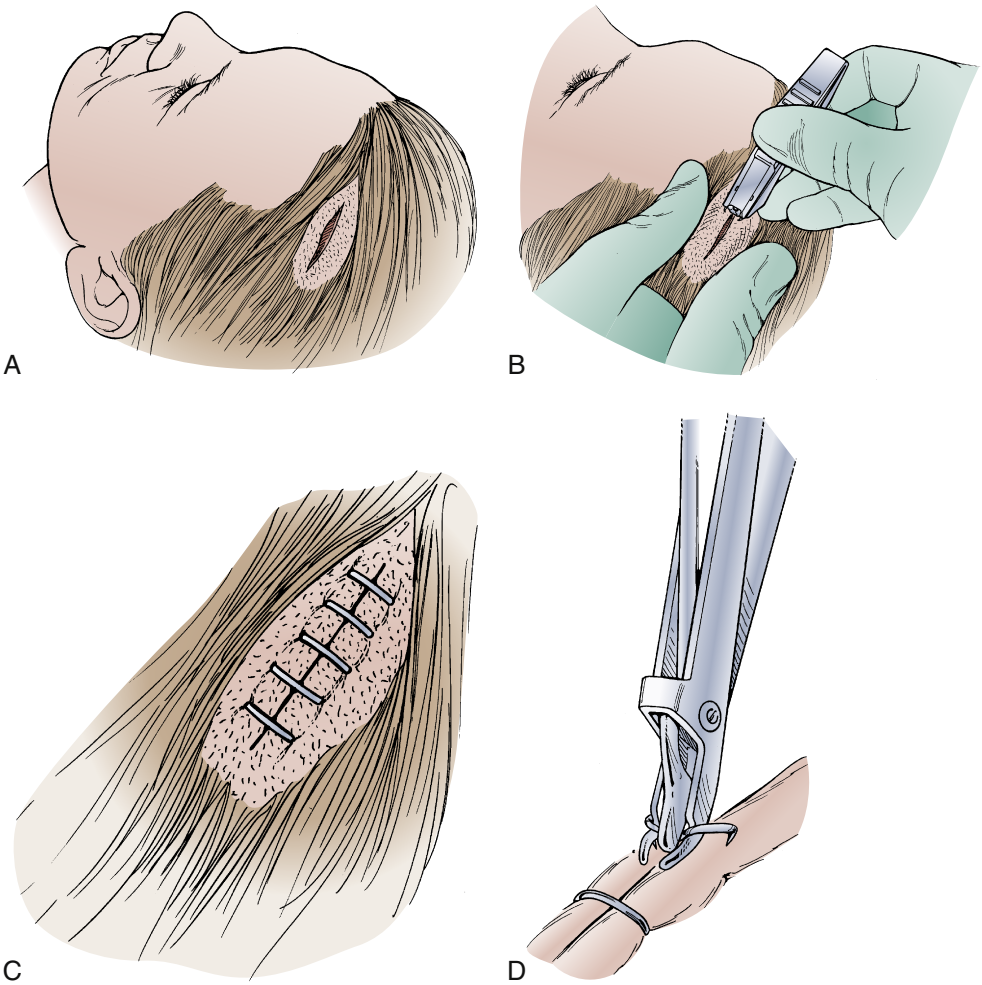

Fig. 50.3 (A–D) Scalp laceration repair. (Adapted from Simon BC. Skin and subcutaneous tissue. In: Rosen P, et al., eds. *Atlas of Emergency Procedures*. St Louis: Mosby; 2001.)

or running technique. Jagged or macerated lacerations may require some debridement and horizontal mattress sutures. To staple a scalp laceration, the adjacent skin margins are pinched together with forceps to evert wound margins. The "mouth" of the stapler is placed gently on the skin surface, taking care not to indent the skin. The handle of the stapler is squeezed carefully to eject the staple into the tissue. Ideally, the staple closely approximates the wound margins without indenting the surface of the skin. For release of the staple, the wrist is pulled back to disengage itself from the last staple.

Vigorously bleeding scalp lacerations often need temporizing measures to control bleeding while the patient is being evaluated and resuscitated. An anesthetic agent with epinephrine is typically used to help control bleeding. Blindly clamping in an attempt to control bleeding is unwise and not likely to be successful. Raney scalp clips can be rapidly applied to the wound margins to quickly gain control of the bleeding. An applicator is used to apply and remove the clips so that they can be replaced with sutures once the patient has been stabilized. The clips are plastic and will not interfere with CT or MRI.

Staple removal is simple, especially if the patient has kept the wound clean and free of dried secretions. The dual prongs on the disposable staple remover slide under the staple crossbar. As the handle is squeezed and the horizontal aspect of the staple is depressed, the sharp edges are eased out of the tissue for removal.

Skin tears. Most commonly seen in elders and the chronically ill, skin tears can be a treatment dilemma for emergency clinicians. These tears are caused by shearing forces that separate the epidermis from the underlying dermal layer of the skin. Often the result of minor trauma, these injuries range from minor tears to large gaping wounds with extensive loss of tissue. Approximating the wound margins by aligning thin, fragile tissue can be very difficult. Studies have confirmed that the use of Steri-Strips and or topical skin **adhesive**s (cyanoacrylate-based derivatives; see later) is the preferred option.[4] Either material may be used alone; however, when tension exists, placing the Steri-Strips first, then the adhesive, may be the optimal approach. Care must be taken in deciding what type of dressing to use. Transparent films can cause fluid to collect and delay healing. Additionally, adhesives are difficult to remove and can cause additional tearing. If the wound must be covered, then hydrogel sheets, hydrocolloid dressings, or both are recommended.

Vertical mattress sutures. Vertical mattress sutures improve wound edge eversion. They are also used to close gaping wounds and deep lacerations that may need more than simple sutures to limit dead space. Areas of lax skin tension, generally where maximal skin mobility is needed (e.g., over joint surfaces), may need assistance to ensure eversion of the wound margins. Vertical mattress sutures can accomplish both tasks.

Procedure. A vertical mattress suture technique is a combination of deep and superficial components. The needle is introduced at a 90-degree angle approximately 1 cm from the wound margin. The needle courses through the depth of the wound and emerges on the opposite side, 1 cm from the laceration margin at a 90-degree angle. The needle is reintroduced 1 or 2 mm from the epidermal edge at the depth used for simple sutures, then carried to the opposite side, introduced in a similar location and then tied for final approximation.

Horizontal mattress sutures. Horizontal mattress sutures are useful to help disperse excess skin tension and to evert wound edges. The scalp, which has minimal skin mobility, is one area where gaping lacerations may benefit from this method. Horizontal mattress sutures may also be beneficial in thin, fragile skin in elders and for lacerations that have lost tissue from the injury or debridement.

Procedure. The initial step is to pass the needle as for a simple interrupted stitch (Fig. 50.4). On exiting the skin, however, the needle is reintroduced approximately 0.5 cm adjacent to the exit point. This second "bite" reemerges 0.5 cm adjacent to the initial insertion point and is tied. Unlike with vertical mattress sutures, each bite is always the same distance from the wound margin.

Dog-ear deformity repair. Redundant tissue may be left on one side of the repair as the closure nears completion, especially with curvilinear lacerations. This redundant tissue generally can be avoided by placing the initial suture in the middle of a curvilinear wound. If the clinician has limited experience, excision and undermining of tissue are likely to result in complications and should not be attempted.

Procedure. The laceration repair begins in a traditional manner and continues to approximately the final 1 cm of the wound (Fig. 50.5). A short incision (approximately 1 cm) is made from the end of the laceration at a 45-degree angle. The angle is cut toward the side of the redundant, bunched tissue. In most cases, the subcutaneous tissue from the start of the dog-ear defect to the newly created end of the wound must be gently undermined to mobilize the skin. The next step, the final step before suturing, is the most important. The work that has just been completed leaves a small triangular piece of excess tissue. The redundant piece is gently lifted with the tissue forceps and excised in a line parallel to the incision made above. The wound can then be closed with simple interrupted suture technique.

Corner stitch (half-buried horizontal mattress sutures). Jagged and triangular wounds create corners that can be difficult to repair. The clinician must avoid placing the suture directly in the tip of the flap, as this practice may "stretch" the tissue and further compromise blood flow to the wound margin. The corner stitch allows optimal tissue approximation with minimal tension.

Procedure. The needle is introduced percutaneously through the non-flap side of the wound a few millimeters from the corner of the wound (Fig. 50.6). The needle is passed horizontally through the dermis of the flap. The final step is to pass the needle into the dermis of the non-flap aspect of the wound a few millimeters from the opposite side of the corner. The suture is led out through the epidermis and tied. This technique can also be used to encompass multiple flaps either individually or simultaneously if the tips are adjacent to one another. The most difficult, but crucial, aspect of the corner stitch is to take bites of equal depth with each pass of the needle. Failure to take equal bites of tissue results in a wound with opposing sides that do not lie flat; this leads to a more obvious scar. When the corner has been repaired, the remaining two sides of the wound may be closed with simple interrupted or running suture technique.

V-Y wound closure. The V-Y closure is indicated for the repair of V-shaped wounds with tissue loss or with nonviable margins that must be trimmed. The tissue loss is such that the adjacent mobile tissue is not sufficient to close the remaining defect.

Procedure. Nonviable tissue is trimmed with fine iris scissors (Fig. 50.7). The long V-shaped portion of the wound is sutured with simple interrupted percutaneous stitches. This first step brings the tip of the flap closer to the newly created corner of the wound. A corner stitch is used to secure the tip of the flap. The remaining limbs of the Y are repaired with simple interrupted stitches. Some degree of undermining is likely to be needed to mobilize tissue to close the defect. Debridement of too much tissue can make the final repair more difficult and distort adjacent anatomy.

Materials

In the Middle Ages and earlier, materials used to close wounds included flax, hemp, fascia, hair, linen strips, pigs' bristles, reeds, grasses, and even the mouth parts of the pincher ant. In the early 1900s, natural organic protein products, including silk, cotton, and catgut, were the only available substances. Polyester (Dacron) and nylon were the first

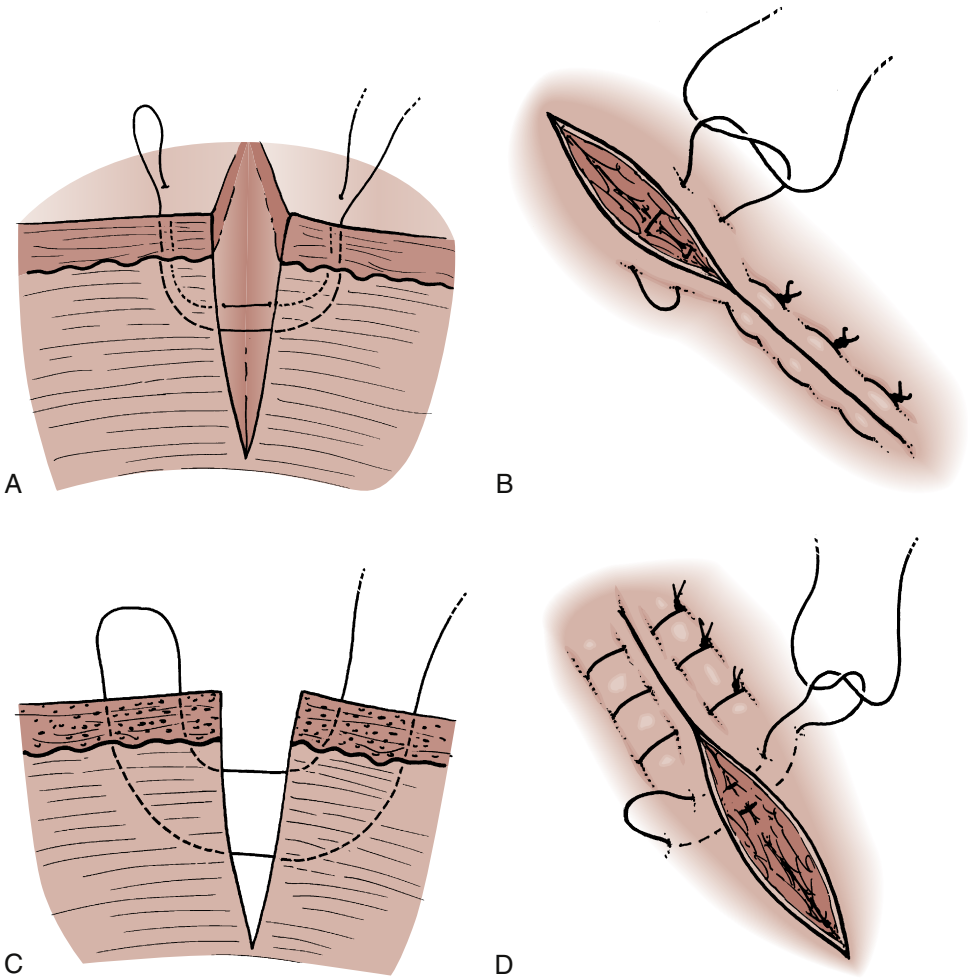

Fig. 50.4 (A–D) Mattress suture. (Adapted from Simon BC. Skin and subcutaneous tissue. In: Rosen P, et al., eds. *Atlas of Emergency Procedures.* St Louis: Mosby; 2001.)

synthetic materials, available in the 1940s. Since then, a host of other synthetic materials have become available.

Suture. The ideal suture is inert to metabolism, resistant to infection and inflammatory reactions, has great tensile strength, does not tear tissue, is easy to work with and tie, and is available in convenient colors with a variety of cutting and noncutting needles. A common classification of suture material relies on relative *absorbability.* In general, the materials that maintain their tensile strength for more than 60 days after implantation have been defined as *nonabsorbable.* Materials that undergo rapid degradation in tissue and lose their strength in less than 60 days are considered *absorbable.* A second classification considers the source and nature of the material. *Biologic* substances, which include catgut, collagen, silk, linen and cotton, generally produce the greatest tissue reaction (and scarring)and have the lowest relative tensile strength but the highest knot security. These characteristics are in contrast to *synthetic* materials, such as polyester (Dacron), polyamide (nylon), polypropylene (Prolene), polyglycolide and polylactide polymers (Dexon and Vicryl), polydioxanone (PDS), and steel, which usually have less tissue reactivity, greater strength, but less knot security.

Knotting properties and handling characteristics tend to vary inversely. Knot security is of particular importance in maintaining wound closure and the patient's confidence in the physician. Sutures with smooth or slippery surfaces produce little friction, glide effortlessly through tissue and are easy to tie. Smoother materials are more difficult to handle and more likely to untie spontaneously. Certain monofilament synthetic materials tend to return or spring back to their original shape. To overcome this suture memory, the first part of the tie should be a "double throw" pulled tightly enough to approximate the tissue, with care taken not to strangulate the margins. The second throw locks the tension of the first part into position. A third throw is used for added security. If this is done properly, additional knotting is not needed after the third throw.

The presence of any suture material in a wound increases the likelihood of infection. Subcutaneous sutures bear the greatest risk. The degree of risk depends on the characteristics of the substances used. Braided multifilament materials, such as the polyesters, polyamides, polyglycolides, and silk, yield the highest infection rates, whereas monofilament synthetic substances have the lowest risk of infection. There are several nonabsorbable monofilament synthetic sutures and one absorbable monofilament (PDS). The degree of infectivity of PDS compares well with the low rates of infectivity of similar materials.

