ACKNOWLEDGMENTS

Never has family meant so much. To my wife, Barb; my children, Andrew, Blake, and Alexa; and their spouses and children, thank you for reminding me why this work is so important. I was inspired and profoundly moved by the response of our specialty, and our colleagues across the healthcare spectrum, to this pandemic scourge. We embrace a brighter future, with a deep and unwavering look to the past, and with enormous gratitude. To Peter and John, thanks again, for all of it.

RMW

It has been both an honor and a pleasure to serve as an editor of this book for 10 editions, and I would like to express my appreciation to those who made this career-spanning journey for me both professionally fulfilling and personally rewarding. To Peter, John, and Ron for their vision and leadership as editors-in-chief, and for their friendship over the years, in good times and bad; to the 28 other leaders in our discipline who gave generously of their time and talent to serve as editors on different editions of the book; to the Elsevier staff (particularly Laura, Kathy, Stephanie, Kate, and Dee) for the support and encouragement they provided over the years; and to my wife Patty for bringing color, perspective, and broader meaning to my life.

RSH

I would like to thank my family for their continued understanding of my work to improve emergency care. My husband, David, and our three children, Katie, Jeremiah, and Sarah, provide the love, joy, and encouragement that makes participation on endeavors as important as this text worthwhile. Finally, I would like to thank my editor colleagues for their leadership and willingness to work through the pandemic to create a truly state-of-the-art textbook.

MGH

I would like to thank my incredible husband, Peter—I love you more each day—and our three amazing daughters, Sam, Jessie, and Avery—being your mom has been the joy of my life. I would also like to thank Denver Health's humanistic, incredibly talented, and brave Emergency Medicine residents—you are the hope for the future of medicine. And finally, I am deeply indebted to our patients, who allow us to witness their most vulnerable moments, and in doing so, offer us a chance to connect through our shared humanity.

KB

Thanks to my family for their understanding and support of all that pulls me away from time to time. Many thanks to Ron, Bob, Marianne, Tim, and Susan for the opportunity to work on this critical resource for our specialty. It has been an honor and a wonderful learning experience.

CAB

Forged during the scourge of the COVID-19 pandemic, this edition was for me a personal tribute to Peter Rosen, whose voice I can still hear and whose wisdom I still need. Looking forward to a brighter, kinder, safer, and more just future for all we serve, including those most dear to me: Deborah, Jacob, Sally, and Jaylin.

DFMB

With sincerest gratitude to Ron for the opportunity to contribute to this humbling body of work, to Bob, Marianne, Tim, and Susan for their sage wisdom and guidance throughout the process, and to Christine, Marisa, and Matthew—you are a source of perpetual strength, grounding, and encouragement that forever reminds me of the really important things in life.

JED

I extend my heartfelt thanks to Valerie, Camille, Isabelle, Celeste, Julian, and my parents, Robert and Gladys. I also give full credit to my mentors and colleagues in Emergency Medicine, Toxicology, Wilderness Medicine, and Global Humanitarian Health. Special thanks (with deep reverence) to the scientists who helped lay the foundation for us all: Paracelsus, Alice Hamilton, Rosalind Franklin, and Percy Lavon Julian.

TBE

To all the faculty, residents, and staff at the Mount Sinai Department of Emergency Medicine—their commitment to excellence in clinical care, teaching, and research inspires me every day. To Silvana, my wife and closest colleague, for her support and for keeping me focused on the important things in life. To Ron for being a mentor throughout my career; and to John and Peter, who live forever in our hearts and in the soul of our specialty.

ASJ

I am grateful to Ron, Bob, Marianne, Tim, and Susan for their incredible mentorship and patience with me, and to our Elsevier team for their editorial guidance. I also want to thank all the faculty, fellows, and residents at Harbor-UCLA Medical Center for inspiring me to always be the better teacher, learner, faculty member, and physician. Thank you!

AHK

To my wife Ami, thank you for your boundless patience. To all the residents I have played a role in training, I hope you have learned from me as much as I have from you.

LDS

I am grateful to my family who put up with late nights, early mornings and weekends, understanding this labor of love. To the authors for incredible work, and to my senior editors, Bob, Marianne, Tim, and Susan for their tremendous guidance. To Ron, for his incredible leadership and artful mentorship and for bringing me on. To the Elsevier team for first class support. To my late mother, Belle Patricia Tyndall, a teacher of English, who made this all possible for me.

JAT

With love and thanks to my wife, Julie, and my three wonderful kids, Izzy, Jack, and Alex, to my family, ever patient and ever supportive, and to my friends and mentors who continue to advance this critical field. This book is more important than ever as our specialty forms the front line of medicine and faces the most challenging clinical and social issues of our time. I remain inspired by all of the emergency providers everywhere who strive to provide expert care to every patient, every day; thank you. And especially to my daughter, Isabella VanRooyen, who is striving toward a career in medicine. May she be as fortunate as I was to find wonderful colleagues, inspiring mentors, and generous patients to lead her into a fulfilling career in a field that she loves.

MVR

I would like to thank Ron for the opportunity to work with this incomparable team of authors and coeditors. I have learned from each of you. I also want to thank my residents. Over the years, I have been fortunate to work with gifted EM residents who push me each day to be a better physician. Their asking the "why" behind the medicine, wanting to know the evidence, and insisting upon excellence from themselves have elevated my knowledge and practice. I am deeply indebted to you all.

SRW

CONTRIBUTORS

Emily L. Aaronson, MD, MPH
Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

Ethan E. Abbott, DO, MSCR, FACEP
Assistant Professor, T32 Research Fellow, Department of Emergency Medicine, Ichan School of Medicine at Mount Sinai, New York, New York

Gallane Abraham, MD
Assistant Professor, Department of Emergency Medicine, Associate Director, Geriatric Emergency Department, Icahn School of Medicine at Mount Sinai, New York, New York

Michael K. Abraham, MD, MS
Adjunct Assistant Professor, Department of Emergency Medicine, University of Maryland School of Medicine, Baltimore, Maryland; Chairman, Department of Emergency Medicine, Upper Chesapeake Health System, Bel Air, Maryland

Miguel Agrait-Gonzalez, MD, CAQ-SM
Assistant Professor, Department of Emergency Medicine, Ponce Health Sciences University, San Lucas Hospital, Ponce, Puerto Rico; Attending Physician, Emergency Medicine, Bayamon Medical Center, Bayamon, Puerto Rico

Saadia Akhtar, MD
Associate Dean for Graduate Medical Education and Residency Program Director, Department of Emergency Medicine, Mount Sinai Beth Israel, New York, New York

Steven E. Aks, DO
Director, The Toxikon Consortium, Department of Emergency Medicine, Cook County Health and Hospitals System; Professor of Emergency Medicine, Department of Emergency Medicine, Rush University, Chicago, Illinois

Patricia Ruth Atchinson, DO
Assistant Professor of Emergency Medicine and Medicine, Department of Emergency Medicine, Geisel School of Medicine, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire

Marc Auerbach, MD, MSci, FAAP
Professor, Departments of Pediatrics and Emergency Medicine, Yale University School of Medicine, New Haven, Connecticut

Tom P. Aufderheide, MD, MS
Professor of Emergency Medicine, Department of Emergency Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Katie Bakes, MD
Rocky Mountain Regional VA Medical Center, Professor of Emergency Medicine and Pediatrics, University of Colorado School of Medicine, Denver, Colorado

Laura L. Banks, DVM, MPH
Associate Professor of Emergency Medicine, University of New Mexico School of Medicine, Albuquerque, New Mexico

Aaron N. Barksdale, MD, FACEP
Associate Professor, Vice Chair of Research, Department of Emergency Medicine, University of Nebraska Medical Center, Omaha, Nebraska

Whitney Barrett, MD
Associate Professor, Department of Emergency Medicine, University of New Mexico School of Medicine, Albuquerque, New Mexico

Bruce M. Becker, MD, MPH
Professor, Departments of Emergency Medicine and Community Health, Warren Alpert School of Medicine at Brown University, Providence, Rhode Island

Zheng Ben Ma, MD, MHCM
Assistant Medical Director of Emergency Services, Memorial Hermann Hospital-Texas Medical Center; Assistant Professor of Emergency Medicine, UT Health McGovern Medical School, Houston, Texas

Kevin Biese, MD, MAT
Departments of Emergency Medicine and Internal Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Michelle H. Biros, MD, MS
Professor, Department of Emergency Medicine, University of Minnesota Medical School, Minneapolis, Minnesota

Robert A. Bitterman, MD, JD, FACEP
President, Bitterman Health Law Consulting Group, Inc., Harbor Springs, Michigan

Thomas H. Blackwell, MD, FACEP, FAEMS
Professor of Emergency Medicine, University of South Carolina School of Medicine Greenville; Executive Director, Greenville County Emergency Medical Services, Greenville, South Carolina

Frederick C. Blum, MD
Professor, Department of Emergency Medicine, West Virginia University School of Medicine, Morgantown, West Virginia

Ira J. Blumen, MD, FACEP, FAMPA
Professor, Department of Medicine, Section of Emergency Medicine, University of Chicago; Program and Medical Director, University of Chicago Aeromedical Network (UCAN), University of Chicago Medicine, Chicago, Illinois

Edward B. Bolgiano, MD, FACEP, FACP
Assistant Professor, Department of Emergency Medicine, University of Maryland School of Medicine, Baltimore, Maryland

Michael C. Bond, MD
Associate Professor, Department of Emergency Medicine, University of Maryland School of Medicine, Baltimore, Maryland

Kelly Bookman, MD
Professor, Department of Emergency Medicine, University of Colorado, Denver, Colorado

Joelle Borhart, MD
Associate Professor, Department of Emergency Medicine, Georgetown University, Washington, DC

Brittany Boswell, MD
Fellow, Pediatric Emergency Medicine, University of Washington, Seattle Children's Hospital, Seattle, Washington

William J. Brady, MD
Professor, Departments of Medicine and Emergency Medicine, University of Virginia, Charlottesville, Virginia

Sabina A. Braithwaite, MD, MPH
Associate Professor and EMS Fellowship Director, Department of Emergency Medicine, Washington University, St. Louis, Missouri; Clinical Associate Professor, Department of Emergency Medicine, University of Kansas Medical Center, Kansas City, Kansas

Aaron Brody, MD, MPH, FACEP
Attending Physician, US Acute Care Solutions, Denver, Colorado

Calvin A. Brown III., MD
Department of Emergency Medicine, Brigham and Women's Hospital, Associate Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

MGH Trustees Endowed Professor, Department of Emergency Medicine, Harvard Medical School; President, Massachusetts General Hospital, Boston, Massachusetts

James E. Brown, MD, MMM
Professor and Chair, Department of Emergency Medicine, Wright State University Boonshoft School of Medicine, Dayton, Ohio

Jennie Alison Buchanan, MD, FACEP, FACMT
Staff Physician, Rocky Mountain Poison & Drug Safety; Department of Emergency Medicine, Denver Health & Hospital Authority; Associate Program Direct, Denver Health Residency in Emergency Medicine; Associate Professor, Department of Emergency Medicine, University of Colorado School of Medicine, Aurora, Colorado

Alice Kidder Bukhman, MD, MPH
Director of Clinical Operations, Brigham and Women's Faulkner Hospital; Instructor in Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Jeffrey Bullard-Berent, MD
Professor of Emergency Medicine and Pediatrics, University of New Mexico, Albuquerque, New Mexico

E. Bradshaw Bunney, MD, FACEP
Professor, Residency Program Director, Vice Chair for Clinical Affairs, Associate CMO for GME, Department of Emergency Medicine, University of Illinois at Chicago, Chicago, Illinois

John H. Burton, MD
Chair, Professor of Emergency Medicine, Department of Emergency Medicine, Carilion Clinic, Roanoke, Virginia

Derya Caglar, MD
Associate Professor, Department of Pediatrics, University of Washington; Fellowship Director, Pediatric Emergency Medicine, Seattle Children's Hospital, Seattle, Washington

John D. Cahill, MD
Senior Attending in Emergency Medicine and Infectious Disease, Global Health Director, Department of Emergency Medicine, Mount Sinai Hospital, New York, New York; Senior Lecturer, International Health and Tropical Medicine, The Royal College of Surgeons, Dublin, Ireland

David J. Carlberg, MD
Assistant Professor of Emergency Medicine, Departent of Emergency Medicine, Georgetown University School of Medicine; Associate Program Director, Program Director-Simulation and Safety Fellowship, Attending Physician, Department of Emergency Medicine, MedStar Georgetown University Hospital/MedStar Washington Hospital Center Emergency Medicine Residency, Washington, DC

Andrew K. Chang, MD, MS
Vincent P. Verdile, MD, '84 Endowed Chair for Emergency Medicine, Vice Chair for Research and Academic Affairs, Department of Emergency Medicine, Professor of Emergency Medicine, Albany Medical College; Attending Physician, Department of Emergency Medicine, Albany Medical Center, Albany, New York

Michael A. Chary, MD, PhD
Instructor, Department of Emergency Medicine, Cornell University, New York, New York

Paul Chen, MD, MBA
Director of Clinical Operations, Department of Emergency Medicine, Brigham and Women's Hospital; Instructor, Department of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Corrie E. Chumpitazi, MD, MS
Associate Professor, Department of Pediatrics, Baylor College of Medicine; Sedation Oversight Committee Co-Chair, Department of Pediatrics, Texas Children's Hospital, Houston, Texas

Stephen John Cico, MD, MEd
Assistant Dean for Graduate Medical Education, ACGME Designated Institutional Official (DIO), UCF-HCA Healthcare GME Consortium, Pediatric Emergency Medicine, University of Central Florida College of Medicine, Orlando, Florida

Ilene Claudius, MD
Associate Professor, Department of Emergency Medicine, David Geffen School of Medicine at University of California Los Angeles, Los Angeles, California; Physician Specialist, Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Wendy C. Coates, MD
Emeritus Professor of Emergency Medicine, Department of Emergency Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California; Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Jon B. Cole, MD
Medical Director, Minnesota Poison Control System; Professor of Emergency Medicine, Department of Emergency Medicien, University of Minnesota Medical School, Hennepin Healthcare, Minneapolis, Minnesota

Christopher B. Colwell, MD
Professor and Vice Chair, Department of Emergency Medicine, University of California at San Francisco; Chief, Department of Emergency Medicine, Zuckerberg San Francisco General Hospital and Trauma Center, San Francisco, California

Theodore Corbin, MD, MPP
Department of Emergency Medicine, Rush University Medical Center, Chicago, Illinois

Robert Cooper, MD, MBA, MPH
Assistant Professor, Department of Emergency Medicine, Ohio State University College of Medicine; Medical Director, Ohio State University Health Plan, Columbus, Ohio

Brian Niall Corwell, MD
Assistant Professor, Departments of Emergency Medicine and Orthopaedics, University of Maryland School of Medicine, Baltimore, Maryland

Amelia M. Curtis, MD
Toxicology Fellow in Training, Department of Emergency Medicine, University of Massachusetts, Worcester, Massachusetts

Shawn D'Andrea, MD, MPH, FACEP
Affiliated Faculty, Harvard Humanitarian Initiative, Harvard University, Boston, Massachusetts

Daniel F. Danzl, MD
Professor and Emeritus Chair, Department of Emergency Medicine, University of Louisville, Louisville, Kentucky

Moira Davenport, MD
Attending Physician, Department of Emergency Medicine, Allegheny General Hospital, Pittsburgh, Pennsylvania

Alysa S. Davis, DO
Department of Emergency Medicine, Unity Point Health-Trinity, Rock Island, Illinois

Jonathan Davis, MD
Professor and Academic Chair, Department of Emergency Medicine, Georgetown University and MedStar Health, Washington, DC

Natalie L. Davis, MD, MMSc
Associate Professor, Department of Pediatrics, University of Maryland School of Medicine, Baltimore, Maryland

Mohamud R. Daya, MD, MSc
Professor, Department of Emergency Medicine, Oregon Health & Science University, Portland, Oregon

Lindsey M. DeGeorge, MD
Attending Physician, Department of Emergency Medicine, MedStar Southern Maryland Hospital, Clinton, Maryland

Robert W. Derlet, MD
Professor, Emergency Department, University of California, Davis School of Medicine, Sacramento, California

Valerie A. Dobiesz, MD, MPH
Department of Emergency Medicine, Brigham and Women's Hospital; Director of Internal Programs, STRATUS Center for Medical Simulation; Assistant Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Alan A. Dupré, MD, FACEP, FAAEM
Assistant Professor, Department of Emergency Medicine, Wright State University/Wright-Patterson Air Force Base, Dayton, Ohio

Petra Duran-Gehring, MD, RDMS, FACEP
Associate Professor, Director of Emergency Ultrasound, Department of Emergency Medicine, University of Florida College of Medicine-Jacksonville, Jacksonville, Florida

Deputy Chair and Brigham Distinguished Chair in Emergency Medicine, Department of Emergency Medicine, Brigham and Women's Hospital, Associate Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Ryan D. Kearney, MD, MPH
Staff Physician, Summit Health, Bend, Oregon

Matthew P. Kelly, MD
Assistant Professor, Department of Emergency Medicine, University of Alabama, Birmingham, Birmingham, Alabama

Hyung T. Kim, MD
Associate Professor of Clinical Emergency Medicine, Department of Emergency Medicine, David Geffin School of Medicine, University of California, Los Angeles, Los Angeles, California

Sean M. Kivlehan, MD, MPH
Fellowship Director, Global Emergency Medicine, Department of Emergency Medicine, Brigham and Women's Hospital, Boston, Massachusetts

Kristi L. Koenig, MD, FACEP, FIFEM, FAEMS
Medical Director, San Diego County EMS Office, San Diego, California; Professor Emerita of Emergency Medicine and Public Health, University of California, Irvine, Irvine, California

Joshua M. Kosowsky, MD
Attending Physician, Department of Emergency Medicine, Brigham and Women's Hospital; Assistant Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Christine E. Koval, MD
Section Head, Transplant Infectious Diseases, Associate Professor, Lerner College of Medicine of Case Western Reserve University; Department of Infectious Diseases, Transplant Center, Cleveland Clinic, Cleveland, Ohio

Alex Koyfman, MD
Assistant Professor, Attending Physician, Department of Emergency Medicine, University of Texas Southwestern Medical Center, Parkland Memorial Hospital, Dallas, Texas

Michael C. Kurz, MD, MS, FACEP, FAHA
Professor and Vice Chair for Research, Department of Emergency Medicine; Professor, Department of Surgery, Division of Acute Care Surgery, University of Alabama School of Medicine, Birmingham, Alabama

Michelle D. Lall, MD, MHS, FACEP
Associate Professor, Department of Emergency Medicine, Emory University, Atlanta, Georgia

Spenser C. Lang, MD
Assistant Professor, Department of Emergency Medicine, University of Cincinnati, Cincinnati, Ohio

Jeffrey E. Lee, MD
Associate Clinical Professor, Residency Program Director, Department of Ophthalmology, University of California San Diego School of Medicine, La Jolla, California; Chief of Ophthalmology, University of California San Diego Medical Center, University of California San Diego Health System, San Diego, California, San Diego, California

Charles Lei, MD
Assistant Professor of Emergency Medicine, Department of Emergency Medicine, Vanderbilt University Medical Center, Nashville, Tennessee