Patient comfort in suture selection is important. Although silk is highly reactive, it ties well, is easy to handle, and is comfortable for the patient. It is an excellent choice for use in and around the lips, where comfort is a major concern. PDS is a comfortable absorbable suture and can be left in intraoral mucosa to be absorbed, with low risks of infection, or it can be removed in 5 to 7 days. Staples or metallic sutures are excellent when strength is needed, but they may be uncomfortable for the patient and thus better placed in less sensitive areas such as the

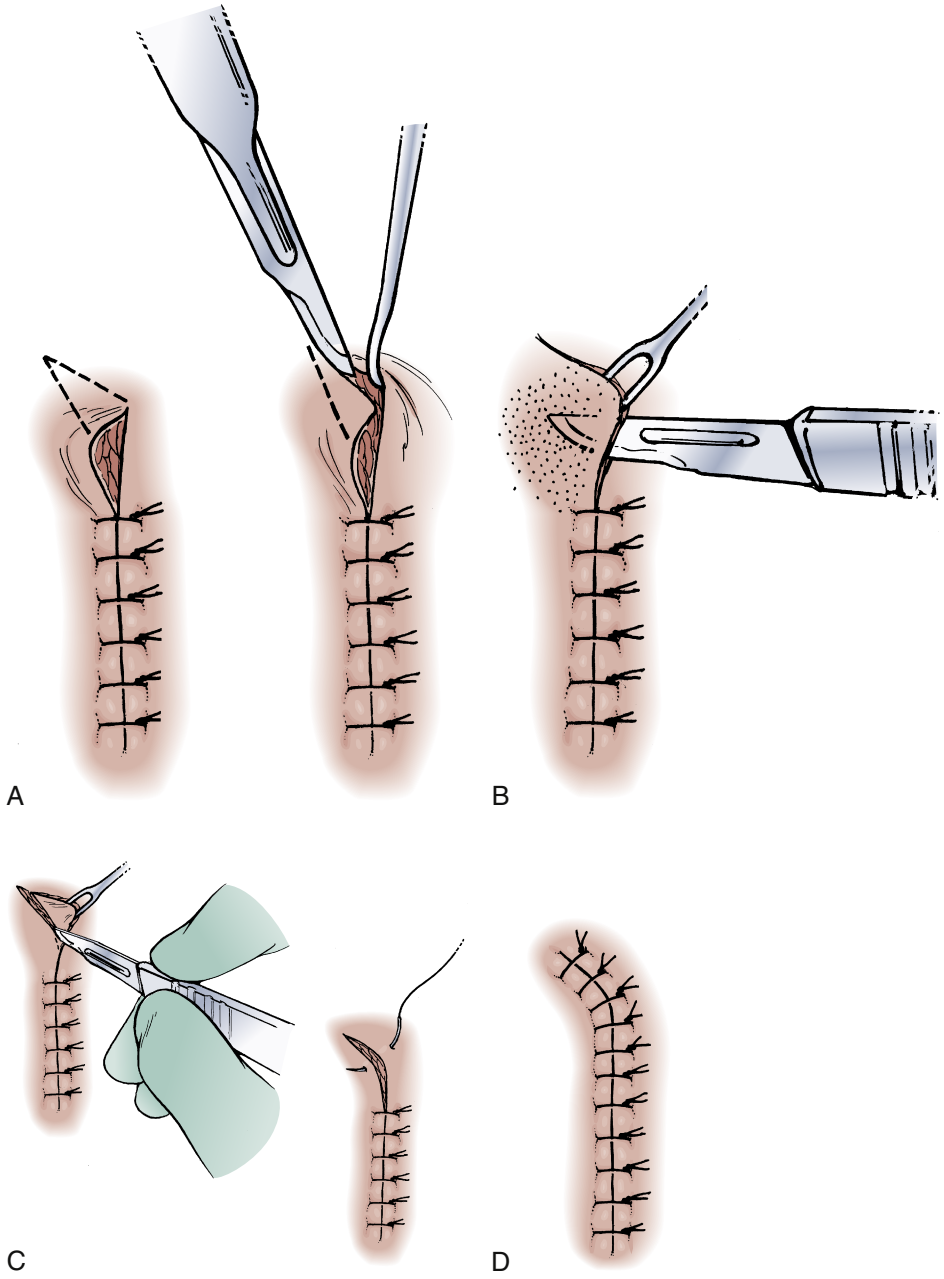

Fig. 50.5 (A–D) Dog-ear repair. (Adapted from Simon BC. Skin and subcutaneous tissue. In: Rosen P, et al., eds. *Atlas of Emergency Procedures.* St Louis: Mosby; 2001.)

scalp. Nylon and polypropylene, which are the most common sutures used on skin, produce little tissue reaction and offer good tensile strength. They tend to be stiff, produce discomfort near the lips, have poor knot security, and may be difficult to work with. A braided, coated polyester nonabsorbable material, such as Ethibond, is easier to work with and has better knot stability. Although Ethibond is more expensive than nylon, its characteristics and added patient comfort suggest that it may be preferable unless the laceration is in a cosmetically sensitive area, since braided suture incites a more vigorous inflammatory reaction compared to monofilament material. Absorbable sutures, such as polyglycolide and polylactide polymers (Dexon and Vicryl), have been used strictly for subcutaneous and mucosal closures. Their highly reactive nature allows them to be broken down and absorbed over weeks. Chromic catgut, another absorbable material, has been shown to be safe and effective for the closure of scalp wounds in children.

Needles. Surgical needles are available in a variety of sizes and shapes with myriad other characteristics. Cutting needles may be reverse cutting, conventional cutting, taper cut, or precision point. Most emergency wounds can be closed with a conventional cutting needle. In addition to its sharp point, it has two opposing cutting edges, with a third on the inside curve. Precision point needles are similarly shaped but are honed 24 extra times to maintain their sharpness longer. These needles are used for delicate plastic or cosmetic surgery. Noncutting needles are reserved for organ repair and subcutaneous suturing. Cutting needles may also be used to repair subcutaneous tissue. Needle nomenclature is confusing and varies by manufacturer.

Tape. Tape closure may be superior to closure with sutures and staples if applied in the appropriate circumstances. In general, the laceration should be linear and subjected to weak static and dynamic forces. Tape is not considered for wounds requiring meticulous

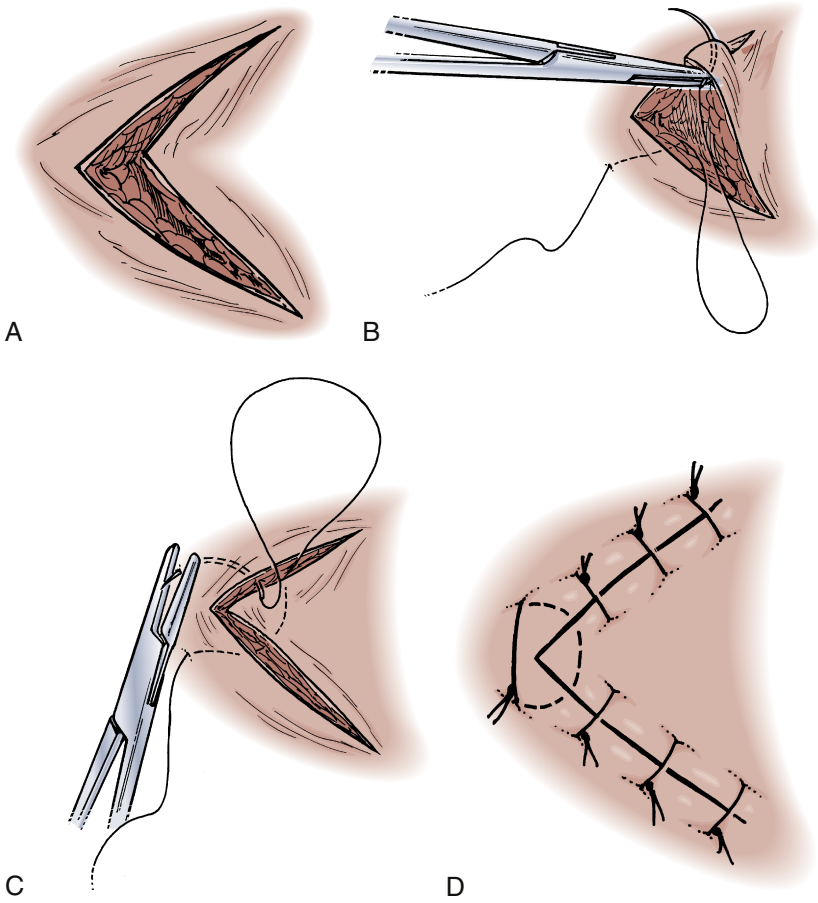

Fig. 50.6 (A–D) Corner stitch (half-buried horizontal mattress). (Adapted from Simon BC. Skin and subcutaneous tissue. In: Rosen P, et al., eds. *Atlas of Emergency Procedures*. St Louis: Mosby; 2001.)

tissue approximation. Compared with other closure materials, tape is associated with a lower risk of infection, less expense, and less physician time. In addition, injectable local anesthetics are not needed.

The ideal wound closure tape allows water and gas exchange and possesses elasticity, strength, and optimal adhesiveness. To maximize adhesiveness, tincture of benzoin is painted on the skin adjacent to the wound and care is taken to avoid introducing benzoin compound in the wound. A nonwoven, microporous tape, which is not reinforced, has been found to best meet these requirements.

Staples. Staples offer several advantages over sutures. Monofilament stainless steel staples offer less risk of infection than even the least reactive suture. The time necessary to accomplish closure may be significantly lessened. Acceptable wounds must be linear and subjected to weak skin forces. Wounds requiring accurate approximation of tissue are not candidates for staple closure. Staples are also uncomfortable while in situ and on removal. Stapled wounds gain tensile strength sooner, and the staples can be removed 1 to 3 days earlier than sutures. After removal, the staples should be replaced with wound closure tape for continued reinforcement.

Various stapling devices are available. The device must allow good visual access and flexible positioning for difficult angles. A pre-cocking mechanism is necessary to allow the physician to hold the staple securely during its placement. The angle of staple delivery is important. One brand releases the staple perpendicular to the wound with its crossbar flush with the skin; this can result in cross-hatching on the skin or tissue strangulation if placed too deeply. The device needs an ejector spring for smooth staple release and must be able to be handled without producing fatigue.

Tissue adhesives. European and Canadian physicians have used tissue adhesives (butyl-2-cyanoacrylates) for many years. In 1998, octyl-2-cyanoacrylates were approved for use in the United States. Tissue adhesives offer many advantages over traditional sutures. The adhesive can be applied quickly and easily with a minimum of patient discomfort. In addition, suture removal in 7 to 10 days is unnecessary because the adhesive sloughs off the skin in approximately the same amount of time. Adhesives not only provide their own dressing but also have antibacterial properties and may decrease the rate of wound infections. Closing wounds with adhesives is less expensive than traditional suturing and carries no risk of needle-stick injuries.

Tissue adhesives achieved cosmetic results similar to those of traditional sutures in randomized trials. Tissue adhesive may be applied in high-tension areas, but only if used in conjunction with subcutaneous or subcuticular sutures. If used alone, tissue adhesives are not recommended for lacerations longer than 4 cm or in areas of higher tension or frequent repetitive movements, such as joints or hands.

Other disadvantages of tissue adhesives include the inability to use antibacterial or other petroleum-based products on the wound; the recommendation not to swim and to limit forces that may prematurely remove the adhesive; and the greater risk of dehiscence. The tensile strength of tissue adhesives is significantly less than that of sutures. Despite these disadvantages, tissue adhesives represent a tremendous advance in the management of routine uncomplicated lacerations in non-tension areas. Patients routinely prefer tissue adhesives over traditional sutures.

Application of tissue adhesive begins with routine skin and wound preparation. The area must be dried and adequate hemostasis achieved

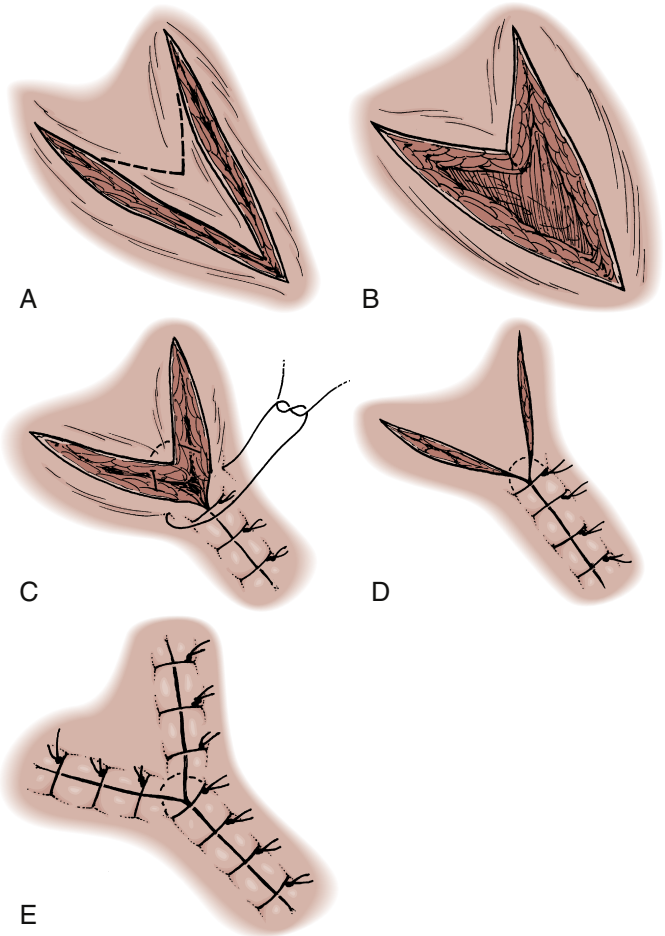

Fig. 50.7 (A–E) V-Y closure. (Adapted from Simon BC. Skin and subcutaneous tissue. In: Rosen P, et al., eds. *Atlas of Emergency Procedures*. St Louis: Mosby; 2001.)

before application. The wound margins are approximated as meticulously as possible in order to prevent the adhesive from getting between the wound margins. Applying tape (Steri-Strips) before application will facilitate wound margin approximation and make it easier to apply with similar results. Adhesive between the wound margins delays healing and increases the likelihood of wound dehiscence. The adhesive is applied to the entire length of the wound sufficient to cover 5 to 10 mm of skin adjacent to the margins. A single layer of adhesive is adequate. The adhesive sets in approximately 95 seconds. Special care is taken to ensure that the adhesive does not run off and disturb adjacent tissues. If the laceration is on the face, having the patient lie on the affected side will help prevent contamination of the eye near the wound and the opposing eye. Newer, high-viscosity formulations are now available that help limit this risk. Wounds may get wet but should not be immersed in water and should be blotted dry and not vigorously rubbed. An additional dressing may be desired by the patient but is not necessary.

Antibiotic Prophylaxis

Routine antibiotic prophylaxis for simple wounds has no scientific basis. A meta-analysis including more than 1700 patients compared the rates of infection in patients with simple non-bite wounds receiving antibiotics with those in control groups. Those treated with antibiotics had a slightly greater incidence of infection. The authors concluded that prophylactic antibiotics had no role in simple non-bite lacerations. Routine antibiotic use has obvious known complications, such as increasing resistance to antibiotics, gastrointestinal side effects (nausea, vomiting, *Clostridioides difficile* colitis), development of vaginal candidiasis, and allergic reactions that are common and may result in significant morbidity and unnecessary cost.

Although irrigation and debridement are the most important means of preventing wound infections, antibiotic prophylaxis is recommended in certain circumstances. Prophylaxis must be tailored to each patient. Some of the following recommendations are supported by scientific data, whereas others have few data to support their use and are based on established practice standards.

Contamination, crush, and host factors. Antibiotic prophylaxis with an antibiotic covering skin flora (e.g., cefazolin IV, cephalexin PO) is recommended for patients with wounds with gross contamination, patients with severe crush injuries, and immunocompromised patients. Some authors recommend not closing these wounds and instead using delayed primary closure. If circumstances require wound closure despite the infection risk, many emergency clinicians recommend prophylaxis despite scarce data.

Similarly, patients with significant crush injuries should receive antibiotics. Crush injuries are high-risk wounds because they produce more devitalized tissue and, despite a dearth of evidence, should be prophylactically treated.

Patients with certain risk factors have increased wound infection rates. Large prospective studies of patients with surgical wounds showed an increased rate of wound infection in patients with diabetes, obesity, malnutrition, chronic renal failure, advanced age, and chronic steroid use. No controlled studies of antibiotic prophylaxis in these patients exist, however, and clinicians should consider antibiotics based on individual circumstances. Finally, prophylaxis should be considered for other host factors, such as prosthetic joints or risk for endocarditis. Little evidence exists to support either recommendation.

Open fractures, joint wounds, and gunshot wounds. Wounds that involve joints or open fractures require prophylactic antibiotics. Prospective randomized controlled studies have documented decreased infection rates in patients receiving antibiotics compared with placebo. Indeed, the time to antibiotic administration in these wounds was found to be the most important factor in decreasing wound infection rates. Open fractures without evidence of significant soft tissue damage (avulsions and crushed or devitalized tissue) need antibiotics for 24 hours. Open comminuted fractures or fractures with significant tissue damage require 72 hours of antibiotics.

For gunshot wounds, which are classified as a type of open fracture, the recommendations vary with the type of missile wound. Low-velocity missile wounds not treated with antibiotics showed no increased infection rate in a randomized controlled trial of 67 patients with fractures treated with a closed technique. High-velocity wounds with fracture, on the other hand, are associated with an increased risk of infection, and antibiotic therapy should be initiated early and maintained for 48 to 72 hours. Patients with shotgun wounds with fracture should receive prophylaxis as well. Appropriate antibiotic therapy would be a cephalosporin (e.g., cefazolin 1 to 3 g IV) with or without an aminoglycoside (e.g., gentamicin 2 mg/kg IV). In patients with severe cephalosporin allergies, clindamycin 600 mg IV can be used instead of cefazolin.

For severely contaminated wounds, gentamicin 1.5 to 2 mg/kg IV is added. Some recent data have proposed limiting aminoglycoside use altogether and only using cefazolin for Gustilo grade I/II open fractures and ceftriaxone for grade III open fractures. A single institution study showed little difference in infection rates after limiting aminoglycoside administration for open fractures.

Bites and puncture wounds. Antibiotics are indicated for through-and-through intraoral lacerations, cat bites, some dog bites, some human bites, and some puncture injuries to the foot. Of all mammalian

bites, school age children account for almost half of all patients in this category, and 70% of animal bites are from pets or animals known to the victim (see Chapter 52).

Cat bites. Antibiotic prophylaxis is required for patients with cat bites, especially bites to the hand. These bites tend to be deep puncture wounds that do not require surface repair but are difficult to irrigate adequately. Cat bites have been reported to cause infections in 10% to 40% of all wounds. In one study, 13% of patients had signs of infection when they visited the ED, and 16% eventually developed infection. Other authors report that 80% of these bites become infected, although obvious selection bias limits this interpretation. Antibiotics seem to decrease the incidence of infection but a Cochrane review on mammalian bites suggested the limited literature on cat bites did not prove antibiotic efficacy, except in hand bites. At this time, we still advocate for antibiotic prophylaxis in all cat bites.

The organisms found in cat bites include *Staphylococcus* species, *Streptococcus* species, and, most often, *Pasteurella multocida*. *P. multocida* is usually found in infected cat bite wounds and is present in the normal oral flora of 70% of all cats. *P. multocida* is sensitive to penicillin, but the infection is often polymicrobial. *P. multocida* is resistant to dicloxacillin, cephalexin, and clindamycin, and there are many erythromycin-resistant strains. Amoxicillin with clavulanate (875 mg bid for 7 days) is the current recommendation for antibiotic prophylaxis for cat bites.

Dog bites. Antibiotic prophylaxis for dog bites is more controversial. The infection rate has been reported as 6% to 16% for patients not receiving antibiotics. Dog bites tend to involve more crush injuries with tearing and avulsions rather than puncture wounds. As such, dog bites are usually more amenable to irrigation and debridement. Seven of eight randomized trials of dog bite wounds showed no benefit with antibiotics. However, pooled data for meta-analysis did show a small but statistically significant benefit from antibiotics. On balance, we believe the use of prophylactic antibiotics should be limited to high-risk wounds, such as hand injuries, deep puncture wounds, bite in extremities with wounds with underlying venous or lymphatic compromise, wounds near or in a prosthetic joint, wounds in patients with diabetes, and wounds in older or immunocompromised patients.

Hand bites. In addition to the previous bite wound recommendations, antibiotic prophylaxis of injuries to the metacarpophalangeal joints is advised. These wounds are assumed to be human bites until proved otherwise. Known as "fight bites," these wounds have a high incidence of infection. Patients without signs of infection may be managed as outpatients. Close inspection, after anesthesia, is necessary to thoroughly evaluate the area for tendon involvement or penetration of the joint. If the joint is involved, irrigation is required. In some institutions, all of these patients are taken to the operating room for a thorough washout. Patients with early signs of infection are admitted for IV antibiotics, debridement and irrigation. The choice of antibiotics reflects the predominant organisms of hand bite infections. *Streptococcus* and *Staphylococcus* species are common, but *Eikenella corrodens* and *Bacteroides* species are also typical pathogens. *Eikenella* is often resistant to clindamycin, first-generation cephalosporins, and erythromycin. Amoxicillin with clavulanate (875 mg BID for 7 days) is the recommended initial therapy. Patients with later infection are treated with intravenous extended-spectrum antibiotics (e.g., ampicillin with sulbactam).

Intraoral lacerations. Lacerations of the oral mucosa involve bacteria-rich oral secretions and may become infected slightly more often (6% to 12%) than other wounds. Rates of infection for through-and-through lacerations may be twice the rates for simple mucosal lacerations. Although few data suggest a clear indication for prophylactic antibiotics, evidence suggests patients benefit from antibiotics if they are compliant with their regimen. Currently, we recommend antibiotic use in high-risk patients with through-and-through wounds. Penicillin (Pen VK) 500 mg bid for 5 days is an appropriate initial regimen.

Puncture wounds of the foot. Puncture wounds of the foot are seen frequently in the ED. These wounds are often caused by common carpentry nails, although other objects (e.g., glass, metal, and wood) must be considered. Despite their simple appearance, these wounds may produce significant morbidity. The infection rate for puncture wounds in the foot has been reported to be 15%. Most wounds occur on the plantar surface, from the neck of the metatarsal to the toes. Simple cellulitis accounts for half of these infections. More significant infections include septic arthritis, abscesses, and osteomyelitis. *Pseudomonas* organisms commonly cause osteomyelitis cases from puncture wounds. No data suggest a benefit from prophylactic antibiotics, but given the high risk of infection and serious complications, their use is recommended in high-risk puncture wounds. *Pseudomonas* organisms should be suspected when the puncture travels through a rubber-soled shoe. Patients with puncture wounds to the foot require early follow-up. Levofloxacin is the drug of choice to treat outpatients with suspected wound infection when *Pseudomonas* is of concern. Cephalexin or dicloxacillin is adequate for staphylococcal and streptococcal coverage unless methicillin-resistant *Staphylococcus aureus* (MRSA) is likely. In cases suspicious for MRSA, sulfamethoxazole-trimethoprim or doxycycline is recommended.

Drains, Dressings, and Immobilization

Drains. Drains have no role in ED wound care. In general, drains are placed when a collection of fluid exists or may develop. The presence of a drain reduces the wound's resistance to infection, regardless of the materials used in its construction, and the use of drains should be avoided. In wounds likely to collect fluid (e.g., around the elbow or knee), it is preferable to place the extremity at rest with a plaster splint or perform delayed primary closure.

Dressings. Various dressing materials are available. The microenvironment created by a dressing affects the biology of healing. The optimal wound climate must not interfere with the activity of fibroblasts and macrophages. The production of granulation tissue and migration of epithelial cells across the wound must be optimized.

Several factors should be considered in choosing the appropriate dressing. Dressings that prevent evaporation of water and keep tissues moist are helpful. A drying wound produces a thick, hardened scab that impedes the process of epithelialization. Excess fluid can lead to maceration of tissue and may be a potential culture medium for bacterial proliferation. Gaseous permeability is essential because epithelialization is accelerated greatly in the presence of oxygen. The wound-covering product should be impermeable to bacteria and other particulate matter that can contaminate the wound. It is important not to traumatize newly established tissue during dressing changes. The optimal dressing should have a nonadherent surface, be permeable to gases, and have a capacity to absorb some fluid but not allow desiccation. The outer barrier of the product should be impermeable to bacteria but permeable to water vapor. These products include films, hydrocolloids, foams, and hydrogels. The choice of dressing for ED wounds is primarily based on the amount of drainage that is expected.

Film dressings are thin membranes that are transparent, adhesive, and waterproof but are not absorptive. They are best reserved for wounds with low levels of drainage. Film dressings may be left in place for up to 7 days, as long as they do not leak or separate from the wound bed. For wounds with a moderate amount of drainage, moderately absorptive hydrocolloid dressings may be indicated. These dressings are thicker than films, semi-occlusive, waterproof, and very comfortable for the patient. Like films, they can be left on for up to 7 days. Foam dressings are more absorptive and made of a soft cushion sponge-like material. Some may require a secondary dressing for adhesion and need to be removed every 3 days. Hydrogel dressings are moisture-donating water-based gels that are available in sheets attached to a

semipermeable film. These dressings do not absorb fluids, so they must be used on relatively dry wounds. Patients often find these dressings to be the most comfortable, but they need to be changed every 1 to 3 days. The least expensive and simplest method of dressing a straightforward, uncomplicated laceration is to use petroleum-impregnated gauze or gauze on top of a thick layer of antibiotic ointment. These should be changed daily to prevent desiccation.

Immobilization. Wounds in proximity to joints must be immobilized as part of routine care. Splinting the injured body part places the injury at rest and hastens healing. Failure to splint appropriately exposes the healing tissue to the dynamic forces of muscular contractions, ultimately slowing the healing process and increasing scar size. In addition, immobilization decreases lymphatic flow and minimizes spread of microflora from the wound.

DISPOSITION

Wound Care Instructions

Discharge instructions must be clear, understandable, and reasonably comprehensive (Box 50.2). They should include daily care, observation for signs of infection, suture removal dates, and a follow-up source. Instruct the patient to elevate the injured extremity during the first 24 to 48 post-traumatic hours and explain that elevation lessens edema, hastens healing, and mollifies pain. The wound should be protected as described previously or cleaned daily to remove crust formations. It is safe for patients to bathe and get the wound wet 24 hours after injury. Daily swabbing with half-strength hydrogen peroxide rids the wound of debris and any blood clot that forms between the sutured edges. Hydrogen peroxide is not to be used after separation of the scab, because it is toxic to the epithelium and may produce bullae.

Wound infection is difficult for the untrained observer to distinguish from the inflammatory response of injury and subsequent healing. Patient education should be cautious and straightforward (e.g., return or seek follow-up for redness, swelling, increased pain, fever, pus, or red lines progressing up an extremity). A high-risk injury must be reexamined 48 hours after the trauma, regardless of its appearance. Highlight the possibility that a foreign body may be present despite efforts to remove it. Return precautions outlining signs of wound infection are essential.

Suture removal times vary, but generally they are 5 days for the face and 7 to 14 days for other body parts. Considerations include cosmetics, dynamic forces in proximity to the injury, static skin tension, blood supply, and anticipated healing rates.

Tetanus Immunization

The incidence of tetanus in the US is rare, with only 233 cases reported during the 2001 to 2008 surveillance period with a case fatality rate of 13.2%. Most tetanus patients in the United States are older than 50 years old. Immunization status is considered in all patients with wounds, regardless of severity. Forty percent of all cases of tetanus occur in individuals who have either minor wounds or no recollection of injury. These numbers raise serious questions regarding the validity of separating immunization recommendations according to clean and tetanus-prone wounds. Studies show that many people are inadequately immunized, especially patients older than 70 years, immigrants, and people with little education beyond grade school. In addition, patient immunization histories are often unreliable. Given the inability to predict which wounds are at high risk, all wounds are approached with suspicion.

The usual incubation period for tetanus is 7 to 21 days (range, 3 to 56 days). Immunization is given as soon as possible but can be given days or weeks after the injury. The dose of tetanus toxoid (T) or diphtheria, pertussis, and tetanus toxoids (DTaP) is 0.5 mL intramuscularly, regardless of the patient's age. Inadequately immunized patients need a dose of Tdap and tetanus immune globulin (TIG). The TIG dose is 250 IU for all ages 7 years old or older and 4 IU/kg IM up to 250 IU for ages younger than 7 years old (Table 50.1). A single injection of TIG provides protective levels of passive antibodies for at least 4 weeks. The immune globulin and toxoid may be given during the same visit but should be administered with a different syringe at separate sites. The literature suggests that emergency clinicians need to be more diligent administering TIG, because it is often not provided when indicated.

Because studies suggest that 10% to 40% of the population in the United States is inadequately immunized against pertussis, pertussis vaccination is recommended along with tetanus toxoid. Immunity to pertussis wanes approximately 5 to 10 years after vaccination. Since the 1980s, the number of reported pertussis cases has steadily increased,

BOX 50.2 Wound Care Instructions

I. Elevate the injured extremity above the level of the heart. Wear a sling when appropriate.
II. Cleanse daily in a gentle manner to remove debris and crusting that develops. Use dilute hydrogen peroxide.
III. Immobilization should be maintained at least until suture removal.
IV. Signs of infection
  A. Redness
  B. Increasing pain
  C. Swelling
  D. Fever
  E. Red streaks progressing up an extremity
V. Wound check
  A. As needed to check signs of infection
  B. Routine at 48 h for high-risk wounds
VI. Suture removal (*Note:* Suture may be removed earlier if Steri-Strips reinforce the wound.)
  A. Face: 5 days (always replace with Steri-Strips)
  B. Scalp: 7–10 days
  C. Trunk: 7–10 days
  D. Arms and legs: 10–14 days
  E. Joints: 14 days

TABLE 50.1 Tetanus Prophylaxis for All Patients With All Wounds[a,b]

Immunization History	DTaP (0.5 mL)	TIG (250 IU or 4 IU/kg)
Fully immunized, <10 years since booster	No	No
Fully immunized, >10 years since booster	Yes	No
Incomplete series (<3 injections)	Yes[c]	Yes

[a]All injections are intramuscular.
[b]Consider more frequent immunization for elderly patients. Tdap recommended for ages 11 to ≥65 years old (Adacel, Sanofi Pasteur and Boostrix, GalaxoSmithKlineBiologicals), although both products likely effective in the older than 65 age group.
[c]Refer these patients to complete their series; DTaP in 6 weeks and 12 months.
DTaP, Diphtheria, pertussis, tetanus toxoids; *TIG,* tetanus immune globulin.

BOX 50.3 Summary of Wound Care

I. Stabilize patient
II. History (include tetanus immunization and allergies)
III. Physical examination
  A. Neurovascular examination
  B. Anesthesia: Bupivacaine 0.5% without epinephrine, regional or local
  C. Bloodless field: Tourniquet or sphygmomanometer for extremities
  D. Thorough examination of anatomic structures, skin, nerves, tendons, blood vessels, bones, muscles, fascia, other (ducts, cartilage)
  E. Consultation if indicated
IV. X-ray films to detect injury to bone or the presence of foreign bodies (plain films, CT or ultrasound)
V. Wound preparation
  A. Cut—do not shave—surrounding hair
  B. Prepare surrounding skin with a chlorhexidine-alcohol solution
  C. Sharp debridement of foreign matter and devitalized tissue
  D. High-pressure irrigation with saline or a 1% povidone-iodine (Betadine) solution
VI. Wound closure
  A. Tape, staples, or suture
  B. Do not use subcutaneous sutures unless the wound is under high tension
VII. Antibiotics
  A. Apply topical antibiotics
  B. No systemic antibiotics unless wound is high risk
VIII. Dress and immobilize: Consider a transparent gas-permeable dressing
  A. Wound care instructions (see Box 50.2)
    Signs of infection
    Elevation
    Wound check if necessary
    Suture removal as soon as possible

especially among adolescents and adults. Children younger than 11 years old should receive the DTaP immunization. In 2005, a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, adsorbed (Tdap) product formulated for use in adults and adolescents was licensed in the United States for people 11 to 64 years old. Updated recommendations allow for Tdap (Boostrix, GlaxoSmithKline Biologicals) to be given to patients 65 years old and older, although it is likely that either Adacel or Boostrix vaccine will provide protection. When possible, it is recommended that this triple combined formulation be used in the ED for tetanus prophylaxis of adolescents and adults. Although all four injections (T, diphtheria and tetanus toxoids [DT], TIG, and Tdap) are considered safe and effective in pregnancy, because of limited experience during pregnancy the recommendation is to use DT. However, Tdap is recommended immediately postpartum, including for breast-feeding women.

Box 50.3 summarizes the principles of wound care management.

CHAPTER 50: QUESTIONS AND ANSWERS

1. Which of the following is associated with an increased risk of infection?
- **a.** Avoidance of epinephrine use in wound anesthesia
- **b.** High-pressure irrigation
- **c.** Use of clippers instead of razors for hair management near wound
- **d.** Use of silk suture material
- **e.** Use of tape over sutures for wound closure

Answer: d. Silk yields the highest infection rates, whereas monofilament synthetic substances have the lowest risk of infection. Other risk factors are listed in eBox 50.1

EBOX 50.1 Risk Factors for Wound Infection

1. Location: Leg and thigh, then arms, then feet, then chest, then back, then face, then scalp
2. Contamination with devitalized tissue, foreign matter, saliva, or stool
3. Blunt (crush) mechanism
4. Presence of subcutaneous sutures
5. Type of repair: Risk greatest with sutures > staples > tape
6. Anesthesia with epinephrine
7. High-velocity missile injuries
8. Diabetes

2. A 32-year-old man presents with 20 stab wounds to his arms and legs sustained in an assault. He weighs 80 kg. Which of the following is an appropriate dosage of wound anesthesia?
- **a.** 240 mg of 1% lidocaine
- **b.** 320 mg of 0.5% bupivacaine
- **c.** 400 mg of 0.5% bupivacaine with epinephrine
- **d.** 700 mg of 1% lidocaine with epinephrine

Answer: a. In adults, the maximal reported safe dose of bupivacaine is approximately 2.5 mg/kg without epinephrine and 3.5 mg/kg with epinephrine, assuming the injection is a wound infiltration technique and not one in a highly vascular area. General dose guidelines for lidocaine are 3 to 5 mg/kg without and 5 to 7 mg/kg with epinephrine, respectively. A 1% lidocaine solution contains 10 mg/mL. The actual percent solution does not matter; the total milligram dose does.

3. A 23-year-old female presents with a laceration to her thigh. As you begin to apply anesthetic, she tells you that when she went to the dentist she had an allergic reaction to procaine. Which of the following should you use?
- **a.** Benzocaine
- **b.** Benzocaine with epinephrine
- **c.** Bupivacaine
- **d.** Lidocaine from a multidose vial
- **e.** Tetracaine

Answer: c. Allergy to local anesthetics is uncommon. Two distinct groups of "caine" anesthetics exist. The esters include procaine, tetracaine, and benzocaine. The second group, including lidocaine and bupivacaine, belongs to the amide family. Allergy to the esters is uncommon. True allergy to agents in the amide family is rare. No cross-reactivity occurs between the amide and ester families, so an agent from a different group may be chosen. A "preservative-free" preparation should ideally be used because the para-aminobenzoic acid in multidose vials may cause an amine-like reaction that may be confused with an allergy to the primary agent.

4. Which of the following factors is most likely to require no antibiotic prophylaxis?
- **a.** Cat bite
- **b.** Diabetic with contaminated wound
- **c.** Dog bite
- **d.** Human bite
- **e.** Puncture wound through rubber sole

Answer: c. Antibiotic prophylaxis is often provided for patients with wounds with gross contamination, patients with severe crush injuries, and immunocompromised patients. Prophylaxis is also required for patients with cat bites. Seven of eight randomized trials of dog bite wounds showed no benefit with antibiotics. Human bites or lacerations to the metacarpophalangeal (MCP) joint are termed "fight bites," and these wounds have a high incidence of infection. Thus, of the choices given, dog bites have the lowest incidence of infection and therefore are the least likely to require prophylactic antibiotics.

5. Antibiotic coverage of a cat bite must target which of the following pathogens?
- **a.** Bacteroides species
- **b.** *Clostridium perfringens*
- **c.** *Eikenella corrodens*
- **d.** *Pasteurella multocida*
- **d.** Pseudomonas species

Answer: e. The organisms found in cat bites include *Staphylococcus* species, *Streptococcus* species, and, most often, *P. multocida*. *P. multocida* is usually found in infected cat bite wounds and is present in the normal oral flora of 70% of all cats. *P. multocida* is sensitive to penicillin, but the infection is often polymicrobial. *P. multocida* is resistant to dicloxacillin, cephalexin, and clindamycin, and there are many erythromycin-resistant strains. Amoxicillin with clavulanate is the current recommendation for antibiotic prophylaxis for cat bites.