Michael D. Levine, MD
Associate Professor of Emergency Medicine, Department of Emergency Medicine, University of California, Los Angeles, Los Angeles, California

Matthew J. Levy, DO, MSc
Assistant Director of Special Operations, Department of Emergency Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland

Phillip D. Levy, MD, MPH, FACEP, FAHA, FACC
Professor of Emergency Medicine, Associate Vice President for Translational Science, Wayne State University, Detroit, Michigan

Christopher S. Lim, MD
Senior Physician, Department of Emergency Medicine. Kaiser Permanente San Jose Medical Center, San Jose, California

Daniel Lindberg, MD
Associate Professor, Departments of Emergency Medicine and Pediatrics, University of Colorado Anschutz Medical Campus; Children's Hospital Colorado, Denver, Colorado

Ari M. Lipsky, MD, PhD
Chair, Department of Emergency medicine, HaEmek Medical Center, Afula, Israel

J. Marc Liu, MD, MPH
Professor, Department of Emergency Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Brit Long, MD
Physician, Department of Emergency Medicine, SAUSHEC, Brooke Army Medical Center, Texas

Wendy Macias-Konstantopoulos, MD, MPH
Associate Professor, Department of Emergency Medicine, Havard Medical School, Boston, Massachusetts

Carolina Barbosa Maciel, MD, MSCR
Assistant Professor of Neurology and Neurosurgery, Department of Neurology and Neurosurgery, University of Florida, Gainesville, Florida; Adjunct Assistant Professor of Neurology, Yale University School of Medicine, New Haven, Connecticut; Adjunct Assistant Professor of Neurology, University of Utah, Salt Lake City, Utah

Patrick J. Maher, MD, MS
Assistant Professor, Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai, New York, New York

Gerald E. Maloney Jr., DO, MS
Associate Medical Director, Emergency Department, Louis Stokes Cleveland VA Medical Center; Associate Professor, Department of Emergency Medicine, Case Western Reserve University, Cleveland, Ohio

Patrick J. Maloney, MD
Clinical Faculty, University of South Carolina School of Medicine-Greenville, Greenville, South Carolina

Catherine Anna Marco, MD
Professor, Department of Emergency Medicine, Wright State University Boonshoft School of Medicine; Attending Physician, Department of Emergency Medicine, Miami Valley Hospital, Dayton, Ohio

Keith A. Marill, MD, MS
Department of Emergency Medicine, Massachusetts General Hospital; Associate Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Joseph P. Martinez, MD
Associate Professor, Departments of Emergency Medicine and Medicine, University of Maryland School of Medicine, Baltimore, Maryland

Aaron G. Matlock, MD, MBA
Attending Physician, Department of Emergency Medicine, Brooke Army Medical Center, Joint Base San Antonio, Texas

Ryanne J. Mayersak, MS, MD
Assistant Professor, Associate Residency Program Director, Director of Residency Wellness, Department of Emergency Medicine, Oregon Health and Science University, Portland, Oregon

Larissa S. May, MD, MSPH
Professor, Department of Emergency Medicine, University of California, Davis, Sacramento, California

Nicole S. McCoin, MD
Chair, Department of Emergency Medicine, Ochsner Medical Center, Metairie, Louisiana

Michael T. McCurdy, MD
Clinical Professor, Departments of Medicine and Emergency Medicine, Division of Pulmonary & Critical Care, University of Maryland School of Medicine, Baltimore, Maryland; Chief, Department of Medicine and Division of Critical Care, Department of Medicine, University of Maryland St. Joseph Medical Center, Towson, Maryland

Jeffry McKinzie, MD
Assistant Professor, Departments of Emergency Medicine and Pediatrics, Vanderbilt University Medical Center, Nashville, Tennessee

Christopher W. Meaden, MD, MS
Assistant Professor, Department of Emergency Medicine. Rutgers New Jersey Medical School, Newark, New Jersey

Timothy J. Meehan, MD, MPH
Associate Professor of Emergency Medicine and Medical Toxicology, The University of Illinois at Chicago, UI Health, Chicago, Illinois

Niyati Mehta, MD
Assistant Professor, Department of Pediatric Neurology, Medical College of Wisconsin, Milwaukee, Wisconsin

William J. Meurer, MD, MS
Professor, Departments of Emergency Medicine and Neurology, University of Michigan, Ann Arbor, Michigan

Nathan W. Mick, MD
Vice Chair, Department of Emergency Medicine, Maine Medical Center, Portland, Maine; Associate Professor of Emergency Medicine, Tufts University School of Medicine, Boston, Massachusetts

Eli M. Miloslavsky, MD
Assistant Professor, Department of Medicine, Division of Rheumatology, Allergy, and Immunology, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

James R. Miner, MD
Professor and Chair, Department of Emergency Medicine, University of Minnesota; Chief, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

Nicholas M. Mohr, MD, MS
Department of Emergency Medicine, University of Iowa Hospitals and Clinics, Iowa City, Iowa

Joel Moll, MD
Associate Professor, Vice Chair of Education, Residency Program Director, Medical Education Fellowship Director, Department of Emergency Medicine, Virginia Commonwealth University, Richmond, Virginia

Jessica Monas, MD
Assistant Professor, Consultant, Department of Emergency Medicine, Mayo Clinic, Phoenix, Arizona

Andrew A. Monte, MD, PhD
Associate Professor, Department of Emergency Medicine, Section of Pharmacology and Toxicology, University of Colorado School of Medicine, Aurora, Colorado; Rocky Mountaint Poison & Drug Safety, Denver Health & Hospital Authority, Denver, Colorado

Martha M. Montgomery, MD, MS
Attending Physician, Department of Emergency Medicine, Highland Hospital-Alameda Health System, Oakland, California

Malia J. Moore, MD
Assistant Professor of Emergency Medicine, Indiana University School of Medicine, Indianapolis, Indiana

Gregory J. Moran, MD
Professor of Clinical Emergency Medicine, David Geffen School of Medicine at University of California Los Angeles, Los Angeles, California; Department of Emergency Medicine and Division of Infectious Disease, Olive View-UCLA Medical Center, Sylmar, California

Mark B. Mycyk, MD
Director, Toxicology Research, Department of Emergency Medicine, Cook County Health; Associate Professor, Department of Emergency Medicine, Rush Medical College, Chicago, Illinois

Jose V. Nable, MD, NRP
Associate Professor, Department of Emergency Medicine, Georgetown University School of Medicine; Attending Physician, Department of Emergency Medicine, MedStar Georgetown University Hospital, Washington, DC

Joshua Nagler, MD, MHPEd
Associate Division Chief, Fellowship Director, Division of Emergency Medicine, Boston's Children's Hospital; Associate Professor of Pediatrics and Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Denise Nassisi, MD
Associate Professor, Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai, New York, New York

Joshua B. Nathan, MD
Clinical Assistant Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Rosalind Franklin University of Medicine and Science, Chicago, Illinois

Lewis S. Nelson, MD
Professor and Chair, Department of Emergency Medicine, Rutgers New Jersey Medical School, Newark, New Jersey

Michael E. Nelson, MD, MS
Attending Physician, Departments of Emergency Medicine, Toxicology, and Addiction Medicine, NorthShore University Health System, Evanston, Illinois; Attending Physician, Departments of Emergency Medicine, Toxicology, and Addiction Medicine, Cook County Hospital (Stroger), Chicago, Illinois

Kim Newton, MD
Clinical Associate Professor, Department of Emergency Medicine, Los Angeles County Medical Center, Keck School of Medicine at University of Southern California, Los Angeles, California

Thomas Nguyen, MD
Associate Professor, Department of Emergency Medicine, Mount Sinai Beth Israel, New York, New York

Adam M. Nicholson, MD
Assistant Professor, Department of Emergency Medicine, University of Wisconsin, Madison, Wisconsin

L. Connor Nickels, MD, RDMS
Ultrasound Director, Attending Physician, Department of Emergency Medicine, University of Florida, Gainesville, Florida

Jenna Karagianis Nikolaides, MD, MA
Assistant Professor of Emergency Medicine and Medical Toxicology, Department of Emergency Medicine, Assistant Professor of Addiction Medicine, Department of Psychiatry, Rush University Medical Center; Medical Toxicologist, Illinois Poison Center, Chicago, Illinois

Micah J. Nite, MD
Assistant Professor, Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai, New York, New York

Michael Nitzberg, MD, FACEM, FAAEM, FACEP
Staff Specialist, Emergency Medicine, Illawarra Shoalhaven Local Health District, Wollongong Hospital, Wollongong, New South Wales, Australia

Marquita S. Norman, MD, MBA
Associate Professor, University of Texas Southwestern Medical Center, Dallas, Texas

Ashley Booth Norse, MD, FACEP
Associate Chair of Operations, Associate Professor, Department of Emergency Medicine, University of Florida COM-Jacksonville, Jacksonville, Florida

Richard M. Nowak, MD, MBA
Chair Emeritus, Department of Emergency Medicine, Henry Ford Health System; Clinical Professor, Department of Emergency Medicine, Wayne State Medical School, Detroit, Michigan; Clinical Professor, Department of Emergency Medicine, University of Michigan Medical School, Ann Arbor, Michigan

Adedamola A. Ogunniyi, MD
Associate Program Director, Department of Emergency Medicine, Harbor-UCLA Medical Center, Los Angeles Department of Health Services, Torrance, California; Assistant Clinical Professor, Department of Emergency Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California

Daniel L. Overbeek, MD
Medical Toxicology Fellow, Departments of Emergency Medicine and Medical Toxicology, University of Rochester Medical Center, Rochester, New York

Patricia Padlipsky, MD, MS
Associate Clinical Professor of Pediatrics, David Geffen School of Medicine, University of California at Los Angeles, Los Angeles, California; Director, Pediatric Emergency Department, Harbor-UCLA Medical Center, Torrance, California