6. A 74-year-old patient presents with a gaping wound from a dog bite, complaining of pain at the site. The dog belongs to a friend, has reportedly had "all his shots," and is in custody. The patient is from Central America but has lived in the US for more than 50 years; he does not recall his immunization history. Besides copious irrigation and wound dressing, which of the following should be included in the treatment of this patient?
- **a.** Diphtheria, pertussis, tetanus toxoids (Tdap) and tetanus immunoglobulin (TIG)
- **b.** Rabies immunization
- **c.** Tetanus toxoid
- **d.** Tetanus toxoid and immunoglobulin
- **e.** B and D

Answer: a. Studies show that many people are inadequately immunized, especially patients older than 70 years old, immigrants, and people with no education beyond grade school. Patient immunization histories are often unreliable. Given the inability to predict which wounds are high risk, all wounds should be approached with suspicion. Inadequately immunized patients need a dose of Tdap and TIG. Because studies suggest that 10% to 40% of the population in the United States is inadequately immunized against diphtheria, diphtheria vaccination should be given along with tetanus toxoid. Many adults are not immunized against pertussis, and the incidence of disease has been rising since the 1980s. In 2005, a new acellular form of the pertussis vaccine became available and is recommended for all adults.

51

Foreign Bodies

Jeffrey M. Goodloe and Jaron Soulek

KEY CONCEPTS

- If the history and mechanism of injury are compatible with ocular penetration or if a small puncture wound of the globe is noted, anteroposterior and lateral radiographs of the orbit are an appropriate initial step when the foreign body is thought to be radiopaque. Computed tomography (CT) and ultrasound are complementary diagnostic studies.
- Although most otic and nasal foreign bodies are amenable to emergency department (ED) removal, instrumentation of these anatomical areas must be undertaken with great care because removal attempts can cause more injury than the foreign body itself.
- Most airway foreign bodies are seen in pediatric patients and may not be visible on plain films. A normal radiograph does not rule out an aspirated foreign body.
- The patient with critical airway obstruction and impending or actual respiratory arrest requires one of three options: (1) forced expulsion of the foreign body; (2) direct laryngoscopy with attempted manual removal with Magill forceps; or (3) cricothyroidotomy to bypass an obstruction, or intubation to push the foreign body distally into the right mainstem bronchus.
- Esophageal foreign bodies are typically found at one of the three constriction locations: (1) proximal esophagus at the level of the cricopharyngeal muscle and thoracic inlet—radiographically, the clavicular level; (2) midesophagus at the level of the aortic arch and carina; and (3) distal esophagus just proximal to the esophageal-gastric junction—radiographically, a level two to four vertebral bodies cephalad to the gastric bubble.
- Esophageal foreign bodies (e.g., coins) usually are oriented in the coronal plane, and airway objects usually are oriented in the sagittal plane.
- Unless caustic or sharp, foreign bodies in the stomach and bowel are increasingly managed with a conservative approach with watchful waiting and tracking of the object's progression through the gastrointestinal tract.
- In the perineal region, foreign body removal tends to be more difficult than anticipated by emergency clinicians and be physically and psychologically traumatic for patients. Consultation with appropriate specialists (e.g., urology or general surgery) is indicated.
- The most important determinant of successful soft tissue foreign body removal is an understanding of the object's precise location.

FOUNDATIONS

Patients often present to the emergency department (ED) with a complaint of a retained foreign body. The anatomical locations vary and determine the management, emergent removal, and need for subspecialty referral or surgical removal under general anesthesia. Patients may be forthright with a complaint of a foreign body, but in some cases, information may be withheld because of embarrassment.

Clinical Features

When people ingest or insert foreign bodies, often a brief history may be sufficient to establish the diagnosis, guide initial management decisions, and predict the process required for definitive removal. Those at higher risk of having a foreign body include neurologically impaired patients, edentulous individuals, patients with certain psychiatric diagnoses, incarcerated individuals, and individuals at the extremes of age. In these same groups, definitive history is often elusive, and the emergency clinician has to rely upon situational clues.

Depending on the location of the foreign body, the physical examination can provide direct or indirect evidence of the object. Specifics are described in the following sections, but there is a recurring theme, which is meticulous examination frequently establishes the correct diagnosis and suggests a successful extraction method.

Differential Diagnoses

Even when patients are fully cooperative, the diagnosis of a foreign body can be complicated by the fact that patients can be unaware of the object's presence. Although foreign body cases are usually not diagnostic dilemmas, the emergency clinician should keep in mind the possibility of foreign body mimics such as angioedema.

Diagnostic Testing

Plain radiography is classically the primary imaging modality that yields foreign body detection and characteristics of location, size, and number. Even when objects are not visualized, radiographs may show secondary changes (e.g., pulmonary air trapping) providing clues to foreign body presence.[1] To assist in the localization, two views—anteroposterior and lateral—are usually necessary. Metallic objects are usually easy to visualize on plain radiography. For non-metallic (e.g., organic) material with a density similar to that of human tissue, visualization requires alternative imaging, such as ultrasound, magnetic resonance imaging (MRI), or computed tomography (CT).[2,3]

Management

Extraction is indicated in most cases. A discussion with the patient (or appropriate surrogates) should outline the benefits and risks of the anticipated course for foreign body removal. Sometimes, a foreign body represents an immediate life threat, as is the case with an airway-obstructing foreign body, and the need for urgent extraction action takes precedence. Even without overt life threats, some foreign bodies require expeditious removal. For instance, illicit drug leakage can kill a body packer, an impacted button battery can cause fatal tissue perforation and hemorrhage, or an otic insect can cause intense pain and damage sensitive ear structures.[4-6] Foreign bodies may serve as a nidus for infection that is recurrent or refractory to antibiotic therapy; definitive

Fig. 51.1 Computed tomography (CT) scan shows right intraocular foreign body (BB pellet) in an intoxicated patient without known trauma history.

resolution only occurs with identification and removal. Specific recommendations for foreign body removal are presented in the following sections outlining management considerations by anatomic location.

Disposition

Most patients can be safely discharged home following uncomplicated foreign body removal. Retained foreign bodies may need surgical specialty follow-up. Depending on anatomic location and a patient's ability to cooperate, some retained foreign bodies require removal under sedation or surgical intervention under general anesthesia.

SPECIFIC DISORDERS

Eye

Foundations

The diagnosis usually is self-evident. Ocular trauma without proper eye protection is the most common history.[7] Foreign bodies are occasionally identified by abnormal ocular examination findings without a stated history of trauma. For example, the cause of reduced vision in an intoxicated patient may be a foreign body (Fig. 51.1). Early diagnosis, care, and follow-up minimize risks, such as endophthalmitis or sight-threatening siderosis bulbi.[7]

Clinical Features

Most patients report a foreign body sensation, even though they cannot see the foreign body. The patient may complain of frequent lacrimation and conjunctival injection. Foreign bodies that have created corneal injury and are no longer present may account for symptoms identical to those noted with a retained foreign body. Occasionally, patients with retained foreign bodies (e.g., malpositioned contact lenses) can present with recurrent conjunctivitis.

An important component of the history is whether radial keratotomy or similar ocular surgery has been performed. Historically, ophthalmologic procedures have been associated with the delayed diagnosis of foreign body entrapment. Although more current literature contains little or no mention of these procedures as foreign body risk factors, the potential for situational relevance (e.g., management of corneal foreign bodies) dictates a need for the emergency clinician to obtain a complete ocular surgical history.

The initial survey includes standard elements of the ED eye examination. Visual acuity at the time of presentation is a consistently reported predictor of ultimate visual outcome.[7] Slit-lamp examination allows the detection of a corneal foreign body by the shadow that it casts on the iris. The slit-lamp may also facilitate the identification of rust rings. Fluorescein can aid in detecting abraded corneal epithelium.

The inner aspects of both lids should be examined. The lower lid can be successfully exposed with gentle manual retraction outward and downward as the patient looks upward. The upper lid can be successfully exposed through eversion, instructing the patient to look downward while upward eyelash traction is applied. During this procedure, an applicator stick can be used to act as a fulcrum on the proximal edge of the tarsal plate. After location and removal of one foreign body, re-examination should occur to evaluate for other ocular foreign objects.

Differential Diagnoses

Selected differential diagnoses of ocular foreign bodies include corneal abrasions, conjunctivitis, iritis, glaucoma, allergic chemosis, and globe perforation.

Diagnostic Testing

If the history and mechanism of injury are compatible with ocular penetration by radiopaque material, or if a small wound of the globe is noted, anteroposterior and lateral radiography of the orbit is typically the initial step to evaluate for deeper penetration into the globe (see Fig. 51.1). However, given its advantages in depicting small ocular foreign bodies and complications such as globe rupture, CT is the best initial approach, especially when there is strong clinical suspicion of intraocular penetration. CT has the additional utility of imaging of the intracranial compartment, which is often indicated in cases in which ocular trauma has occurred.

When globe penetration is strongly suspected, fluorescein should be avoided because its application can obscure findings in subsequent physical examination. Fortunately, the incidence of intraocular perforation in the setting of low-velocity (non-explosive) exposures is very low. When perforation is judged unlikely and fluorescein is administered, the identification of rivulets of fluorescein tracking from a puncture (i.e., positive Seidel test) helps identify intraocular penetration.

Ultrasound is a useful adjunct to CT scanning in patients with foreign bodies that are difficult to localize. For patients in whom a foreign body is suspected despite negative ED evaluation, outpatient referral to ophthalmology is recommended because CT, ultrasound, and even MRI have all missed ocular foreign bodies in patients who subsequently developed complications. Given the paucity of reported case series and justifiable concerns about eye damage from the mobilization of ferromagnetic foreign objects, the use of MRI for ophthalmologic foreign body imaging remains controversial. When there is any chance of the presence of a metallic object in the eye, the emergency clinician should not order MRI without consulting both ophthalmology and radiology specialists.

Management

In nearly all cases, therapy is the removal of the ocular foreign body. If the object is located on the bulbar or palpebral conjunctiva (*not* the cornea), it often can be removed easily by sweeping the site with

a moist cotton-tipped applicator. For small corneal foreign bodies, after application of topical ocular anesthesia, it is often necessary to use an eye spur, small-gauge tuberculin syringe needle, or the edge of an IV catheter (needle removed) to move gently underneath one end of the object and flick or scoop it out. It is prudent for the emergency clinician to avoid significant corneal procedures in patients who have had corneal surgery, such as laser-assisted in situ keratomileusis (LASIK).

After the removal of a corneal foreign body that leaves no rust ring, treatment is essentially the same as for corneal abrasion. When there is a rust ring, ED management should be dictated by standing protocol (designed in collaboration with ophthalmologists) or referred to ophthalmology for removal.

Disposition

If attempts at foreign body removal are not indicated or are unsuccessful, the patient should be referred to ophthalmology for object removal within 24 to 48 hours. Ophthalmology referral should be initiated after removal of metallic foreign bodies because there may be subtle retained fragments or rust rings requiring removal.

Ear

Foundations

Otic foreign body extraction can prove problematic, and the difficulty is rarely diagnosis. Instead, with otic foreign bodies, the challenge usually lies in working in a sensitive anatomical region in a patient population that is often uncooperative.

Clinical Features

If the foreign body is an insect, the patient may report feeling motion or hearing buzzing. As compared to insect foreign bodies in the nose or throat, those in the ear are far more likely to be alive and moving.[4] Less specific complaints include itching, discharge, or otalgia. Similar secondary symptoms may be present when non-insect foreign bodies are within the ear canal. Nonspecific presentations are common in children, who can be fearful of reporting a foreign body. The child presents only when there are secondary problems (such as purulent discharge) from the affected ear.

If the ear canal foreign body erodes into the middle or inner ear, complications may range from malocclusion to eustachian tube dysfunction and serious infections (such as mastoiditis and meningitis). Although these situations are infrequent, recent literature outlines the risk entailed with impression material (e.g., silicone) used for indications, such as the molding of hearing aids.[8]

History should include home attempts at foreign body removal. Such efforts may have caused problems, such as ear canal trauma or tympanic membrane perforation.

The cylindrical external auditory canal has two anatomic points of narrowing (and, thus, foreign object lodging). The first point is near the inner end of the cartilaginous portion of the canal, and the second is at the point of bony narrowing called the *isthmus*.

Adequate lighting and an appropriately sized otoscope are essential to optimizing the visual search for otic foreign bodies. With any examination involving the external auditory canal, grasp the pinna of the ear and retract it in a posterosuperior direction to straighten the canal. This maneuver affords a more complete view of both the canal and the tympanic membrane.

If the tympanic membrane has been ruptured by the foreign object or by prior removal attempts, documentation should indicate the presence of rupture before ED attempts at foreign object removal. As in other body locations, the risk of multiple foreign objects warrants consideration.

Differential Diagnoses

The selected differential diagnoses of ear foreign bodies include otitis media, otitis externa, ear canal trauma, tympanic membrane perforation, Ménière's disease, and otologic tumors.

Diagnostic Testing

Diagnostic imaging is rarely required in otic foreign bodies. CT or MRI may be performed to characterize infectious or erosive sequelae.

Management

The treatment for otic foreign bodies is their removal, which should usually occur in the ED. Success rates for ED removal of ear canal foreign bodies vary with patient population and constituent foreign body types.

Even in a very young patient, the presence of a foreign body for more than 1 or 2 days does not constitute an independent risk factor for foreign body removal failure or complication. In the absence of clear contraindications (e.g., obvious tympanic membrane rupture), the emergency clinician should proceed with otic foreign body removal efforts, even in children with objects in the ear canal for a few days.

The patient should be informed about the extreme sensitivity of the auditory passage and the likely discomfort and potential for minor bleeding. Lidocaine instillation may aid in topical anesthesia; liquid 1% or 2% solution is preferred to gel preparations, which impair subsequent visualization.

Infrequently, foreign body removal requires local anesthesia of the external ear canal. The anesthesia instillation procedure may cause patient discomfort and iatrogenic injury if performed in an uncooperative patient. The procedure entails injecting all four quadrants of the canal with lidocaine via a tuberculin syringe inserted through an otic speculum. Given the complexity of local anesthesia to the canal, systemic procedural sedation and analgesia may be preferable.

When the ear canal is inhabited by an insect, it is important to kill or immobilize the creature to facilitate its removal. Any of a number of agents can be used to kill the insect. Topical anesthetics are recommended, and hydrogen peroxide should be avoided because of the risk of injury to the inner ear if there is tympanic membrane perforation. Efficacious formulations include lidocaine as a 10% spray or less concentrated liquid, 2% lidocaine gel, mineral oil with 2% or 4% lidocaine, and alcohol. Alternatively, a novel approach has been recently described in the literature in which a provider may remove a live insect by turning the lights off in the exam room, exert posterior and superior traction on the pinna while pulling forward on the tragus, and shine a bright light source into the ear canal.[9] The light may cause the insect to self-extricate as it tries to avoid illumination.

Several extrication methods may prove effective, and various instruments may be useful. With soft or irregularly shaped objects, it is often possible to grasp the foreign body with forceps (alligator forceps are usually best) and remove it either in one piece or in fragments. If the object cannot be grasped, it may be possible to remove it by passing a blunt-tipped right-angle hook or ear curette beyond the foreign body and gently coaxing it out. Alternatively, a balloon-tipped catheter can be passed distal to the object, with subsequent attempts to withdraw the (inflated) balloon, extracting the object. Any balloon-tipped catheter design may be used as long as its caliber is small enough (about 18-gauge or smaller) to allow comfortable introduction into the ear canal.

Irrigation techniques take advantage of the elliptic shape of the external ear canal. A stream of lukewarm or room-temperature water or saline should be directed at the foreign body's periphery via a 20-mL syringe and a 14- or 16-gauge catheter; this arrangement has been studied in the laboratory and demonstrated to generate pressures that are well below those required to perforate the tympanic membrane.

Irrigation should not be used if there is known history, clinical suspicion, or physical examination evidence of tympanic membrane perforation.

The removal of objects from the middle ear with cyanoacrylate adhesive-tipped swabs is not recommended and carries the risk of contaminating the ear canal with a substance that is difficult to remove and has been associated with ear canal and tympanic membrane injury. When cyanoacrylate has been instilled into the ear, acetone instillation is recommended to facilitate its safe removal.

The removal of otic foreign bodies must be undertaken with care and steadiness. Patient apprehension and sudden movements can risk untoward foreign body movement and avoidable damage to the ear canal.

Otic foreign body sequelae are usually not serious. There are sporadic reports usually related to missed diagnoses and persistent ear canal objects of serious complications ranging from chronic otitis to hearing loss, facial palsy, and deep-seated infections, such as mastoiditis.[8,10] The most common complications include external ear canal bleeding (10%), otitis externa, and (in about 2% of patients) tympanic membrane perforation.[11] Complications are more likely when the otic foreign body has been in place for prolonged periods, when patients are unable to be cooperative with removal attempts, and when practitioners are less experienced.[11]

After removal of the foreign body, the canal examination is repeated to ensure the lack of retained material and to evaluate otic anatomy. In cases in which the tympanic membrane is ruptured and the middle ear is at risk for infection, appropriate oral and topical antibiotics are recommended.