Jessica Palmer, MS, MD
Attending Physician, Department of Emergency Medicine, MedStar Georgetown University Hospital, Washington Hospital Center, Washington, DC

Linda Papa, MD, MSc
Director of Academic Clinical Research, Department of Emergency Medicine, Orlando Regional Medical Center; Adjunct Professor, Department of Emergency Medicine, University of Central Florida, Orlando, Florida; Adjunct Professor, Departments of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; Adjunct Professor, Department of Emergency Medicine, University of Florida, Gainesville, Florida

David A. Peak, MD
Associate Residency Director, Department of Emergency Medicine, Massachusetts General Hospital; Assistant Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Ryan Anthony Pedigo, MD, NHPE
Associate Residency Program Director, Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California; Assistant Professor of Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California

Jack Perkins Jr., MD
Department of Emergency Medicine, Virginia Tech, Roanoke, Virginia

James A. Pfaff, MD
Attending Physician, San Antonio Univformed Services Health Education Consortium (SAUSHEC), Emergency Medicine Residency, Brooke Army Medical Center, Joint Base San Antonio, Texas

Camiron L. Pfennig, MD, MHPE
Prisma Health-Upstate Department of Emergency Medicine, Emergency Medicine Residency Director, Associate Professor, University of South Carolina School of Medicine Greenville; Clemson University School of Health Research, Greenville, South Carolina

Michael P. Phelan, MD
Associate Professor, Lerner College of Medicine of Case Western Reserve University, Emergency Medicine Institute, Cleveland Clinic, Cleveland, Ohio

Ava E. Pierce, MD
Associate Chair of Diversity and Inclusion, Department of Emergency Medicine, University of Texas Southwestern Medical Center, Dallas, Texas

Melissa A. Platt, MD
Professor, Department of Emergency Medicine, University of Louisville, Louisville, Kentucky

Elizabeth P.D. Pontius, MD
Associate Professor of Emergency Medicine, Emergency Department, Georgetown University School of Medicine; Attending Physician, Emergency Department, Assistant Program Director, Emergency Medicine Residency, Georgetown/MedStar Washington Hospital Center, Washington, DC

Trevor R. Pour, MD
Associate Residency Program Director, Department of Emergency Medicine, Mount Sinai Hospital, New York, New York

Kian Preston-Suni, MD, MPH
Assistant Chief, Department of Emergency Medicine, Greater Los Angeles VA Medical Center; Assistant Professor of Clinical Emergency Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California

Timothy G. Price, MD
Professor, Department of Emergency Medicine, University of Louisville, Louisville, Kentucky

William B. Prince, MD
Clinical Assistant Professor of Pediatrics, Seattle Children's Hospital, University of Washington School of Medicine, Seattle, Washington

Marc Probst, MD, MS
Assistant Professor, Director of General Emergency Medicine Research, Department of Emergency Medicine, Columbia University Irving Medical Center, New York, New York

Michael Pulia, MD, MS
Assistant Professor, Director, Emergency Care for Infectious Diseases (ECID) Research Program, Department of Emergency Medicine, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Michael A. Puskarich, MD
Director of Research, Department of Emergency Medicine, Hennepin County Medical Center; Associate Professor of Emergency Medicine, Department of Emergency Medicine, University of Minnesota, Minneapolis, Minnesota

Tammie E. Quest, MD
Professor, Department of Emergency Medicine, Emory University School of Medicine, Decatur, Georgia; Division Chief, Palliative Medicine, Family and Preventive Medicine, Emory University, Atlanta, Georgia

Ali S. Raja, MD, MBA, MPH
Executive Vice Chair of Emergency Medicine, Mooney-Reed Endowed Chair, Massachusetts General Hospital; Professor of Emergency Medicine, Harvard Medical School Boston, Massachusetts

Neha P. Raukar, MD, MS, California QSM
Associate Professor, Department of Emergency Medicine, Mayo Clinic, Rochester, Minnesota

Robert F. Reardon, MD
Professor, Department of Emergency Medicine, University of Minnesota; Assistant Chief, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

Kevin C. Reed, MD
Vice Chief, Department of Emergency Medicine, MedStar Georgetown University Hospital; Assistant Professor of Emergency Medicine, Georgetown University School of Medicine, Washington, DC

David B. Richards, MD, FACEP
Associate Professor, Department of Emergency Medicine, University of Colorado School of Medicine; Denver Health Medical Center, Denver, Colorado

Megan L. Rischall, MD
Faculty Physician, Department of Emergency Medicine, Hennepin County Medical Center; Assistant Professor, Department of Emergency Medicine, University of Minnesota Medical School, Minneapolis, Minnesota

Daniel W. Robinson, MD, MHPEc
Emergency Physician, Veteran's Affairs Puget Sound; Clinical Instructor, Departments of Emergency Medicine and Family Medicine, University of Washington, Seattle, Washington

Howard Rodenberg, MD, MPH
Physician Advisor, Clinical Documentation Integrity, Baptist Health, Jacksonville, Florida; Emergency Physician, Speaker, Consultant, and Blogger, University of Missouri-Kansas City School of Medicine, Kansas City, Missouri

Matthew A. Roginski, MD, MPH
Assistant Professor of Emergency Medicine and Medicine, Departments of Emergency Medicine and Medicine, Section of Pulmonary and Critical Care Medicine, Geisel School of Medicine, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire

Chad E. Roline, MD
Emergency Medicine Physician, Emergency Physicians Professional Association, North Memorial Health Hospital and Maple Grove Hospital, Bloomington, Minnesota

Emily Rose, MD
Associate Professor of Clinical Emergency Medicine (Educational Scholar), Department of Emergency Medicine, LA County + USC Medical Center, Keck School of Medicine of the University of Southern California; Director for Pre-Health Undergraduate Studies, Medical Education, Keck School of Medicine of the University of Southern California, Los Angeles, California

Jeremy Rose, MD, MPH, FRCPC
Associate Professor, Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai, New York, New York

Nicholas G.W. Rose, MD, PhD, FRCPC, Dip Sports Med (CASEM)
Clinical Assistant Professor, Department of Emergency Medicine, University of British Columbia, Vancouver General Hospital, Vancouver, British Columbia, Canada

Tony Rosen, MD, MPH
Assistant Professor of Emergency Medicine, Department of Emergency Medicine, Weill Cornell Medical College, NewYork-Presbyterian Hospital, New York, New York

Weston Ross, DO, MBA
Emergency Medicine Staff Physician, Bellevue Medical Center, Bellevue, Nebraska

C. Craig Rudy, MD
Attending Physician, Department of Emergency Medicine, Samaritan Health Services, Albany, Oregon

Anne-Michelle Ruha, MD
Chair, Medical Toxicology, Banner-University Medical Center Phoenix; Professor, Departments of Internal Medicine and Emergency Medicine, University of Arizona College of Medicine, Phoenix, Arizona

Megan M. Rybarczyk, MD, MPH
Assistant Professor of Clinical Emergency Medicine, Department of Emergency Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, Pennsylvania

Carolyn Joy Sachs, MD, MPH
Clinical Professor, Emergency Department, David Geffen School of Medicine, University of California, Los Angeles; Chair, Domestic Violence Committee, UCLA Health Sciences, David Geffen School of Medicine at University of California, Los Angeles, Ronald Reagan-UCLA Medical Center, Los Angeles, California; Voluntary Medical Director, FNS Sexual Assault Examination Program, Long Beach, California

Matthew Salzberg, MD, MBA
Assistant Professor, Department of Emergency Medicine, University of Colorado Medical School; Assistant Medical Director, Department of Emergency Medicine, University of Colorado Anschutz Medical Center, Aurora, Colorado

León D. Sánchez, MD, MPH
Chief, Department of Emergency Medicine, Brigham and Women's Faulkner Hospital; Associate Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Arthur B. Sanders, MD, MHA
Professor, Department of Emergency Medicine, University of Arizona College of Medicine Tucson, Tucson, Arizona

Christopher E. San Miguel, MD
Assistant Professor of Emergency Medicine, Wexner Medical Center, The Ohio State University, Columbus, Ohio

Richard J. Scarfone, MD
Associate Professor, Department of Pediatrics, Perelman School of Medicine at the University of Pennsylvania; Attending Physician, Division of Emergency Medicine, Medical Director, Emergency Preparedness, Division of Emergency Medicine, Program Director, Pediatric Emergency Medicine Fellowship, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Andrew Schmidt, DO, MPH
Assistant Professor, Department of Emergency Medicine, University of Florida-Jacksonville, Jacksonville, Florida

Eric R. Schmitt, MD, MPH
Health Sciences Associate Clinical Professor of Emergency Medicine, Department of Emergency Medicine, University of California, San Francisco Fresno Medical Education Program; Attending Physician, Department of Emergency Medicine, Community Regional Medical Center, Fresno, California

Benjamin H. Schnapp, MD, MEd
Assistant Professor, Department of Emergency Medicine, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Benjamin Schoener, MD
Assistant Professor, Department of Emergency Medicine, Central Michigan University, Saginaw, Michigan

Carl H. Schultz, MD, FACEP
Professor Emeritus of Emergency Medicine and Public Health, University of California, Irvine, School of Medicine, Irvine, California; EMS Medical Director, Emergency Medical Services, Orange County Health Care Agency, Santa Ana, California

Raghu Seethala, MD
Department of Emergency Medicine, Brigham and Women's Hospital; Instructor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts; Associate Visiting Professor, Department of Emergency Medicine, University of California San Franscisco-Fresno, Fresno, California

Jeffrey A. Seiden, MD, MHA
Medical Director, Pediatric Emergency Medicine, CHOP at Virtua, Voorhees, New Jersey; Associate Professor of Clinical Pediatrics, Perelman School of Medicine at The University of Pennsylvania, Philadelphia, Pennsylvania

Todd A. Seigel, MD
Senior Physician, Emergency Medicine and Critical Care Medicine, Kaiser Permanente, Oakland Medical Center, Oakland, California; Clinical Assistant Professor, Department of Clinical Science, Permanente Bernard J. Tyson School of Medicine, Pasadena, California

Sarah Tolford Selby, DO
Assistant Professor, Department of Emergency Medicine, University of Colorado School of Medicine; Medical Director, Forensic Nursing Program, University of Colorado, Denver, Colorado

Wesley H. Self, MD, MPH
Vice President, Vanderbilt Institute for Clinical and Translational Research, Vice Chair, Department of Emergency Medicine, Vanderbilt University Medical Center, Nashville, Tennessee

Joseph Sexton, MD, FACEP
Emergency Physician, Lehigh Valley Health Network, Allentown, Pennsylvania

Huma Shaikh, MD
Assistant Professor, Department of Pediatrics, Baylor College of Medicine, Houston, Texas

Michael A. Shapiro, MD
Assistant Professor, Department of Psychiatry, University of Florida, Gainesville, Florida

Nathan I. Shapiro, MD, MPH
Professor of Emergency Medicine, Department of Emergency Medicine, Beth Israel Lahey Health, Harvard Medical School, Boston, Massachusetts

Eric Shappell, MD, MHPE
Assistant Professor, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

Dag Shapshak, MD
Associate Professor, Department of Emergency Medicine, University of Alabama, Birmingham, Birmingham, Alabama

Andrea C. Sharp, MD, MS
Assistant Professor, Department of Emergency Medicine, Mayo Clinic Florida, Jacksonville, Florida

Trent She, MD
Department of Emergency Medicine, Mount Sinai St. Luke's and West, New York, New York

Pranav Shetty, MD, MPH
Health Sciences Assistant Clinical Professor, Department of Emergency Medicine, EMS and Disaster Medicine Fellow, Harbor-UCLA Medical Center, Torrance, California

Sanjay N. Shewakramani, MD
Associate Professor, Department of Emergency Medicine, University of Cincinnati, Cincinnati, Ohio

Ashley Shreves, MD
Senior Physician, Department of Emergency Medicine, Ochsner Medical Center, New Orleans, Louisiana

Barry C. Simon, MD
Chairman, Department of Emergency Medicine, Alameda County Medical Center, Oakland, California; Professor, Department of Emergency Medicine, University of California, San Francisco, California

Leslie V. Simon, DO
Associate Professor, Emergency Medicine, Department of Emergency Medicine, Mayo Clinic Florida, Jacksonville, Florida

Manpreet Singh, MD, MBE
Assistant Professor in Emergency Medicine, Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Sonia Singh, MD, MPH, MBA
Fellow, Department of Emergency Medicine, UC Davis School of Medicine, Sacramento, California

Aaron B. Skolnik, MD
Assistant Professor, Department of Emergency Medicine, Consultant, Department of Critical Care Medicine, Mayo Clinic, Phoenix, Arizona

Corey M. Slovis, MD
Professor of Emergency Medicine and Medicine, Chairman Emeritus, Department of Emergency Medicine, Vanderbilt University Medical Center; Medical Director, Nashville Fire Department, Nashville International Airport, Nashville, Tennessee

Janet Smereck, MD
Associate Professor of Clinical Emergency Medicine, Department of Emergency Medicine, MedStar Georgetown University Hospital, Washington, DC

Clay Smith, MD
Associate Professor of Emergency Medicine, Internal Medicine, and Pediatrics, Department of Emergency Medicine, Vanderbilt University Medical Center, Nashville, Tennessee

Peter E. Sokolove, MD
Professor and Chair, Department of Emergency Medicine, University of California San Francisco School of Medicine, San Francisco, California

Philippa Soskin, MD, MPP
Assistant Professor, Department of Emergency Medicine, MedStar Georgetown University Hospital, Washington, DC

Jaron Soulek, MD
Associate Program Director, Department of Emergency Medicine, University of Oklahoma School of Community Medicine, Tulsa, Oklahoma

Lauren T. Southerland, MD
Associate Professor, Department of Emergency Medicine, The Ohio State University Wexner Medical Center, Columbus, Ohio

Brian L. Springer, MD, FACEP
Associate Professor, Department of Emergency Medicine, Wright State University, Dayton, Ohio

Bryan A. Stenson, MD
Clinical Fellow, Emergency Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Hanni Stoklosa, MD, MPH
Department of Emergency Medicine, Brigham and Women's Hospital, Assistant Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts; CEO, HEAL Trafficking

Christopher R. Tainter, MD, RDMS
Clinical Professor, Department of Anesthesiology, Division of Critical Care, University of California, San Diego, San Diego, California

Sukhjit S. Takhar, MD, SM
Attending Physician, Department of Emergency Medicine/Infectious Disease, Mills Peninsula Medical Center, Burlingame, California

Nelson Tang, MD, FACEP
Vice Chair of Operational Medicine, Department of Emergency Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland

Todd Andrew Taylor, MD
Associate Professor, Department of Emergency Medicine, Emory University, Atlanta, Georgia

Jillian L. Theobald, MD, PhD
Associate Professor, Department of Emergency Medicine, Medical College of Wisconsin; Associate Medical Director, Wisconsin Poison Center, Milwaukee, Wisconsin

Molly E.W. Thiessen, MD
Emergency Physician, Department of Emergency Medicine, Denver Health Medical Center, Denver, Colorado; Associate Professor, Department of Emergency Medicine, University of Colorado School of Medicine, Aurora, Colorado

Anita A. Thomas, MD, MPH
Assistant Professor, Pediatric Emergency Medicine, University of Washington, Seattle Children's Hospital, Seattle, Washington

Natasha Thomas, MD, MPH
Assistant Clinical Professor, Assistant Director, Adult Emergency Department, Director, Trauma Recovery Center, Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Holly Thompson, MD, FACEP, FAAEM
Associate Program Director, Department of Emergency Medicine, The Brooklyn Hospital Center, Brooklyn, New York

Trevonne M. Thompson, MD
Associate Professor/Director of Medical Toxicology, Department of Emergency Medicine, University of Illinois at Chicago, Chicago, Illinois

Joseph E. Thornton, MD, DFAPA
Adjunct Clinical Associate Professor, Department of Psychiatry, University of Florida College of Medicine, Gainesville, Florida

J. Adrian Tyndall, MD, MPH
Executive Vice President for Health Affairs, Professor and Dean, Morehouse School of Medicine, Atlanta, Georgia

Sam Torbati, MD
Co-Chair, Department of Emergency Medicine, Medical Director, Ruth and Harry Roman Emergency Department, Associate Professor, Emergency Medicine, Cedars Sinai Medical Center, Los Angeles, California

Michael VanRooyen, MD, MPH
Chair, Department of Emergency Medicine, Brigham and Women's Hospital, Massachusetts General Hospital; Enterprise Chief of Emergency Medicine, Mass General Brigham, J. Stephen Bohan Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Meagan B. Verbillion, DO
Assistant Professor, Department of Emergency Medicine, Wright State University/ Wright-Patterson Air Force Base, Dayton, Ohio

Taher T. Vohra, MD
Residency Program Director, Vice Chair of Education, Department of Emergency Medicine, Henry Ford Hospital; Clinical Associate Professor, Department of Emergency Medicine, Wayne State University School of Medicine, Detroit, Michigan

Leslie R. Vojta, MD, FACEP
Assistant Professor, Department of Military and Emergency Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland

Christopher P. Waasdorp Jr., DO, FAWM, FAAEM
Assistant Professor of Emergency Medicine, Assistant Professor of Family & Community Medicine, Virginia Tech Carilion School of Medicine; Assistant Program Director of Wilderness Medicine Fellowship, Attending Physician, Physician Informaticist, Carilion Clinic, Roanoke, Virginia

David A. Wacker, MD, PhD
Assistant Professor, Division of Pulmonary, Allergy, Critical Care, and Sleep Medicine, Department of Internal Medicine, University of Minnesota Medical School, Minneapolis, Minnesota

Mary Jo Wagner, MD
Chief Academic Officer/DIO, GME, Central Michigan University Medical Education Partners; Professor, Department of Emergency Medicine, Central Michigan University College of Medicine, Saginaw, Michigan

Laura E. Walker, MD
Assistant Professor, Department of Emergency Medicine, Mayo Clinic Alix School of Medicine; Consultant, Department of Emergency Medicine, Mayo Clinic, Rochester, Minnesota

Joshua Wallenstein, MD, FACEP
Associate Professor, Department of Emergency Medicine, Emory University, Atlanta, Georgia

Ron M. Walls, MD
Neskey Family Professor of Emergency Medicine, Department of Emergency Medicine, Harvard Medical School; Chief Operating Officer, Mass General Brigham, Boston, Massachusetts

George Sam Wang, MD, FAAP, FAACT
Associate Professor of Pediatrics, Section of Emergency Medicine and Medical Toxicology, University of Colorado School of Medicine, Aurora, Colorado

Gabriel Wardi, MD, MPH
Assistant Clinical Professor, Department of Emergency Medicine, Division of Pulmonary , Critical Care, and Sleep Medicine, University of California, San Diego, San Diego, California

Matthew A. Waxman, MD, DTM&H
Clinical Professor of Emergency Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California; Department of Emergency Medicine and Internal Medicine, Olive View-University of California Los Angeles Medical Center, Sylmar, California

Lori Weichenthal, MD, FACEP
Professor of Clinical Emergency Medicine, Department of Emergency Medicine, University of California San Francisco, Fresno, Fresno, California