Disposition

If ED methods of removal are unsuccessful, the patient should be referred to an otolaryngologist within a week. More urgent referral is recommended for cases in which the tympanic membrane is ruptured or in cases where foreign body removal proves particularly traumatic (in such cases, the follow-up is aimed at assessing for external otitis).

Nose

Foundations

Although seen less frequently than otic foreign bodies, objects in the nasal passages are still commonly encountered in the ED. Compared with patients with otic foreign bodies, children with nasal foreign bodies tend to be younger, most commonly younger than 5 years old.[11]

ED removal is nearly always successful and with proper technique, serious sequelae are rare. Sedation with agents (such as ketamine) is often necessary. Although evidence is sparse, the overall risk of nasal foreign bodies' entering the bronchial tree is low. Cases of intranasal magnets or alkaline button batteries, which may cause electrical or chemical burns and tissue necrosis, are exceptions and could cause more serious complications.

Clinical Features

Most patients seek medical attention within 24 hours. Presentation delays are directly associated with secondary complications, such as infection.[11]

Patients seen in the ED with nasal foreign bodies usually have one of two histories. More commonly, the patient admits to having, or was seen placing, an intranasal object. The less common history is one of purulent or bloody discharge (usually unilaterally) suggestive of an unreported foreign object.[12] Unresolving rhinitis or sinusitis despite appropriate antibiotic therapy should raise suspicion for a nasal foreign body.

Preparing the patient for examination and subsequent removal attempts is advised. Because of the risks of iatrogenic movement of the foreign body further posteriorly, children may need to be restrained to permit the examination. The nasal mucosa is normally quite sensitive, and this sensitivity is increased by any infection or irritation. Examination is facilitated by the application of topical anesthesia and vasoconstrictors to the nasal mucosa. Examination should include both nares, with adequate lighting and visualization facilitated by the use of a nasal speculum. The presence of the foreign body and any secondary tissue damage should be documented. Necrosis of the nasal mucosa and septum may accompany button battery impaction.[13]

Differential Diagnoses

The select differential diagnoses of nasal foreign bodies include nasal polyps, septal hematomas, nasal tumors, infectious and allergic rhinitis, and anterior and posterior epistaxis.

Diagnostic Testing

Diagnostic imaging does not usually play a major role, although plain radiography is important when there is suspicion for a metallic foreign body, such as a button battery. When intrasinus foreign bodies are suspected, CT can be helpful. The potential risk of MRI for the detection of foreign bodies may become more relevant with an increasing frequency of foreign bodies related to magnetic jewelry (i.e., nose rings and studs).

Management

The emergency clinician is highly successful at the removal of nasal foreign bodies. Rarely, subspecialty consultation is required for removal in the operating room.[4] Foreign bodies that have eroded into the sinus space are an obvious exception to the rule of ED removal; admission for endoscopy in the operating room is recommended in such cases.

Occasionally, positive pressure applied to the patient's mouth by a parent or relative achieves rapid foreign body dislodgment while obviating the need for restraint, sedation, and other requirements attendant to more invasive removal techniques. The underlying principle is that a short burst of air blown into the mouth of a child with finger occlusion of the non-obstructed naris may force the foreign object out of the nose. Insufflation, preferably a mouth-to-mouth maneuver from a parent, can also be provided by a manual ventilation bag (with a pop-off valve to prevent pressure rising above 30 mm Hg) or a similar positive-pressure device.

Insufflation may be self-applied. Children can be instructed to take a deep breath and blow hard through their nose, as a parent closes the unaffected naris.

When insufflation is not warranted or is unsuccessful, ear, nose, and throat instruments and removal techniques may be required. Regardless of the method, the patient (usually a child) may benefit from some combination of restraint, sedation, and pretreatment with vasoconstrictive agents (e.g., nebulized racemic epinephrine) and anesthetic (e.g., benzocaine spray).[4] Adequate illumination is essential. Depending on the nature of the foreign object, necessary instruments include a blunt-tipped right-angle probe, suction catheter, and alligator forceps. The forceps are used when the foreign body is to be directly grasped, and the right-angle probe is used in an attempt to reach behind the foreign object and displace it forward.

Other useful instruments include Fogarty (vascular) and Foley catheters; commercially available "specialized balloon-tipped catheters can also be used. Magnets may be useful when the intranasal foreign body is metallic and appropriately constituted. In some cases, suction can be used to withdraw foreign bodies directly.

Cyanoacrylate-tipped swabs may be useful in certain circumstances, although there are obvious risks of inadvertent contact between the glue and nasal mucosa.

Antibiotics are rarely indicated for nasal foreign bodies. If the history or physical exam suggest prolonged impaction or obvious signs of infection, then oral antibiotic(s) to include coverage for streptococcal and staphylococcal species is appropriate.

Disposition

Patients with a simple foreign body presentation for whom the object is easily removed do not require special follow-up. In cases where the nasal foreign body was in place for an extended period of time, or in cases for which removal was difficult or traumatic, otolaryngology follow-up in 24 to 48 hours should occur to assess for post-extraction complications.

Airway

Foundations

Background and Importance. Children and the elderly are at high risk for foreign body aspiration. Most airway foreign body patients are younger than 9 years old, and there is a decline in incidence as mastication is facilitated by the emergence of permanent teeth. In adults, the elderly are at significant risk because of the presence of comorbidities such as neurological and dental conditions.

The most common airway foreign bodies vary with the particular case series, and the case report literature includes an array of respiratory tract objects ranging from dental appliances to turban pins and wall plugs.[14] In most series, food items are commonly aspirated as are medications.

Diagnostic delay is associated with increased complications in all patient age groups. One pediatric study identified a doubling of complication rates with presentations delayed beyond 48 hours. Patients with altered mental status from a variety of causes are at heightened risk for occult aspiration. Even in large-series reports of aspiration, the elusive nature of specific and reliable indicators of airway foreign body presence means that a concerning history should prompt a diligent foreign body search.

Anatomy and Pathophysiology. Foreign bodies can be located as proximally as the oropharynx, with retained objects having been found in the palatal and pharyngeal mucosal regions.[15] Foreign body impaction at the laryngeal or subglottic level often is caused by inappropriately executed attempts to finger sweep an oropharyngeal foreign body.

Airway foreign bodies that pass beyond the laryngeal inlet may cause complete obstruction. Foreign bodies passing beyond the carina are less likely to cause acute hypoxia because there is an unobstructed contralateral airway. Right-sided bronchial aspiration is the more common location because the carina is positioned right of the midtrachea in 40% of infants, and the proximal right bronchus is both wider and more steeply angled than the left.

Foreign objects can be bilateral, and the rule for airway foreign bodies mirrors that for other foreign bodies: when one object is identified, there should be a search for a second.

Clinical Features

Clinical presentation can range from chronic nonspecific respiratory complaints to acute airway obstruction.[16] In one series of ambulance-transported airway foreign body patients, 50% suffered cardiopulmonary arrest prior to ED arrival.[16] In most aspiration cases, foreign body presence can be suspected after a thorough history. Patients with airway foreign bodies may have noisy breathing, inspiratory stridor, rhonchi, vomiting, changes in voice, and hemoptysis.[12]

Some patients may give a history, known as the *penetration syndrome,* including a choking sensation accompanied by wheezing and coughing.[17] Coughing may not eject the foreign body completely but rather results in its impaction in the subglottic region. Therefore, coughing after suspected aspiration should prompt a search for a foreign body even if the symptoms improve.

In pediatric patients with suspected foreign body aspiration, the sudden onset of choking or intractable cough associated with wheezing and respiratory distress is present in more than 63% of cases. In addition to coughing and choking, stridor is frequent. The absence of early cough and choking is correlated with delayed diagnosis and chronic presentations (e.g., recurrent pneumonia).[12,18]

With the sudden onset of dyspnea and odynophagia, an impacted subglottic object may be present. If the object is known to be sharp and thin, the emergency clinician should suspect embedding between the vocal cords or in the subglottic region with resultant partial obstruction.

Other components of the history can help diagnose and characterize foreign bodies in patients with aspiration of nonfood objects. Many types of items may be aspirated by children who are exploring their environment. Another at-risk population comprises individuals who normally store small items in their mouths for quick access; examples of the latter include construction workers (nails) and seamstresses (pins).

Trauma patients with injured and loose teeth may have aspirated in the field or during emergency laryngoscopy for oral intubation. The incidence of airway aspiration of avulsed teeth or prosthetic dental appliances is low (0.5% of 1411 facial trauma patients), but both the initial trauma and subsequent airway management pose risks. In some cases of penetrating or blast trauma, the patient may be unaware of the potential for aspiration and not attribute symptoms to this entity. Patients aspirating objects that are long and thin (e.g., needles, hatpins) may have minimal or no symptoms other than a mild cough or chronic hemoptysis or odynophagia.

The child with respiratory difficulty after eating can represent a diagnostic dilemma. Children with stridor or other respiratory symptoms may have airway foreign body aspiration or esophageal bolus impaction with external compression of the trachea.[18] The pediatric trachea is soft, especially posteriorly, and may be compressed by a large esophageal body pressing anteriorly on the trachea. In addition, the trachea itself may be displaced anteriorly and kinked, causing a partial obstruction. Fever and localized infection may indicate bony aspiration (e.g., into the piriform fossa) that may occur when bone-containing foods are fed to very young children. Unfortunately, missed esophageal foreign bodies in children can result in wheezing and stridor from fistula formation; the result is long-term, yet mistaken, diagnosis and treatment for asthma.

The presentation of patients with a retained airway foreign object may include only infectious complications. A foreign object may cause retropharyngeal abscess. A patient with atypical or recurrent pneumonia may have pulmonary infection secondary to the persistence of a foreign object serving as a nidus of infection.

Physical findings depend on the degree of airway obstruction and the duration of the object's presence. Depending on the size and location of the foreign body, the examination may show a normal patient, one with cyanosis and respiratory arrest, or anything in between these two extremes.[19] There are some useful findings. Unilateral diminution of breath sounds, present in over a third of cases in one large pediatric series, may help diagnose an aspirated foreign body. Patients may be stridulous or hoarse with upper airway foreign objects, and intercostal or sternal retractions may be noted in patients with high-grade obstruction from tracheal foreign bodies. Hypoxemia may be present;

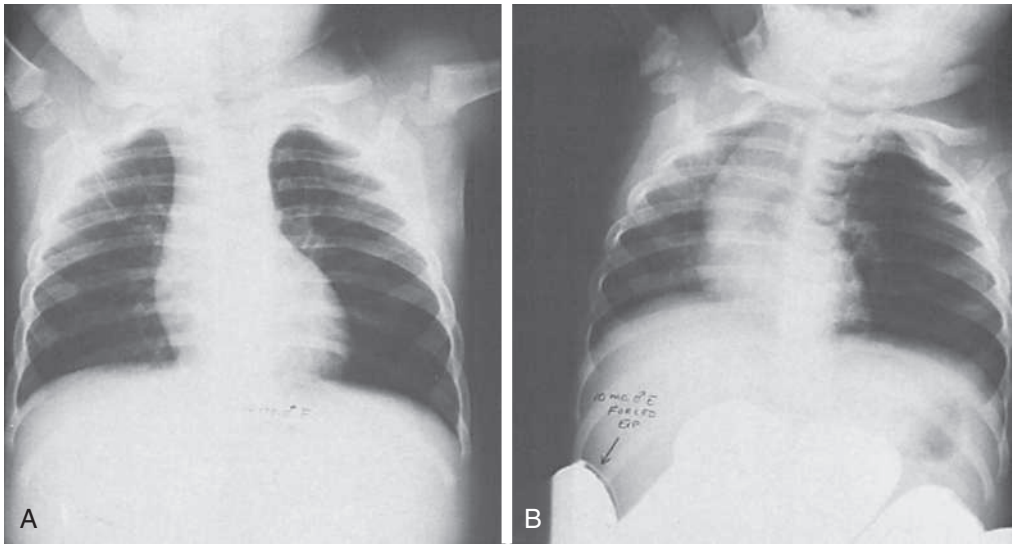

Fig. 51.2 (A) Normal inspiratory chest film in a child with a left mainstem bronchus foreign body. (B) Forced expiratory view shows expanded lung on the left with a shift of mediastinum to the uninvolved right side.

however, normoxia does not rule out a foreign body. Patients with secondary infection may have fever.

Oropharyngeal examination may reveal a foreign body posteriorly or donor sites of fractured teeth. The examination should include a search for fractured or missing dental prostheses. Oropharyngeal examination frequently can be augmented by indirect or direct laryngoscopy or nasopharyngoscopy, but these procedures should be performed only if the procedural stress does not pose an undue risk of airway compromise.

Coughing may result from local irritation caused by bronchial foreign bodies. Localized or apparently generalized wheezing is frequently auscultated in patients with lower respiratory tract foreign bodies.[1] Complete obstruction of a mainstem bronchus may be associated with absent ipsilateral breath sounds; however, breath sounds can be transmitted across the thorax, and the only physical abnormality may be asymmetric chest rise. Occasionally a foreign body acts as a one-way valve, allowing air into the lung during inspiration but permitting none to exit during expiration. The involved lung becomes hyperexpanded, and this finding may be detected as hyper-resonance to percussion.

Differential Diagnoses

The selected differential diagnoses of airway foreign bodies include anaphylactic reactions, acute pharyngitis, acute epiglottitis, retropharyngeal abscess, neck tumors, pulmonary carcinomas, pneumonia, bronchitis, bronchiolitis, and tuberculosis.

Diagnostic Testing

The main reason to characterize the type of airway foreign object is to determine the likelihood of radiopacity. Imaging decisions are informed by understanding whether a foreign body is likely to be radiopaque.

Most airway foreign bodies are not visible with plain films.[12,18] In 3,149 aspirated foreign body cases, 84% of airway foreign bodies consisted of organic material (usually nuts) difficult to see on x-rays.[20] Nearly half of fatal choking cases in children are a result of radiolucent food aspiration. In the stable patient, plain radiography of the neck and chest remains the mainstay of initial airway foreign body imaging. Air trapping may be visible when inspiratory and expiratory films are compared, but more recent literature casts doubt on the clinical necessity for adding expiratory views to plain radiography. Decubitus chest x-ray positioning does not offer significant benefits to standard radiographs of the chest.

A normal radiograph cannot rule out an aspirated foreign body in a patient with a suggestive history. Studies of series of patients who underwent endoscopy with confirmed foreign body aspiration demonstrate both low sensitivity and poor specificity.[12]

Specific findings on plain radiography are categorized as direct (i.e., identification of the foreign body itself) or indirect (e.g., hyperinflation). Radiographic findings are indirect in most cases, with hyperinflation and emphysema being far more common than pneumothorax.

If doubt exists as to the radiopacity of the suspected foreign body, and if the patient has brought a piece of the object, it may be tested for radiodensity by placing it over the shoulder while taking the radiographs. When subglottic foreign body impaction is suspected, plain soft tissue radiographs of the neck are the best initial step, provided that they are performed under the close supervision of a physician trained in airway management. Negative plain radiographs are not diagnostic, but clear identification of an airway foreign body can provide a rapid diagnosis, leading to admission for endoscopy.

Indirect or secondary signs, such as subglottic space narrowing (from an embedded foreign object), are an important aid in foreign body radiography. Air trapping and atelectasis are the most common early clues to airway foreign body presence, with bronchiectasis and pneumonia developing later. In air trapping, a comparison of inspiratory and expiratory films shows a flat, fixed diaphragm on the involved side and the heart and mediastinum shift to the uninvolved side during expiration (Fig. 51.2). In one pediatric series, air trapping was found in 90% of patients with lower airway foreign bodies, but subsequent years' clinical experiences confirm that the indirect signs of airway foreign body are easily missed on initial x-ray readings. If obstruction becomes complete, the involved lung becomes atelectatic and pneumonia can develop; patients with persistent atelectasis or pneumonia should have foreign objects considered as the explanation. An additional indirect radiographic sign of more proximal foreign bodies is prevertebral swelling or soft tissue emphysema seen on neck films.

In a stable patient when a foreign body is seen on the chest radiograph, but its airway-versus-esophageal location is in doubt, the anteroposterior orientation of the object may help (Fig. 51.3). Esophageal foreign bodies usually are oriented in the coronal plane, and airway objects, because they need to traverse the narrow vocal cord aperture,

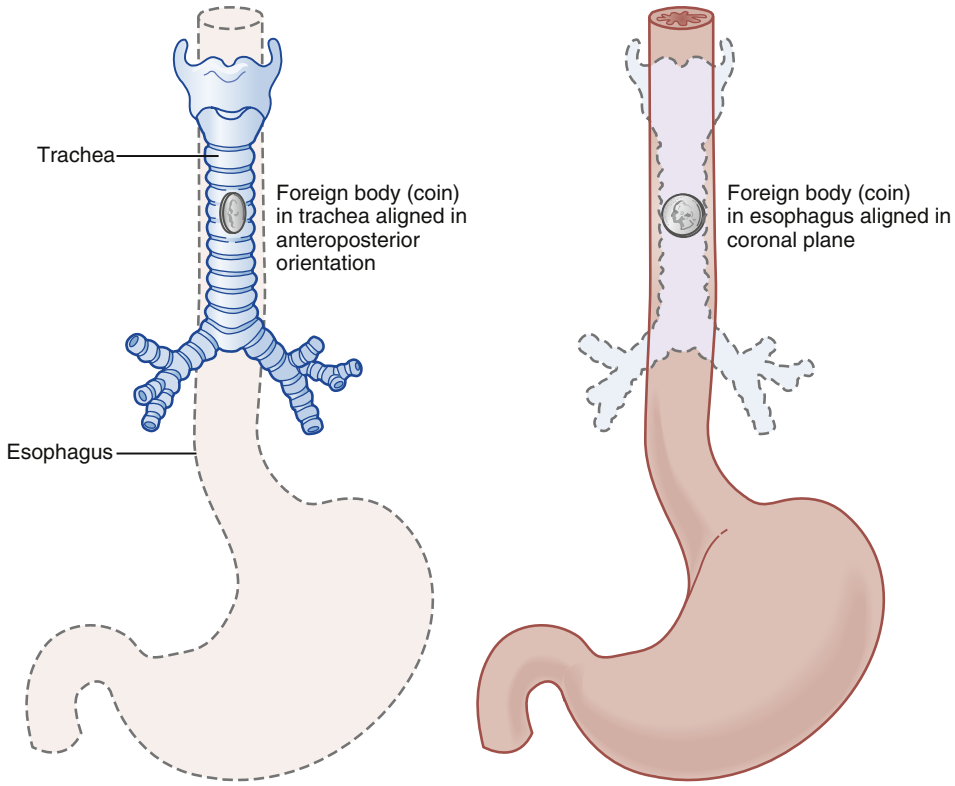

Fig. 51.3 Coronal Orientation of an Esophageal Foreign Object *(Left)* and Sagittal Orientation of a Tracheal Foreign Object *(Right).*

are oriented in the sagittal plane (Fig. 51.4). X-ray films also can provide useful information by showing whether the object is within or outside of the tracheal air column (Fig. 51.5).

Advanced imaging with CT or MRI is indicated when there is high clinical suspicion and plain radiography does not provide definitive results.[12] These imaging modalities usually require a more extended period outside of the ED, so patients must be sufficiently stable and able to lay supine to be considered for these studies.[19]

CT or MRI benefits include characterization of extra-airway anatomical complications, such as perforation or bleeding. Visualization of a foreign body by advanced imaging can also allow the elimination of diagnostic flexible bronchoscopy in favor of movement directly to therapeutic rigid bronchoscopy for foreign object retrieval.

In usual practice, CT tends to be more rapidly completed and widely accessible and therefore is the advanced imaging modality of choice for foreign body searches. The role of MRI tends to be in the diagnosis of foreign objects that are radiolucent (e.g., nuts with high-fat content).

CT (and less commonly, MRI) offers an additional utility—virtual bronchoscopy. Multidetector imaging provides a three-dimensional view of the tracheobronchial airway with proven utility in respiratory foreign body cases. CT virtual bronchoscopy has been shown to have very high (98%) positive predictive value in identifying tracheobronchial foreign bodies. CT virtual bronchoscopy should be considered when clinical suspicion is high and initial radiography is nondiagnostic.

Fluoroscopy was historically useful in airway foreign body evaluation. This modality has been supplanted by other advanced imaging techniques (e.g., CT, bronchoscopy).

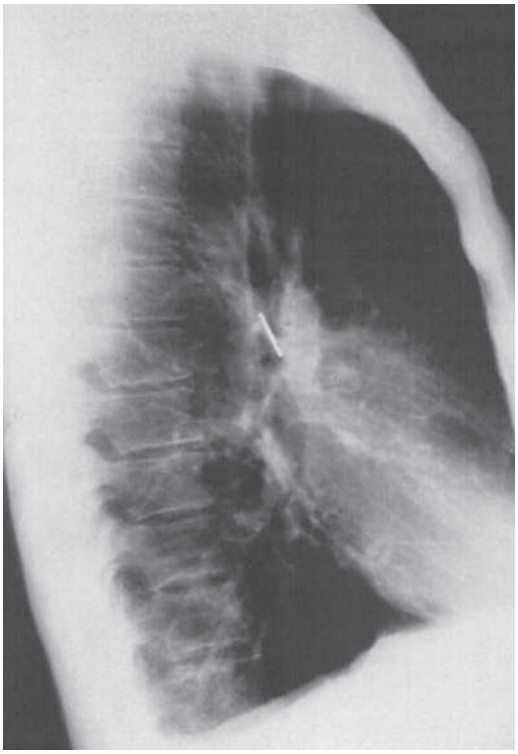

Fig. 51.4 Lateral X-Ray Study of a Chest Shows an Aspirated Coin in the Tracheal Air Column.

Management

Management of an airway tract foreign body is removal, which generally leads to rapid recovery of the patient. When the foreign object is distal to the oropharynx and the patient is minimally symptomatic, subspecialty consultation is the safest means for foreign body removal.

In rare cases, even oropharyngeal foreign bodies (e.g., small needles) may necessitate subspecialist consultation and operative removal. As a general rule, early consultation with an otolaryngologist to perform bronchoscopy in any patient with a suspected foreign body is key to

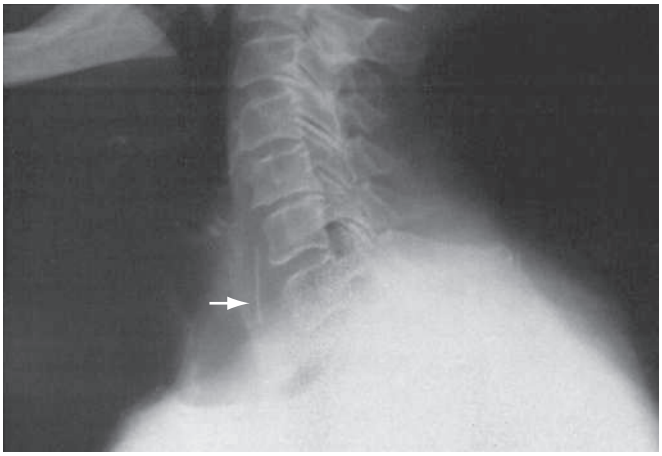

Fig. 51.5 Lateral X-Ray Study of a Neck Shows a Foreign Body (Chicken Bone) in the Esophageal Soft Tissue Shadow *(Arrow).*

reducing morbidity and mortality; the role of endoscopic management remains important given the limitations of other diagnostic methods.[20]

In a patient with critical airway obstruction and impending or actual respiratory arrest, the emergency clinician must act quickly to identify and remove the foreign body. There are generally three options: (1) attempt to extract the foreign body with maneuvers, (2) perform laryngoscopy or fiberoptic nasopharyngoscopy with attempts at removal under direct visualization, or (3) control the patient's airway. We recommend emergent consultation with other specialties who can assist in advanced airway management as resources and time allow (e.g., otolaryngology, anesthesiology, surgery).

Oropharyngeal foreign bodies may be removed with the use of pediatric or adult Magill forceps after visualizing the foreign body in the mouth. Blind finger sweeps should never be performed to remove a foreign body as it is more likely to push the foreign object deeper into the airway than result in retrieval.

The basic life support management of a choking infant (typically defined as up to 1 year of age) includes up to five back blows with the patient in a head-down position, followed by chest thrusts. In children, the Heimlich maneuver may be considered in the choking but conscious patient. In children who are unconscious, chest compressions are begun in cycles of five, and the oropharynx is visualized between cycles to see if the foreign body has been expelled into the mouth. If basic maneuvers fail to dislodge the foreign body allowing removal from the mouth, direct or video laryngoscopic visualization followed by removal of the object with Magill forceps should be performed. When a foreign body is not visualized on laryngoscopy but highly suspected, it is assumed to lie below the level of the vocal cords or is in the esophagus. If the patient is in extremis or is unresponsive and apneic, the emergency clinician should intubate the patient to establish an airway. Although it is indicated in these cases, the emergency clinician should be aware that intubation can change the position of the foreign body and the nature of the obstruction.

Intubation can force a tracheal foreign body distally into the right mainstem bronchus as long as the endotracheal tube tip is passed beyond the carina. If this is successful, the endotracheal tube can then be withdrawn back above the carina to facilitate left lung ventilation. It is important to have a stylet in place when advancing the tracheal tube as it will provide both the rigidity needed to move more stubborn foreign objects and a plug that will prevent the lumen of the tube from being occluded by softer objects. If the foreign body is in the esophagus, endotracheal intubation may provide necessary stenting of the trachea to keep the airway open.

In cases in which intubation fails because of the fixed positioning of a proximal foreign object (at or just above the vocal cords), surgical cricothyrotomy (needle cricothyrotomy in young children) is indicated. Cricothyrotomy may bypass such proximal obstruction and provide sufficient oxygenation to bridge the time gap to further definitive care by surgical subspecialists.

Patients who do not require immediate intubation or cricothyrotomy for complete airway obstruction may require airway management for other indications. These patients may have poor oxygenation, severe respiratory distress, and or hypoventilation. Especially in pediatric patients requiring bronchoscopy, the laryngeal mask airway may be an appropriate approach if ED airway management is necessary.

In noncritical situations, the only airway foreign objects generally amenable to emergency clinician removal are those in the oropharynx, which is best removed by forceps under direct or video laryngoscopic visualization performed after administration of topical anesthesia. Care should be taken when nonobstructing foreign objects appear to be impaled in the oropharynx because postremoval hemorrhage can occur. These should be removed in the operating room under general anesthesia. The removal of a laryngeal foreign object, even with general anesthesia, can be dangerous. Risks include hemorrhage, laryngeal trauma, and airway obstruction from the mobilized foreign object. Also, special care should be taken to prevent posterior displacement of oropharyngeal foreign objects or dropping of incompletely grasped proximal foreign bodies into the more distal airway.

The management decisions for endoscopic evaluation and treatment depend on the clinical presentation. When there is time-critical airway obstruction, rigid bronchoscopy is employed with flexible instrumentation used for diagnostic purposes in less acute patients.

At the other end of the clinical spectrum, patients may present with truly life-threatening cardiopulmonary distress because of airway foreign bodies. Future management strategies may increasingly take advantage of resources such as extracorporeal membrane oxygenation (ECMO), which has already appeared in published case series.[21]

Disposition

Pediatric data suggest that the performance of bronchoscopy within 24 hours of initial ED presentation reduces complications by half. Even after foreign body removal, sequelae may occur and can range from bleeding to infectious complications. Patients with a lower airway foreign body should be admitted for foreign body removal and observed for development of sequelae with post-discharge follow-up within a few days of removal of the foreign body.

Gastrointestinal Tract

Foundations

Most cases of gastrointestinal foreign bodies occur in pediatric patients, but adults are also at risk particularly if they are edentulous or if there are psychiatric conditions. Higher risk is present in cases in which chemical or electrical mucosal injury is likely (e.g., button battery or magnet ingestions). Perforation occurs in approximately 3% of cases and most frequently involves the esophagus or the ileocecal region. The duration of foreign body impaction and contour sharpness of the foreign body have been identified as the two major risk factors for complication development.[22]

Pharynx and Esophagus

Clinical Features

Foreign bodies lodged in the pharynx and esophagus are usually a sharp object (e.g., fishbone) that is impaled in the wall of the pharynx, hypopharynx, or esophagus or a larger bolus, usually a coin or food, that cannot pass beyond the anatomic points of esophageal constriction. In

pediatric patients, coins are the most common culprit, comprising well over half of ingested foreign bodies.

Esophageal constriction locations, where foreign objects tend to lodge, are (1) the proximal esophagus at the level of the cricopharyngeus muscle and thoracic inlet or, radiographically, the clavicular level; (2) the mid esophagus at the level of the aortic arch and carina; and (3) the distal esophagus just proximal to the esophagogastric junction or, radiographically, a level two to four vertebral bodies cephalad to the gastric bubble. In pediatric patients, as many as 90% of esophageal foreign bodies are impacted at the cricopharyngeal level. Foreign bodies may lodge at any level of the esophagus (or remainder of the gastrointestinal tract) with abnormal anatomy.

The complication rate for esophageal foreign body ingestion depends on the nature of the foreign body, the presence of impaction, and the duration of impaction. Overall, complications are rare, but there are important exceptions for perforating foreign bodies or those (e.g., button batteries) that mediate chemical damage. Complications become more likely with increasing impaction time and include esophageal erosion or perforation, tracheal compression, mediastinitis, esophagus-to-airway or esophagus-to-vascular fistulae, spondylodiskitis, extraluminal migration, abscess development, and formation of strictures or false esophageal diverticula.

In addition to coins, other common objects impacting the esophagus include but are not limited to food, toys, bones, batteries, wood, and glass. Esophageal rupture is a particular risk from the button (disk) battery. These batteries cause pathologic changes through pressure, electrical current, leakage of corrosives, or heavy metal poisoning. The identification of button batteries has both prognostic and therapeutic ramifications. Esophageal button battery impaction is considered an indication for prompt endoscopic intervention and removal. Although not as likely as button batteries or sharp foreign bodies to cause esophageal rupture, practically any ingested foreign body (e.g., meat) can cause rupture if patients vomit repeatedly after impaction.

Children usually are brought to the ED within 6 hours of foreign object ingestion. The most frequent presenting symptoms are dysphagia, drooling, retching, vomiting, and, occasionally, respiratory distress from extrinsic tracheal compression.[12] Pain, usually odynophagia, may be the major complaint. Anorexia, wheezing, or chest or neck pain also may be present.

Patients may complain that they can feel the object in the throat or chest, are unable to pass it, and are often able to localize the foreign body accurately. This presentation is particularly common if the foreign object is lodged in the upper esophagus. Drooling is consistent with high-grade obstruction.

Patients with suspected esophageal foreign body impaction rarely have complaints of shortness of breath or air hunger. When these findings are present, the emergency clinician should suspect a large esophageal foreign body impinging anteriorly and compressing the trachea. Infants and children may experience coughing, choking, croup-like symptoms, or significant respiratory compromise from foreign bodies lodged in the upper esophagus.

Patients may manifest late sequelae. Foreign bodies serving as a nidus for infection can result in fever. Signs of mediastinitis indicate esophageal perforation. Perforation of the esophagus with erosion into the vasculature or pulmonary tree can result in presentations ranging from hemoptysis to pulmonary abscess or life-threatening hemorrhage.

The history should include any known esophageal anatomic abnormality or prior instrumentation. A patient with a history of esophageal stenting should be considered to have stent migration when the history is dysphagia. Migration typically occurs within the first week of placement.

Examination begins with a careful inspection of the pharynx and hypopharynx. This search may reveal the foreign body or identify an oropharyngeal mucosal scratch that can cause foreign body symptoms even in the absence of an impacted object. Oropharyngeal examination also may provide indirect clues; for example, a missing dental plate on examination should lead the emergency clinician to suspect this item as a possible gastrointestinal tract foreign object. The base of the tongue, vallecula, supraglottic area, epiglottis, and piriform sinus should be examined. Topical anesthesia facilitates the examination. If adequate visualization is not obtained with the indirect laryngoscopy mirror, fiberoptic nasopharyngoscopy or direct laryngoscopy may be performed.

Subcutaneous emphysema found by neck palpation indicates probable esophageal perforation.

Differential Diagnoses

The selected differential diagnoses pharyngeal and esophageal foreign bodies include acute pharyngitis, acute epiglottitis, retropharyngeal abscess, esophagitis, strictures, esophageal webs, and oral cancers. When the history is unclear, the emergency clinician should consider an ingested foreign body in the differential diagnosis of atypical chest pain, wheezing, stridor, or signs of respiratory distress.

Diagnostic Testing

The fact that most foreign bodies (e.g., coins) are radiopaque accounts for reports that radiography contributes to diagnosis and management in most cases of esophageal impaction. The initial step is a posteroanterior and lateral chest radiograph and lateral cervical spine x-ray study using a soft tissue technique. The primary utility of plain radiography lies in the detection of radiopaque objects, with indirect findings (e.g., soft tissue swelling) more likely of utility in cases where there are chronic foreign bodies with complications.

Overall, the sensitivity of plain radiography for the detection of esophageal foreign bodies depends on the nature of the foreign body. In patients who are transferred to the ED from an outlying hospital, repeat radiography may be useful to assess whether the foreign object has passed into the stomach in the interval since prior films (Fig. 51.6). Additionally, cases have been described in which high-voltage radiographs can show visible markings on coins, thereby helping to differentiate from a disk battery.[23]

Esophageal foreign objects usually align themselves in the coronal plane and are posterior to the tracheal air column on lateral view. Coins in the esophagus lie in the coronal position in virtually all cases because the opening into the esophagus is much wider in this orientation (see Fig. 51.3).

Certain common foreign bodies are not radiopaque. Fish and chicken bones are frequently ingested, are difficult to visualize directly or radiographically, and often scratch the esophageal mucosa. Although some studies suggest that technique variation improves fish bone detection, plain x-ray examination remains insufficiently sensitive as a means to rule out these foreign bodies, and CT is recommended when initial imaging is negative.

When plain films fail to visualize foreign bodies and suspicion remains high, one option is contrast esophagography, which can be useful with radiopaque and sometimes with radiolucent foreign bodies. If perforation is not a concern, barium may be used as the contrast medium because it provides higher-quality images. If an esophageal leak is suspected, a water-soluble contrast solution should be used. When initial contrast films are not definitive, patients may be asked to swallow a contrast-soaked cotton ball, which may localize the foreign body by lodging proximal to the object.