Katherine Louise Welker, MD, MPH
Staff Physician, Emergency Department and Toxicology, Kaiser (Southern California Permanente Group), San Diego, California

Amanda L. Wessel, MD
Assistant Professor, Department of Emergency Medicine, Vanderbilt University Medical Center, Nashville, Tennessee

Benjamin White, MD
Department of Emergency Medicine, Massachusetts General Hospital; Associate Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

William White, MD
Fellow, Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Susan R. Wilcox, MD
Chief, Division of Critical Care, Department of Emergency Medicine, Massachusetts General Hospital; Associate Professor of Emergency Medicine, Harvard Medical School; Associate Chief Medical Officer, Boston MedFlight, Boston, Massachusetts

Craig A. Williamson, MD, MS
Clinical Assistant Professor, Neurosurgery and Neurology, University of Michigan, Ann Arbor, Michigan

Allan B. Wolfson, MD, FACEP, FACP
Professor of Emergency Medicine, Vice Chair for Education, Department of Emergency Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania

Andrea W. Wu, MD, MMM
Vice Chair of Clinical Operations, Department of Emergency Medicine, Harbor-UCLA Medical Center, Los Angeles Department of Health Services, Torrance, California; Associate Clinical Professor, Department of Emergency Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California

Donald M. Yealy, MD
Professor and Chair, Department of Emergency Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania

Henry W. Young II., MD
Assistant Professor, Assistant Program Director, Department of Emergency Medicine, University of Florida, Gainesville, Florida

Ken Zafren, MD
Department of Emergency Medicine, Stanford University Medical Center, Stanford, California; Department of Emergency Medicine, Alaska Native Medical Center, Anchorage, Alaska; International Commission for Mountain Emergency Medicine (ICAR MedCom), Zürich, Switzerland

Michael J. Zdradzinski, MD
Assistant Professor, Department of Emergency Medicine, Emory University School of Medicine, Atlanta, Georgia

Brian J. Zink, MD
Professor, Department of Emergency Medicine, Senior Associate Dean for Faculty and Faculty Development, University of Michigan Medical School, Ann Arbor, Michigan

Leslie S. Zun, MD, MBA
Professor of Emergency Medicine, Rosalind Franklin University of Medicine and Science, Chicago Medical School, Chicago, Illinois

PREFACE TO THE TENTH EDITION

We introduce this tenth edition of the most important textbook in our field with a deep humility, born of the uncertainty that has shaken our beliefs and our world community. Through the extraordinary challenges of 2020 through 2022 we learned anew the precious and inestimable joy of companionship—of family, friends, loved ones, and colleagues. We learned to rely on one another as never before, and we learned the strength of numbers, of teams, of collective effort to face down a daunting and unfamiliar foe. We learned about the indominable spirit that drives our specialty, and the unquestioning trust our patients place in us. And we affirmed, as never before, the power of science to lift us all up, to transform and respond, to solve and to cure, and to relentlessly breach the faulty logic of the deniers.

This edition of *Rosen's* was born in three labors. In the first, we set about to build a creative new editorial team, one that would make this current edition undeniably better, but also position us to expand the influential leadership position of this book as a source of truth for the next generation of learners and practitioners. We celebrated the contributions of editors departing and welcomed a new and diverse team to lead us into the future. Ron reprised his role as Editor-in-Chief. Tim and Susan joined Bob and Marianne as Senior Editors, Tim moving from his role of Associate Editor for the ninth edition, Susan stepping into the role directly from the solid foundation of her body of work in emergency medicine and critical care. We welcomed our outstanding returning Associate Editors, Katie Bakes, Andy Jagoda, Amy Kaji, and Mike VanRooyen, who generously agreed to again shoulder the enormous load as primary editors. We bolstered our team with new Associate Editors from leading academic centers: Calvin Brown III, David Brown, and Leòn Sanchez, from the Harvard Medical School affiliates Brigham and Women's Hospital and Massachusetts General Hospital; Adrian Tyndall, from the University of Florida; and Jonathan Davis, from Georgetown University. With our outstanding editorial team from Elsevier, we held detailed discussions about how to make the book better, more succinct, easier to access, and with more clear guidance for our readers. We brainstormed new topics and chapters, identified promising new authors, debated whether some existing topics should be consolidated or retired, and what content should be in the book versus available online only. Little did we know, when we held our planning meetings in Cambridge, MA, in June, 2019, that we would never again be together in one room until after the book was in print.

The second labor was, in reality, a pause. When the pandemic hit in full force in spring of 2020, we recognized that neither authors nor editors should be distracted from their complete commitment to caring for their teams, patients, and communities. From month to month, we gathered editors in virtual meetings to discuss the evolving situation, so we could collectively decide when it would be appropriate to turn our attention back to the important work of editing. These meetings kept us together as a team, reminded us of the long future ahead in a post-pandemic world, and also informed us about new information that was sorely needed, such as how to safely intubate patients with high infectivity, high morbidity respiratory disease, and the need to shift coronaviruses from a brief topic in a general chapter on viruses to a chapter all of its own. Through it all, we supported one another and a found common purpose.

The third labor was in bringing the book over the finish line when we resumed our task, reconnected with authors, and attacked the work with renewed energy. Fortunately, at the time of our pause, the book was well ahead of schedule, a tribute to the diligence of our authors and editors, which made the final steps less daunting than otherwise would have been the case. Our editorial team from Elsevier never missed a beat, always ready to help, support, cajole, remind, problem-solve, bolster, and cheer; often with a moment or two of humor, encouragement, and respite.

And we got there. Not just there, not just to a good place, not simply to the relief of finishing, but to the profound satisfaction of producing what we know, without the slightest doubt, represents yet another significant advance in the evolution of Peter Rosen's vision from almost 40 years ago. So, to you, the reader, we submit this, our finest work, born of one of our finest hours, and perhaps the finest hour of our specialty.

PREFACE TO THE NINTH EDITION

When we began planning for this ninth edition, we challenged ourselves to make substantial and meaningful improvements to a book that has become the trusted standard in our field. With broad and rapid changes occurring in health care and information sciences, we recognized that relevance is not an accidental or passive concept. To advance in relevance and consolidate the book's position as the defining reference in our specialty, we carefully and deliberately undertook bold changes that we know make the book at once fresh, directive, and current in a way we have never before dared.

First, we created a substantially enhanced role for our editors, one that would demand a great deal more of their time, creativity, and energy. This helped us build a substantially different team of editors, a perfectly balanced blend of those with great experience with prior editions and those who would bring new ideas and challenge our assumptions. Ron Walls was asked to serve as Editor-in-Chief, with Bob Hockberger in his long-standing role as senior editor. Marianne Gausche-Hill, a highly respected academic emergency physician with service as editor on four previous editions, stepped up to complete our senior editorial ranks. At the editor level, Dr. Andy Jagoda returns and is joined by six brilliant new editors drawn from academic programs from coast to coast—Drs. Katherine Bakes, Jill Baren, Timothy Erickson, Amy Kaji, Michael VanRooyen, and Richard Zane. This dynamic and innovative editorial team has dramatically redrawn our text's blueprint by preserving what has served our readers the best, such as well-written discussions of the pathophysiologic basis of illness and injury, while moving in entirely new directions in providing pithy, clear, and succinct recommendations for diagnosis and treatment.

We collectively determined that all references prior to 2010 have been sufficiently long in the public domain that they no longer warrant citation. The infrequent exception to this is for guidelines that were issued in 2007 or later and have not been reissued or supplanted since. Strict adherence to our referencing policy required authors to diligently provide well-researched and detailed updates to their chapter content, based on only the most recent and relevant medical literature. In cases in which the literature is controversial or unclear, we have used the combined experience and expertise of our authors and editors to present cogent analyses of diagnostic and treatment options, make specific recommendations, and give the reader clear indications of the preferred actions. This makes the book much more immediately relevant for emergency clinicians. We recognize that emergency medicine is practiced by specialist emergency physicians, other physicians, residents and other trainees, and a variety of nonphysician practitioners, so were careful to ensure that we are addressing all these groups with the same concise, highest quality information and recommendations.

We revisited page counts for every chapter, adjusting allocations where indicated, and added new chapters on several important topics. We focused anew on consistency and redundancy, enhancing the former and minimizing the latter. We moved some chapters to online access only, allowing us to add new topics of interest, such as drug therapy for older patients, and have provided a rich array of dynamic videos and images, especially in emergency ultrasound. We substantially expanded and reorganized the pediatric emergency medicine section, introducing dedicated pediatric chapters on airway management, procedural sedation, and drug therapy. We introduced significant new material on emergencies in the pregnant woman, the patient with cancer, and a variety of other highly important clinical conditions. And, in every possible case, we insisted on adherence to referencing and writing requirements, a focus on relevant directive information, and appropriate use of prose and illustrations to provide the perfect balance of depth, breadth, and ready accessibility.

We are enormously proud of the result, a different, more readable "Rosen," preserving the gravitas earned over 30 years as the most important book in our specialty while embracing the modern era of emergency medicine practice and research and an entirely new generation of learners and practitioners. For those who have owned prior editions, we appreciate your loyalty over so many years and hope to reward it with a significantly improved and useful companion for your continuing learning and practice of this great specialty. For our newer readers, welcome, and thank you for inspiring us to make significant changes to an iconic and timeless part of our academic heritage.

Ron M. Walls
Robert S. Hockberger
Marianne Gausche-Hill

HOW THIS MEDICAL TEXTBOOK SHOULD BE VIEWED BY THE PRACTICING CLINICIAN AND JUDICIAL SYSTEM

The editors and authors of this text strongly believe that because of the variations of human diseases, the unpredictability of pathologic conditions, and the functions, dysfunctions, and responses of the human body, the complex practice of medicine cannot be definitively explained or comprehensively dictated by any written document. Therefore, it is neither the purpose nor intent of our textbook to serve as the definitive source of truth regarding any medical condition, treatment plan, or clinical intervention. Specifically, our textbook is intended to educate and inform learners and practitioners, and is not to be used to rigorously define a standard of care that should be followed by all clinicians in all settings.

Our written word represents our best efforts to present the clinician with scientifically based and clinically sound information to provide reasonable and reliable clinical guidance. This science is interpreted by our authors and editors through the lenses of their own knowledge, years of clinical experience, teaching of others, and the study of adverse outcomes and human and system error. No textbook can fully account for the range of limited information, varying clinical clues, instincts, judgments, and responses that occur during the care of emergency and critical care patients. In fact, other experts might interpret the same evidence differently, based on their own experience and analysis of available information. No human being can possibly assimilate the entire depth and breadth of the treatments, procedures, and medical conditions described in this textbook—in fact, that is why this book and others exist. Finally, many of the described complications and adverse outcomes associated with implementing or withholding complex medical and surgical interventions may occur, even when the clinicians have used sound clinical judgment and made decisions and performed interventions according to the tenets of this and other standard medical references.

The editors and authors of *Rosen's Emergency Medicine: Concepts and Clinical Practice,* Tenth Edition

Airway

Calvin A. Brown III and Ron M. Walls

KEY CONCEPTS

- Anticipating the clinical course of the patient's condition and assessing the likelihood of deterioration are crucial to the decision to intubate, especially if the patient is to leave the emergency department (ED) for a period of time (e.g., interfacility transfer, diagnostic testing).
- Although videolaryngoscopy (VL) has reduced the chance of a failed intubation attempt caused by difficult anatomic features that often thwart direct laryngoscopy (DL), an assessment of the patient for potential difficult intubation, bag-mask ventilation (BMV), ventilation using an extraglottic device (EGD), and cricothyrotomy is an essential step before a neuromuscular blocking agent (NMBA) is administered. The mnemonics *LEMON, ROMAN, RODS,* and *SMART* can serve as useful aids.
- Physiologic derangement can contribute to morbidity and mortality during emergency airway management. Cardiovascular optimization with fluids, blood, and pressor agents should be undertaken, when time allows, to reduce the risk of circulatory collapse and cardiac arrest.
- In the absence of a crash patient (agonal, unresponsive to laryngoscopy) or difficult airway, rapid sequence intubation (RSI) is the airway management method of choice for ED patients.
- Tube placement confirmation using end-tidal carbon dioxide ($ETco_2$) is essential after intubation; failure to detect adequate quantities of exhaled CO_2 is evidence of esophageal intubation until proven otherwise.
- VL increases first-attempt intubation success, even when compared with DL combined with various optimization techniques. First-attempt success (FAS) is associated with fewer adverse events and better outcomes. Emergency airway managers should learn, and adopt, VL as the method of choice for emergency intubation.
- Cricothyrotomy is indicated in the "can't intubate, can't oxygenate" failed airway situation and should be performed once this has been identified. Delays may increase the likelihood or severity of hypoxic injury to the patient.
- Etomidate is used in more than 90% of all RSIs. Either rocuronium or succinylcholine is a reasonable NMBA for use during RSI. Rocuronium has less potential for adverse effects but a longer duration of action.
- EGDs are rarely used in ED airway management but offer additional options for rescue oxygenation of the failed airway and are used in many prehospital systems.

PRINCIPLES

Background

Airway management is the cornerstone of resuscitation and is a defining skill for the specialty of emergency medicine. The emergency clinician has primary airway management responsibility, and all emergency airway techniques lie within the domain of emergency medicine. Although rapid sequence intubation (RSI) is the most commonly used method for emergent tracheal intubation, emergency airway management includes various intubation techniques and devices, approaches to the difficult airway, and rescue techniques when intubation fails.

Anatomy, Physiology, and Pathophysiology

The decision to intubate should be based on careful patient assessment and appraisal of the clinical presentation with respect to three essential criteria: (1) failure to maintain or protect the airway; (2) failure of ventilation or oxygenation; and (3) the patient's anticipated clinical course and likelihood of deterioration.

Failure to Maintain or Protect the Airway

A patent airway is essential for adequate ventilation and oxygenation. If a patient is unable to maintain a patent airway, patency should be established by using airway maneuvers such as repositioning, chin lift, jaw thrust, or insertion of an oral or nasal airway. Likewise, the patient must be able to protect against the aspiration of gastric contents, which carries significant risks for morbidity and mortality. Historically, the presence of a gag reflex has been advocated as a reliable indicator of the patient's ability to protect the airway, but this has been definitively proven to be unreliable because the gag reflex is absent in 12% to 25% of normal adults, and there is no evidence that its presence or absence corresponds to airway protective reflexes or predicts the need for intubation. The patient's ability to swallow or handle secretions is a more reliable indicator of airway protection. The recommended approach is to evaluate the patient's level of consciousness; ability to phonate in response to voice command or query, which provides information about the integrity of the upper airway and level of consciousness; and ability to manage his or her own secretions (e.g., pooling of secretions in the oropharynx, absence of swallowing spontaneously or on command). In general, a patient who requires a maneuver to establish a patent airway or who easily tolerates an oral airway requires intubation for airway protection, unless there is a temporary or readily reversible condition, such as an opioid overdose.

Failure of Ventilation or Oxygenation

Gas exchange, both oxygenation and removal of carbon dioxide, is required for vital organ function. Ventilatory failure that is not easily reversible or persistent hypoxemia despite maximal oxygen supplementation is a primary indication for intubation. This assessment is clinical and includes an evaluation of the patient's general status, oxygen saturation by pulse oximetry, and ventilatory pattern. Continuous capnography also can be helpful, but is not essential if oximetry readings are reliable. Arterial blood gases (ABGs) are neither required

to determine the patient's need for intubation, nor practical to obtain before an emergency intubation. In addition, ABGs may be misleading, causing a false sense of security and delay in intubating a deteriorating patient. If obtained, they should be interpreted in the context of the patient's clinical status. Patients who are clinically improving despite severe or apparently worsening ABG alterations may not require intubation, whereas a rapidly tiring asthmatic, for example, may require intubation, even though ABG values are only modestly disturbed. In most cases, clinical assessment, including pulse oximetry with or without capnography, consideration of the timeline of the patient's respiratory emergency, and observation of improvement or deterioration in the patient's clinical condition will lead to a correct decision.

The need for prolonged mechanical ventilation generally mandates intubation. An external mask device, continuous positive airway pressure (CPAP), and bilevel positive airway pressure (BiPAP) have all been used successfully to manage patients with exacerbations of chronic obstructive pulmonary disease (COPD) and congestive heart failure, obviating the need for intubation (see Chapter 2), but, despite these advances, many patients who need assisted ventilation or positive pressure to improve oxygenation require intubation.

Anticipated Clinical Course

Certain conditions indicate the need for intubation, even without an immediate threat to airway patency or adequacy of ventilation and oxygenation. These conditions are characterized by a moderate to high likelihood of predictable airway deterioration, worsening physiologic derangement, or the need for intubation to facilitate a patient's evaluation and treatment. Intubation may be indicated relatively early in the course of certain overdoses. Although the patient initially may be protecting the airway and exchanging gas adequately, intubation is advisable to guard against the strong likelihood of clinical deterioration, which can occur after the initial phase of care when the patient is no longer closely observed. Patients with septic shock have high metabolic demand, myocardial depression, increased peripheral oxygen extraction, and vascular permeability. The combination of ventilatory fatigue, depressed pump function, and the need for directed fluid resuscitation predictably results in the need for intubation as pulmonary vascular congestion, hypoxia, and the work of breathing worsen. A patient who has sustained significant multiple traumatic injuries may require intubation, even if the patient is ventilating normally through a patent airway and has adequate oxygen levels. For example, a multiple trauma patient with hypotension, an open femur fracture, and diffuse abdominal tenderness warrants early intubation, even if the patient is initially awake and alert, without airway injury or hypoxemia. Active resuscitation, pain control, need for invasive procedures and imaging outside of the emergency department (ED), and inevitable operative management dictate the need for early airway control. In addition, a patient with penetrating neck trauma may have a patent airway and adequate gas exchange. Nevertheless, early intubation is advisable when there is evidence of vascular or direct airway injury, because these patients tend to deteriorate and increasing hemorrhage or swelling in the neck will compromise the airway and confound later attempts at intubation.

The common thread among these indications for intubation is the anticipated clinical course. In each case, it can be anticipated that future events may compromise the patient's ability to maintain and protect the airway or ability to oxygenate and ventilate. Waiting until these occur may result in a difficult airway.

Identification of the Difficult Airway

In most patients, intubation is technically straightforward. Although early ED-based observational registries reported cricothyrotomy rates of approximately 1% for all intubations, more recent studies have shown a lower rate, less than 0.5%.[1] As would be expected with an unselected, unscheduled patient population, the ED cricothyrotomy rate is greater than in the operating room, which occurs in approximately 1 in 200 to 2000 elective general anesthesia cases.[2] Bag-mask ventilation (BMV) is difficult in approximately 1 in 50 general anesthesia patients and impossible in approximately 1 in 600. However, BMV is difficult in up to one-third of patients in whom intubation failure occurs, and difficult BMV makes the likelihood of difficult intubation 4 times higher and the likelihood of impossible intubation 12 times higher. The combined failure of intubation, BMV, and oxygenation in elective anesthesia practice is estimated to be exceedingly rare, approximately 1 in 30,000 patients.[3] These numbers cannot be extrapolated to populations of ED patients who are acutely ill or injured and for whom intubation is urgent and unavoidable. Although patient selection cannot occur, as with a preanesthetic visit, a preintubation analysis of factors predicting difficult intubation gives the provider the information necessary to formulate a safe and effective plan for intubation.