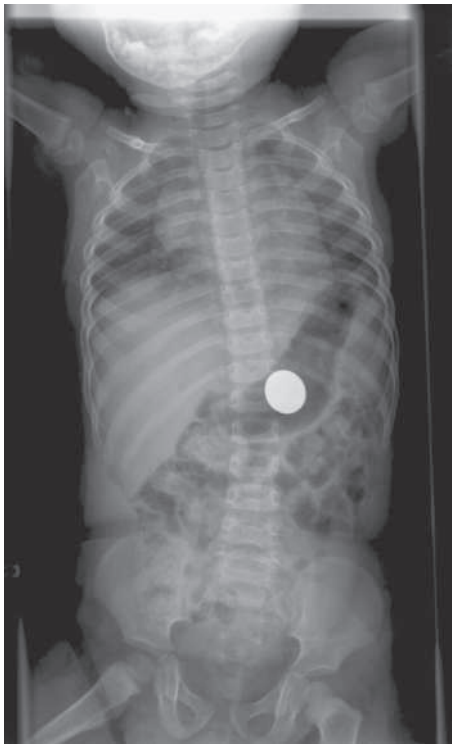

Fig. 51.6 Radiograph of a Child After Ingestion of a Coin, Located in the Stomach.

Contrast studies, even performed with barium, have limitations when the suspected object is an impacted bone. Barium swallow yields better results but risks aspiration and coats the object and esophagus, reducing the effectiveness of subsequent endoscopy.

CT scans with coronal and sagittal reconstructions are useful in identifying foreign bodies or more completely characterizing objects that are only vaguely appreciated on plain films. For some suspected foreign bodies that tend to be radiolucent, CT may be the primary diagnostic modality because it can give information about foreign body size, type, location, and orientation with respect to other anatomic structures. CT also can assist with the identification of complications because it can assess extra-esophageal anatomy.

One interesting modality reported in the detection of metal foreign bodies is the handheld metal detector. This modality does not involve risk or ionizing radiation, has no complications, and is quite useful with reported sensitivity approaching 90%. Especially when results are positive and indicate a foreign body below the diaphragm, or when the metal detector is used to track foreign body progress (e.g., coin passage) over time, this modality can obviate the need for radiography.

Management

Pharyngeal foreign bodies visualized by direct or video laryngoscopy usually can be removed with forceps or a clamp. The emergency clinician should guard against the possibility of inducing trauma or airway obstruction during extraction attempts.

With an esophageal food bolus or coin, the emergency clinician may be able to provide definitive management. With sharp objects, displaced esophageal stents, or impacted button batteries, more invasive and specialty consultation is necessary. Treatment strategy depends on the nature of the foreign body, length of time the object has been lodged, and expertise of the clinicians managing the case. In addition, the patient's age and prior medical and surgical history may be relevant. The overall success rate for endoscopic (i.e., nonsurgical) removal of esophageal objects is very high.

When the esophageal impaction is food, pharmacologic maneuvers are the first basic strategy for foreign body management. These steps are appropriate only if the object is known to be an impacted food bolus. The first medication that may be administered in an attempt to move a distal esophageal food bolus into the stomach is intravenous glucagon (0.5 to 2 mg), although its efficacy in causing the bolus to pass distally remains controversial. The drug appears to act by lowering the smooth muscle tone at the lower esophageal sphincter without inhibiting normal esophageal peristalsis and is effective in about one-third of cases. It should be noted that glucagon is less effective in esophageal eosinophilic infiltration, which the diagnosis may be increasingly reported by food-impaction patients presenting to the ED.[24]

Although it remains reasonable to try glucagon, the drug should be given slowly. If glucagon is given rapidly, there is theoretical risk that the induced vomiting could cause rupture of an obstructed esophagus.

Gas-forming agents have been historically used for the ED treatment of impacted esophageal food bolus, and this approach has poor evidentiary support. These medications also incur a known risk of mucosal injury and are not recommended.

Nitroglycerin, which had fallen out of favor for esophageal food bolus impaction management in the ED, has recently seen renewed interest. In one case report of steak bolus, a 0.4 mg nitroglycerin tablet was dissolved in 10 mL of water and swallowed and was effective in relieving obstruction.[25] The mechanism of nitroglycerin action is esophageal smooth muscle relaxation. A last approach, enzymatic degradation of an impacted meat bolus by use of the proteolytic enzyme papain, has fallen into disfavor because of the risks of esophageal perforation.

Early endoscopy is preferred when available and more effective as a first-line approach compared to medical therapies.[26] Endoscopic techniques can employ novel tools such as magnetic retrieval devices to aid in the removal of non-penetrating prone metallic foreign bodies (e.g., open safety pins).[27] Flexible endoscopy is the optimal approach for a variety of esophageal foreign bodies, including coins. The procedure does not require general anesthesia, can be performed in a sedated (nonintubated) patient, and may be diagnostic and therapeutic.[24]

The final strategy for foreign body removal, bougienage, involves pushing the foreign object into the stomach. The emergency clinician is generally not responsible for patient selection or actual performance of this procedure.

Expectant management, hoping for spontaneous foreign object passage into the stomach, is often successful. This approach is best suited for patients seen within 24 hours of ingestion who have a radiographically identified "safe" object (small and smooth-edged) in the distal esophagus.

Disposition

If a disk battery or magnetic object has been ingested, the location must be ascertained. If lodged in the esophagus, ED consultation for emergent removal by endoscopy is needed. If the object has passed distal to the esophagus, observation may be appropriate, but consultation with a gastroenterologist is suggested.

Regardless of the method used for esophageal foreign body therapy, there should be a follow-up evaluation of esophageal anatomy and patency after the removal of any esophageal object. Referral for such evaluation should be made by the emergency clinician.

Stomach and Bowel

Foundations

Foreign bodies that reach the stomach (Fig. 51.7) rarely cause major difficulties, although problems may occur, such as perforation and

Fig. 51.7 Radiograph of a Child After Ingestion of a Fishing Lure Without Hooks.

Fig. 51.8 Radiograph of a Patient After Body Packing. (Note the appearance of previously prepared drug packages.)

infection (e.g., after occult fish bone ingestion). Objects may still become impacted, most often at the gastric outlet or the ileocecal valve, although complications can arise at any point throughout the intestinal portion of the gastrointestinal tract. The increasing frequency of pediatric magnet ingestions contributes to an increasing complication rate seen with gastrointestinal foreign objects.[6]

Clinical Features

Symptoms of intraluminal objects range from none to vague abdominal pain to obstruction or perforation-associated peritonitis. Most patients have a specific history of ingested items.

The hiding of illicit drugs is a relatively frequent motivation for foreign body ingestion. Rupture of these drug-containing packages, especially when cocaine is involved, can result in rapid and lethal consequences.[28] Less often, such packages can cause bowel obstruction. Even when an obstruction is not present, vomiting may be reported. *Body packing,* which entails systematic gastrointestinal tract placement of previously prepared drug packages (Fig. 51.8), should be clinically differentiated from *body stuffing,* which denotes the hurried ingestion of hastily prepared packages in the face of imminent police presence. Because of the poorly organized wrapping of illicit drugs, body stuffers are more likely to experience toxicity and are less likely to have well-delineated findings on plain radiography. Drugs most often seen with body packing or body stuffing are cocaine and heroin.

Another important component of the history is medical implants in the gastrointestinal tract. Dental hardware and biliary stents are among the implants that can migrate and cause complications in the distal gastrointestinal tract.

Patients with gastrointestinal tract foreign bodies should be asked about history possibly related to bezoar presence. A habit of chewing hairs can result in trichobezoars, which infrequently extend from the stomach into the small intestine as a "tail" (Rapunzel syndrome). Phytobezoars (composed of vegetable matter) and lactobezoars (from milk curds) also have caused complications usually in the stomach. Other bezoars may be composed of infectious material (e.g., fungal bezoars) or inorganic substances (e.g., lithobezoars). Ingested toothpicks can lodge in the bowel wall, causing gastrointestinal complications and erosions or compression of nearby structures.

If the foreign body is a bezoar (a mass of indigestible food or nonfood material), there may be a palpable mass on abdominal examination. Physical findings may also include abdominal examination abnormalities typical of bowel obstruction or peritonitis.

Differential Diagnoses

The selected differential diagnoses of stomach and bowel foreign bodies include peptic ulcer disease, gastroesophageal reflux disease (GERD), gastric outlet obstruction, gastric tumors, bowel obstruction, intestinal polyps, and small and large bowel carcinomas.

Diagnostic Testing

Because most ingested foreign bodies are radiopaque, the initial imaging modality of plain radiography is often diagnostic (Fig. 51.9, see also Fig. 51.6).[29] Even when suspicion is low, radiography can identify foreign bodies as the explanation for symptoms. Two-view plain radiography has proved useful for situations ranging from coin ingestion to body packing (see Figs. 51.6 and 51.8).

The sensitivity of plain radiography varies widely depending on the nature of the foreign material. When plain films are nondiagnostic, CT is recommended. Contrast administration for some CT-delineated foreign bodies can identify the objects and assess for complications, such as perforation.

In the setting of body packing or body stuffing, oral contrast may confound identification of ingested packs so is most often done without oral contrast, but even this approach has been reported to have a sensitivity of well under 50% for either the detection or enumeration of packs.[30] Ultrasound is useful in drug packet cases in which plain radiography is nondiagnostic, when there is a need for an initial screening test, or when previously identified packets need to be tracked without ionizing radiation.[31] Negative ultrasound results are nondiagnostic.

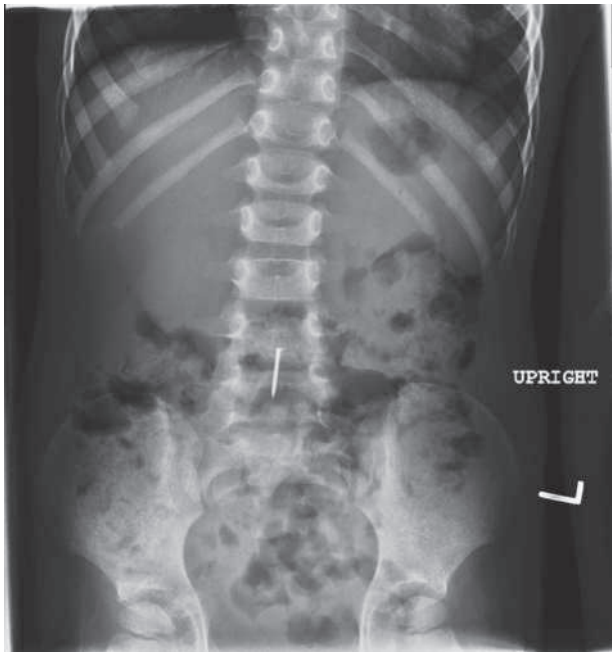

Fig. 51.9 Radiograph of a Child After Ingestion of a Nail (Which Ultimately Passed After Observation).

Management

The general rule for the management of gastric or intestinal foreign bodies is observation, with radiographic and stool follow-up to confirm passage. As is the case with esophageal impactions, early endoscopy is the preferred approach because of the modality's low risk and high efficacy.[32] However, for the routine cases that involve small, smooth-edged objects, most are expected to pass spontaneously if patients have normal anatomy.

Management decisions are based in part on the nature of the ingested object. Blunt objects can be expected to pass through the bowel with expulsion verifiable by stool collection and examination. If there is a particular concern, serial radiographs may be obtained after a week. Sharp objects (such as needles) are generally removed via endoscopy, but consultants (with whom all sharp gastrointestinal foreign bodies should be discussed) may decide to manage these cases expectantly. Early removal generally is required for objects wider than 2 cm because they do not pass the pylorus or longer than 5 to 6 cm because they do not clear the duodenal curvature. Overall, surgery is rarely required in intestinal foreign body cases, but there are cases (e.g., bowel obstruction) in which clinical circumstances prompt early operative intervention.

Button or disk battery ingestion has become increasingly common, garnering increased public awareness and media coverage. These batteries merit special considerations because of the possibility of the leakage of toxic substances and electrical mucosal burn.[12] The National Battery Ingestion Triage and Treatment Guideline advises oral honey administration followed plain radiography of the neck, esophagus, and abdomen. If an esophageal battery is identified, an aggressive endoscopic approach is recommended. However, batteries in the stomach and beyond can likely be monitored at home with a regular diet in the asymptomatic patient.[33]

When chosen, observation should be continued until (1) the object is found in the patient's stool; (2) the object becomes associated with bowel obstruction or perforation, necessitating immediate surgical intervention; or (3) the object shows no evidence of progression through the gastrointestinal tract on two radiographic examinations performed 24 hours apart, indicating impaction and the need for active removal.

In a body packer or body stuffer (see Chapters 135 and 144), regardless of law enforcement pressures, the emergency clinician should perform only interventions justified medically as reasonable steps to prevent injury from the ingested object or substance. If emergent drug package retrieval is medically unwarranted, the patient should be admitted for close observation for package passage or signs of toxicity. Monitoring drug metabolites in the urine may be helpful. Usually, the package passes through the gastrointestinal tract spontaneously. This passage can be facilitated with polyethylene glycol solution, laxatives, or both. Immediate removal of drug-containing packages should be considered if the patient develops intestinal obstruction or drug intoxication. Endoscopic removal of drug-containing packages is associated with theoretical risk because of package rupture and drug intoxication, but endoscopy remains a therapeutic mainstay in patients who are not passing ingested packets spontaneously.

Button batteries and magnets represent an additional group of foreign body types with specific management implications. Intact objects of this category that are ingested and pass into the stomach can be observed without the immediate removal necessary in cases of esophageal impaction. Administration of polyethylene glycol solution may speed distal movement. If the foreign body has not been passed after the first few clear-liquid stools, repeat radiography may identify objects in the rectum where they may be digitally evacuated. The emergency clinician should obtain early consultation (for endoscopy or surgery) when button batteries or magnets are encountered in the gastrointestinal tract because the complication rates with these objects are higher than for other foreign bodies. Available evidence is insufficient to confirm the usefulness of adjuvant medications (e.g., steroids, antireflux agents, prophylactic antibiotics) in cases of button battery ingestion.

Disposition

For button battery or magnet ingestions that are managed expectantly, repeat radiographs should be taken the next day to ensure movement of the object into the intestinal tract. X-rays should be repeated at least every 3 to 4 days thereafter to confirm continued distal movement. Management of other foreign bodies and bezoars depends on type and location. Infants with lactobezoars should be changed to elemental diets with close follow-up; most cases resolve without surgery.

Rectum

Foundations

Most anorectal foreign bodies result from retrograde introduction, typically as a result of sexual practices.[34] Prompt diagnosis is crucial because delay in definitive treatment is strongly associated with complications.

Clinical Features

Patients with anorectal foreign bodies are often hesitant to provide accurate histories. Studies have found that many patients with self-introduced anorectal foreign bodies do not freely admit to insertion but rather report anal pain or simply constipation. Other complaints include rectal pain, bleeding, or the inability to void when large objects impinge on the urethra.

It is possible for ingested food or objects (e.g., fish bones) to lodge in the rectum after passing through the proximal gastrointestinal tract. The duration for which the object has been in the anorectum has implications for mucosal failure and rupture.

Patients with anorectal perforation may have findings of peritonitis or abdominal tenderness. On digital rectal examination, the

Fig. 51.10 Radiograph of a Patient Who Inserted an Aerosol Can Into the Rectum.

foreign body might be directly palpated; this is the method of diagnosis in a large number of cases. In the absence of direct foreign body palpation, digital rectal examination may reveal findings (e.g., bloody discharge, loose sphincter tone) that raise suspicion for anorectal foreign body.

When the digital rectal examination findings are negative or when better visualization is required, anoscopy is the next step. Although the anoscope's diameter limits the size of foreign bodies that may be extracted through the instrument, anoscopy affords an improved view of the object's nature and positioning. Rigid sigmoidoscopy may be performed, with special care taken to minimize pressure on possibly ischemic anorectal mucosa.

In many patients, especially patients in whom multiple examinations or removal attempts have been made, sedation and analgesia may be required to enable invasive examination techniques. When there is any doubt about the integrity of the anorectal mucosa, invasive examination is best done in the operating room with the use of general anesthesia.

Differential Diagnoses

The selected differential diagnoses of rectal foreign bodies include internal and external hemorrhoids, anal fissures, rectal and anal tumors, perirectal and anal abscess, and rectal vault stool impaction.

Diagnostic Testing

With rectal foreign bodies, the history usually renders imaging unnecessary unless there is a need to assess for complications, such as perforation or abscess. When diagnostic radiography is needed, plain films are recommended as the initial step and often demonstrate the foreign body (Fig. 51.10). An important secondary finding on plain films is free intra-abdominal air secondary to anorectal perforation. Foreign objects contained within the lower rectum or anal region may not show free air on plain radiography despite perforation because it resides below the peritoneal reflection. If the object is not visualized on plain x-ray studies, a contrast study can be performed, with care taken to minimize hydrostatic pressures on potentially compromised mucosa. Water-soluble contrast should be used if perforation is suspected. CT should be employed to provide defining detail when plain films are nondiagnostic or if complications (e.g., perforation) are suspected.

Management

With patience and judiciously administered procedural sedation and analgesia, the emergency clinician often can remove rectal foreign bodies. Surgical intervention may be necessary on occasion. Depending on the nature of the foreign body and the presence of damage or perforation of the rectal wall, transanal removal (with or without sedation and local anesthesia) is successful in roughly half of the patients. Some advocate early triage of patients for operating room removal if ED foreign body extraction carries undue risk of anal sphincter injury. The emergency clinician should not attempt to retrieve objects that pose a high risk for rectal injury (e.g., light bulbs).

Initial efforts at foreign body removal in the ED should begin with the examiner's digit. Small rectal objects occasionally can be hooked by the finger and withdrawn. The digits should be lubricated with lidocaine jelly, and gentle abdominal pressure may be applied posteriorly and inferiorly in an attempt to mobilize foreign objects distally.

When digital extraction fails, the emergency clinician should attempt to use an anoscope or small vaginal speculum to visualize the foreign body. Ring forceps are placed through the visualizing apparatus to grasp and remove small objects. Sometimes, the mucosa may become tightly adherent to the distal end of the foreign body, creating a vacuum that prevents object withdrawal. Passage of a Foley catheter beyond the foreign object (sometimes via a rigid sigmoidoscope) with proximal air inflation of the catheter balloon usually breaks the vacuum and permits retrieval. When the emergency clinician possesses the appropriate expertise and equipment or if consultants are available, the next step may be removal with a vacuum device that is well-suited for some foreign bodies or forceps; sigmoidoscopy may be a necessary adjunct to such an approach. As with other removal means, the physician should be careful to minimize the risk of anorectal perforation. Caution should be used when enemas or cathartics are administered to patients with known rectal foreign bodies, especially foreign bodies with sharp edges.

An assessment for rectal injury is indicated after removal of the foreign object. When foreign body retrieval has been simple and the patient does not show increased pain, tenderness, or rectal bleeding, further imaging or direct visual evaluation for rectal trauma is unnecessary. However, many cases have been described to result in complications before or during removal necessitating surgical intervention. Some clinicians have posited the benefits of post-retrieval imaging and colonoscopy to rule out inadvertent injury to the colorectum.[35] Appropriate antibiotics are indicated in all cases of suspected bowel wall perforation and peritonitis.

Disposition

If any signs or symptoms of pain or rectal bleeding are present, post-removal sigmoidoscopy may identify small abrasions requiring close follow-up with a gastrointestinal or colorectal specialist. In general, hospitalization is indicated if emergent surgery is needed or if a rectal laceration or perforation is found.

Genitourinary Tract

Foundations

The literature describes a wide variety of genitourinary tract foreign objects ranging from easily extracted tampons and condoms to penile rings removed with great difficulty. As is the case with other foreign body locations, the genitourinary tract has also been the site at which a variety of odd foreign objects have been reported (e.g., radio antennae, telephone wires, electric cables).

Clinical Features

The patient history has major value in the diagnosis of most genitourinary objects because these are often placed by the patient or the patient is aware of their placement (e.g., body piercing). However, in children who fear parental disapproval of foreign object placement, secondary signs are the more common presentation. They are brought to medical attention when parents note foul-smelling, purulent discharge or bleeding from the urethra, the vagina, or both. Another common presentation in infants is penile constriction caused by the inadvertent wrapping of hairs around the shaft, usually just proximal to the corona.

In children, intentional insertion is the more common cause as a way to explore anatomy or even stimulation. However, sexual abuse and psychiatric disorders should be assessed and explored. In adolescents and adults, metal objects are usually placed for autoerotic stimulation. Constricting bands may be placed proximal to the scrotum or more often on the penile shaft. These patients frequently have presentations delayed by 12 hours or more. The swelling that renders these constricting bands so difficult to remove also hinders the physical examination, emphasizing the need for an accurate history.

Occasionally, an object (e.g., tampon) is forgotten until it causes purulent discharge. Secondary symptoms also can bring foreign bodies to physicians' attention. The migration of both physician-placed intrauterine devices and patient-placed wires into the bladder has occurred with a diagnosis made because of symptoms of cystitis.

Genitourinary tract foreign bodies may be infectious. The term *bezoar,* traditionally considered to delineate indigestible material in the gastrointestinal tract, also has been used (along with *urobezoar*) to describe foreign material collections throughout the urinary tract.[36] One common urinary tract bezoar is the *Candida* bezoar. Fungal bezoars are usually, but not always, seen in immunosuppressed patients or in patients with diabetes mellitus, neurogenic bladder, antibiotic use, or an indwelling urinary catheter.

Patients of all ages require a careful, gentle examination because of frequent anxiety about the anatomic region being examined. In a pediatric patient, a nasal speculum may be used to help visualize a vaginal foreign body. Thorough vaginal examination is indicated in patients with symptoms of vaginitis, with the search directed for infectious agents and foreign bodies. A vaginal foreign body may be palpated during digital rectal examination.

In children and adults, the presence of blood or discharge at the urethral meatus or vagina should be noted. Patients with intraurethral foreign objects also may have perineal induration and a high incidence of associated infection, which may progress to sepsis. In males with penile shaft swelling, the emergency clinician should perform careful inspection for constricting objects. In any child (including an infant) with penile or labial swelling, a coronal constricting hair should be sought.

In patients with retained penile rings, especially in those cases presenting after some hours' delay, examination often will reveal a swollen penis with mottling, duskiness, and excoriation. The interruption of venous and lymphatic outflow results in increasing penile enlargement with risks of tissue damage. Damage is especially likely if there have been previous attempts—as is usually the case—by the patient at self-removal of the constricting device. Examination may reveal indirect evidence of other genitourinary objects as well (e.g., multiple abscesses from embedded metal objects).

Differential Diagnoses

The differential diagnoses of genital urinary tract foreign bodies include urethritis, urethral strictures, penile tumors, penile hematomas and priapism, vaginitis, cervicitis, Bartholin cysts, and retained products of conception.

Diagnostic Testing

Often, no imaging is necessary and the foreign body's contours and extent are evident on examination. Plain films may be used when urethral or bladder radiopaque foreign bodies are suspected. Plain radiography also has proved useful in unusual cases of embedded metallic objects that may be difficult to palpate because of regional swelling and tenderness on palpation.

Ultrasound is increasingly utilized to locate foreign bodies sensed in the genitourinary tract.[12,37,38] Ultrasound is also useful to investigate for hydronephrosis. Acoustic shadowing may not be seen depending on the nature of the foreign body; *Candida* bezoars lack acoustic shadowing. These bezoars and other genitourinary tract objects are generally identifiable on CT. Urethrocystography and cystourethroscopy may be useful tools for the urologist identifying and locating genitourinary tract foreign objects.

MRI is often the most sensitive in the detection of foreign bodies in the genitourinary tract because of its soft tissue differentiation capacity, but availability limits widespread use in most EDs including tertiary centers.[12]

Management

Vaginal foreign bodies usually are removed easily. If the object has been present for some time, there may be associated bacterial or fungal infection. This should be treated with appropriate antimicrobials (e.g., metronidazole 500 mg two times daily for a week for bacterial infection; fluconazole 150 mg in a single oral dose for candidal vaginitis).

In males or females, foreign bodies located just inside the urethral meatus usually can be grasped with a clamp and removed. After failure of one or two attempts at removal by the emergency clinician, the best course is early urology consultation. Objects located in the proximal urethra or bladder usually require cystoscopy for extrication. One exception is the *Candida* bezoar, which generally is treated with antifungal agents. Penile urethral foreign bodies may be associated with urinary retention and secondary infection; in these cases, early urology consultation for endoscopic intervention is necessary.

Constricting penile foreign bodies are removed as early as possible because progressive swelling makes removal more difficult. Sedation and analgesia may be necessary. Also, care should be taken when removing constricting objects with instruments such as ring cutters, because penile shaft lacerations may be easily caused because of the tautness of the thin underlying skin. Hair and string foreign bodies are removed relatively easily with forceps and scissors or scalpel.

Disposition

After penile ring removal and confirmation of ability to void, patients usually can be discharged with close follow-up. Consultation with a urological specialist should be obtained for patients with penile trauma. Vaginal tears secondary to foreign body insertion or extraction may require admission and emergent gynecological surgery.

Soft Tissues

Foundations

Soft tissue foreign bodies present unique diagnostic and management dilemmas. Foreign bodies may be present not only in patients with known wounds but also in patients with secondary symptoms who are unaware or uncertain of foreign body entry.

Clinical Features

All patients with wounds should be considered for soft tissue foreign body contamination. In straightforward cases, patients have symptoms such as pain or foreign body sensation and may specifically report a foreign body. Meticulous examination and use of diagnostic aids are

in order when the patient is certain of a foreign body not readily seen by the emergency clinician. Particularly for radiolucent objects, such as wood splinters, the history and patient sensation are used as a guide to exploration. In more difficult cases, patients have symptoms related to complications. Soft tissue infections, especially if recurrent, should suggest a foreign body serving as a nidus. A careful history in patients with soft tissue complaints should include a search for antecedent trauma, no matter how remote, that may have resulted in foreign body entry.

The diagnosis is frequently obvious on visual inspection or standard wound evaluation. For smaller objects, the use of magnification may be a significant aid in foreign body identification and removal. In addition to the location of the foreign body, the examination should address injuries collateral to the object's presence. Distal neurovascular function should be tested.

Differential Diagnoses

The selected differential diagnoses of soft tissue foreign bodies include skin infections, arthropod bites, lipomas, ganglion cysts, melanoma, and basal and squamous cell carcinomas.

Diagnostic Testing

Depending on the nature of the foreign object, anteroposterior and lateral radiographs of the involved area of the body can be diagnostic. Plain radiography has been shown to be more than 98% sensitive when the foreign body is metal or other radiopaque material, such as gravel. If silver nitrate sticks were used to achieve hemostasis before imaging, the deposited metal can be expected to appear on plain radiography.

One common foreign body is glass, which is usually radiopaque. The size of glass that can be seen on x-rays depends on composition and alignment, but most glass shards greater than 0.5 mm in cross-sectional diameter are visible on plain films. Not seen easily on plain radiographs are items such as vegetable material (e.g., wood) and plastic.

When plain radiographs are negative and suspicion for a foreign body remains, ultrasound or CT is the next step. Ultrasound is readily available in many EDs and has been the subject of intensive study, and the technique continues to evolve. With the use of a 10-MHz or 7.5-MHz probe for shallow depths and a 5-MHz probe for deeper searching, ultrasound is clearly useful when positive. The main imaging findings include hyperechoic foci (most common), posterior acoustic shadowing, and a halo sign indicating infection (fluid around the foreign body).

Overall, given the availability of ultrasound in the ED and the multiple case reports of its utility in foreign body localization and removal, it is reasonable to employ this technique with the understanding that a positive test result is much more useful than a negative one. In specific situations, ultrasound may even be the best available imaging modality. For example, B-scan ultrasound as performed by ophthalmologists is better than both CT and MRI for identifying wooden foreign bodies in the posterior segment of the eye.

Like organic matter, tiny glass foreign bodies can prove elusive during an initial diagnostic evaluation. Ultrasound can aid in detecting when traditional radiographs are nondiagnostic yet suspicion remains. In cases where glass remains hidden, despite magnification (Fig. 51.11), ultrasound performed in a water bath (Figs. 51.12 and 51.13) can help identify the foreign object. The use of ultrasound for foreign body detection and guided removal continues to evolve, although it seems to be most useful in objects embedded within subcutaneous soft tissues.

In addition to characterizing objects seen on plain films, CT can help identify items (e.g., plastic, wood) missed on plain radiographs. CT may also prove valuable in localizing small or deeply seated objects.

Fig. 51.11 Radiograph of a Finger With a Glass Foreign Body That Is Not Identifiable.

Fig. 51.12 Picture of the setup of a water bath to facilitate high-quality ultrasound images of soft tissue foreign body identification.

CT also is useful for identifying foreign body sequelae (e.g., abscess). For objects such as gravel, glass, and metals, MRI streaking can hamper image interpretation and CT is preferred.[39]

MRI can assist in identifying foreign body presence and complications in a variety of anatomical areas.[12,40-42] Soft tissue objects can induce a chronic inflammatory reaction and lytic or blastic osseous changes that allow MRI to locate foreign bodies. In other cases, MRI is less optimal. Wood, especially if rich in water (as is the case with chronic foreign bodies), is better imaged with CT than MRI.[39]

Management

The most important determinant of successful foreign body removal is knowledge of the object's precise location. Standard radiopaque markers can aid in wound localization. Fluoroscopy or ultrasound may

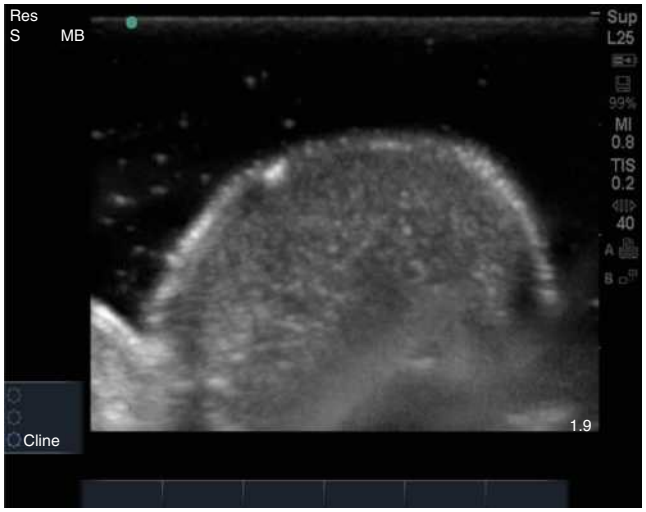

Fig. 51.13 Ultrasound Image of Glass Foreign Body Not Identifiable on a Radiograph. (Patient encounter case study archives. University of Oklahoma Department of Emergency Medicine. Lori J Whelan.)

allow simultaneous visualization and removal. When objects are not radiopaque, judicious probing of wounds with fine-gauge needles or forceps may allow tactile detection of the foreign body. For metallic foreign bodies, magnets may facilitate removal.

For removal of a foreign body, it may be necessary to extend the original wound or, if it is located away from the entrance site, to make a separate incision. The emergency clinician can perform limited wound extension or make separate incisions in regions where adequate analgesia and a relatively bloodless field can be achieved. Retrieval of foreign bodies, especially those linear in shape, is best achieved if the orientation of the foreign body is understood. The proximal end of the foreign body is grasped, and the object is gently removed following the plane of orientation.

In contrast to ingested fishbone foreign bodies, as previously discussed, an impaled fishhook in soft tissues is readily apparent without the aid of imaging. Many successful strategies for fishhook removal minimizing further soft tissue disruption have been described, including the "string-yank method" and the "advance and cut (the barb)" approaches. Both of these are demonstrated in videos on numerous online resources. Particularly, in the setting of "clean" fishhooks, routine prophylactic antibiotic use is not recommended.[43]

When inorganic objects are deeply embedded, it may be better to leave them in place than to create large surgical wounds to effect removal. Depending on foreign body location, operative intervention may be necessary for safe foreign body extraction. After foreign body removal, the emergency clinician should consider tetanus prophylaxis and empiric antibiotic treatment.

Disposition

Patients with suspected vascular or neurologic injuries require early evaluation by appropriate subspecialists. Soft tissue foreign bodies that are not suspected or undetected can lead to infectious sequelae. Therefore, careful discharge instructions and timely follow-up are crucial in these patients.

CHAPTER 51: QUESTIONS AND ANSWERS

1. A 33-year-old construction worker presents with left eye pain. On gross inspection, you note a watery discharge and moderate erythema. The patient tells you she was working with her coworker when she felt something hit her eye. She admits to not wearing protective goggles. Fluorescein examination of the eye reveals rivulets of dye tracking from a corneal defect. What is the next appropriate step in the patient's management?

a. Attempt ultrasound to find a foreign body
b. Check intraocular pressures
c. Obtain orbital computed tomography (CT) scan and consult ophthalmology
d. Obtain plain radiographs of the orbits
e. Topical antibiotics and ophthalmology follow-up in 24 hours

Answer: c. Rivulets of fluorescein tracking from the puncture (i.e., positive Seidel test) are helpful in identifying intraocular penetration. Ultrasound is, as always, operator dependent, and the pressure of the probe on the orbit may risk further injury to an open globe. Checking for intraocular pressures with an open globe is contraindicated. Compared with plain radiographs, CT delivers less radiation to the lens. Multiplanar reconstruction minimizes streak artifacts, affording better localization of intraorbital objects.

2. A 2-year-old presents with purulent drainage from the right naris and was brought to the ED by a parent concerned about sinusitis. The patient's vital signs are heart rate 110 beats/min, respiratory rate 15 breaths/min, and temperature 37.7°C. On physical examination, you see a small plastic ball in the naris surrounded by swelling and purulent discharge. What should be the next step?
   a. Attempt to displace the foreign body posteriorly
   b. Blow air into the contralateral naris to help dislodge the foreign body
   c. Consult the otolaryngologist for removal under anesthesia
   d. Make sure you have a right-angle probe, suction, and alligator forceps
   e. Treatment with topical vasodilators to facilitate removal

Answer: d. The emergency clinician can remove most nasal foreign bodies. Posterior movement of a nasal foreign body risks aspiration; objects should be removed anteriorly via suction or traction. In some circumstances, it may be prudent to place patients in lateral decubitus, perhaps with additional Trendelenburg positioning, to help prevent the aspiration of objects. Foreign bodies can sometimes be easily removed via positive pressure applied to the patient's mouth (not the contralateral naris, which should instead be clamped closed to increase pressure on the involved-side naris). Pretreatment with vasoconstrictive spray may improve chances of success. If positive-pressure techniques are not indicated or do not work, it is important to have necessary instruments close at hand to proceed with foreign body removal attempts. These instruments include a blunt-tipped right-angle probe (to maneuver posterior to the foreign body), suction equipment, and alligator forceps.

3. A 14-month-old girl presents in respiratory distress after eating a hot dog for lunch. Her mother states that she had stepped out of the kitchen, and when she came back, her daughter was sitting forward with noisy breathing and obvious distress. Which of the following management interventions is contraindicated?
   a. Back blows
   b. Blind finger sweep as the first step
   c. Chest thrusts
   d. Direct laryngoscopic visualization
   e. Intubate for respiratory distress