Preintubation assessment should evaluate the patient for anatomic features that would herald a difficult airway. This includes an assessment for potential difficulty with laryngoscopy and intubation, BMV, placement of and ventilation with an extraglottic device (EGD; see later discussion), and cricothyrotomy. Knowledge of all four domains is crucial to successful planning. A patient who exhibits difficult airway characteristics is highly predictive of a challenging intubation, although the emergency clinician should always be ready for a difficult to manage airway because some difficult airways may not be identified by a bedside assessment.[4]

Airway difficulty exists on a spectrum. Some patients may have a single minor anatomic or pathophysiologic reason for airway difficulty, whereas others may have numerous difficult airway characteristics, complicating laryngoscopy, bag ventilation, use of an EGD, and cricothyrotomy. Although both sets of patients represent potential intubation challenges, the latter group, especially if obstructing upper airway pathology is part of the problem, more often has crossed a threshold of difficulty beyond which neuromuscular blockade would be avoided because a "can't intubate, can't oxygenate" (CI:CO) failed airway may ensue. In these cases, the preferred approach is to use topical anesthesia methods, with titrated parenteral sedation, to achieve intubation without the use of a neuromuscular blocking agent (NBMA). This is particularly true when intubation is undertaken with conventional laryngoscopy (versus use of a video laryngoscope or flexible endoscope) or when use of NBMAs would result in immediate physiologic deterioration and instability. Patients with refractory hypoxemia or severe metabolic acidosis may be intolerant to even brief periods of apnea. In such patients, an awake approach is preferred, particularly if anatomic difficulty coexists.[4] Airways predicted to be anatomically difficult when using a traditional laryngoscope may not prove difficult when a videolaryngoscope is used (see later discussion). Occasionally, RSI remains the preferred method, despite assessment that the patient has a difficult airway, as part of a planned approach to airway management. This may include physiologic optimization, use of videolaryngoscopy (VL), and a double setup, in which a rescue approach, such as cricothyrotomy, is fully prepared for immediate use in the event of intubation failure. Regardless of the results of a reassuring bedside assessment for airway difficulty, significant challenges may be encountered with intubation and BMV, and the clinician must be prepared for unanticipated difficulty with every intubation.

Difficult Direct Laryngoscopy: LEMON

Glottic visualization is paramount in emergency airway management. With direct laryngoscopy (DL), if the vocal cords can be seen (Cormack and Lehane [CL] grade I or II view; Fig. 1.1), the chance of

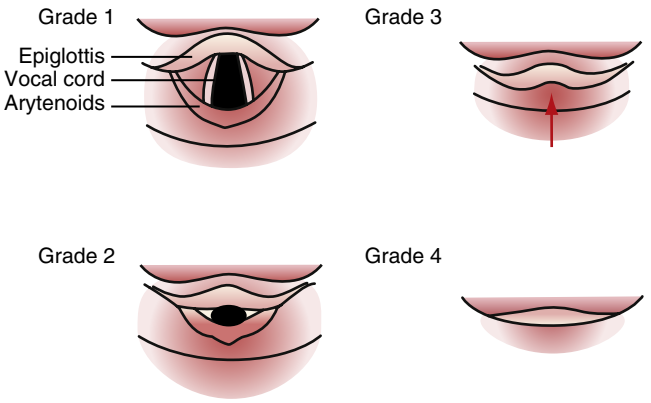

Fig. 1.1 Cormack and Lehane Grading System for Glottic View. (patency.)

intubation success is high. However, when the glottic aperture cannot be visualized (CL grade III or IV), intubation success is less likely. Very few of the difficult airway markers thought to limit DL access have been scientifically validated, yet applying them in combination can provide a reasonable assessment of anticipated airway difficulty. On the other hand, VL rarely fails to provide adequate laryngeal visualization but may introduce difficulty with indirect tube placement. Characterization of difficult VL predictors is not well studied, and although mnemonics exist that attempt to cover predictors of both difficult direct and VL, the components are too broad to be clinically useful (see discussion later).[5] Like DL, adequate video views are highly correlated with intubation success, although the strength of this association can depend on the device used and operator experience. Whether DL or VL is planned, a standard screening process for difficulty should be undertaken with every patient. Our recommended approach uses the mnemonic *LEMON* (Box 1.1), which has been shown to have reasonable sensitivity and high negative predictive value.[6]

L—look externally. The patient first should be examined for external markers of difficult intubation, which are determined based simply on the intubator's clinical impression or initial gestalt. For example, the severely bruised and bloodied face of a combative trauma patient, immobilized in a cervical collar on a spine board, should (correctly) invoke an immediate appreciation of anticipated difficulty. Subjective clinical judgment can be highly specific but insensitive and so should be augmented by other evaluations whether or not the airway appears to be challenging.

E—evaluate 3-3-2. The second step in the evaluation of the difficult airway is to assess the patient's airway geometry to determine suitability for DL. Glottic visualization with a direct laryngoscope necessitates that the mouth opens adequately, the submandibular space is adequate to accommodate the tongue, and the larynx be positioned low enough in the neck to be accessible. These relationships have been explored in various studies by external measurements of mouth opening, oropharyngeal size, neck movement, and thyromental distance. The 3-3-2 rule is an effective summary of these assessments. The 3-3-2 rule requires that the patient be able to place three of his or her own fingers between the open incisors, three of his or her own fingers along the floor of the mandible beginning at the mentum, and two fingers from the laryngeal prominence to the underside of the chin (Fig. 1.2). A patient with a receding mandible and high-riding larynx is exceptionally difficult to intubate using DL because the operator cannot adequately displace the tongue and overcome the acute angle for a direct view of the glottic aperture. In practice, the operator compares the size of his or her fingers with the size of the patient's fingers and then performs the three tests.

M—Mallampati scale. Oral access is assessed with the Mallampati scale (Fig. 1.3). Visibility of the oral pharynx ranges from complete visualization, including the tonsillar pillars (class I), to no visualization at all, with the tongue pressed against the hard palate (class IV). Classes I and II predict adequate oral access, class III predicts moderate difficulty, and class IV predicts a high degree of difficulty. A meta-analysis has confirmed that the four-class Mallampati score performs well as a predictor of difficult laryngoscopy (and, less so, of difficult intubation), but the Mallampati score alone is not a sufficient assessment tool. A Mallampati score necessitates an awake compliant patient to perform the assessment in the way in which it was originally described. Nearly 50% of ED patients requiring intubation cannot cooperate with this assessment, but it can be improvised by using a direct laryngoscope blade as a tongue depressor in obtunded or uncooperative patients.

O—obstruction or obesity. Upper airway (supraglottic) obstruction may make visualization of the glottis, or intubation itself, mechanically impossible. Conditions such as epiglottitis, head and neck cancer, Ludwig angina, neck hematoma, glottic swelling, or glottic polyps can compromise laryngoscopy, passage of the endotracheal tube (ETT), BMV, or all three. Examine the patient for airway obstruction and assess the patient's voice to satisfy this evaluation step. Although obesity alone may not be an independent marker of difficult DL, it likely contributes to challenges in other areas of airway management. Nevertheless, obese patients generally are more difficult to intubate than their nonobese counterparts, and preparations should account for this and for the more rapid oxyhemoglobin desaturation and increased difficulty with ventilation using BMV or an EGD (see later).

N—neck mobility. Neck mobility is desirable for any intubation technique and is essential for positioning the patient for optimal DL. Neck mobility is assessed by flexion and extension of the patient's head and neck through a full range of motion. Neck extension is the most crucial motion but placing the patient in the full sniffing position provides the optimal laryngeal view by DL.[7] Modest limitations of motion do not seriously impair DL, but severe loss of motion, as can occur in ankylosing spondylitis or rheumatoid arthritis, may make DL impossible. Cervical spine immobilization in trauma patients artificially reduces cervical spine mobility, but DL is still highly successful in this group of patients.

A modified mnemonic, *LEMONS*, has been described, with the "S" referring to the patient's oxygen saturation. Although not a direct contributor to difficulty with DL, a low starting oxygen saturation will result in a shorter period of safe apnea and a reduced time to perform laryngoscopy and achieve ETT placement. Some providers may prefer "LEMONS" over "LEMON," but we consider oxygen status (and overall clinical status) a part of preintubation assessment that is distinct from difficult airway assessment. An alternative mnemonic, "HEAVEN" (***H***ypoxemia, ***E***xtremes of size, ***A***natomic challenges, ***V***omit/blood/

fluid in the airway, ***E***xsanguination, and ***N***eck mobility) has been shown, in a retrospective review of aeromedical RSIs, to predict difficulty with both video and DL.[5] However, the components of HEAVEN are a broad mixture of physiologic and anatomic attributes, some of which are either vague (anatomic challenges) or self-evident (blood/vomit in the airway). The "HEAVEN" mnemonic lacks sufficient detail and specificity required to apply it at the bedside reliably, and we recommend use of the LEMON mnemonic. As noted, identification of a difficult intubation does not preclude use of an RSI technique. The crucial determination is whether the emergency clinician judges that the patient has a reasonable likelihood of intubation success, despite the difficulties identified, and that ventilation with BMV or an EGD will be successful in case intubation fails (hence the value of the BMV and EGD assessments; see Boxes 1.2 and 1.3).

Difficult Bag-Mask Ventilation: ROMAN

Attributes of difficult BMV have largely been validated and can be summarized with the mnemonic *ROMAN* (see Box 1.2).

- ***R***esistance/***R***adiation—Resistance to ventilation (requiring high ventilation pressures) caused by intrinsic pulmonary disease such as asthma, COPD, adult respiratory distress syndrome [ARDS]), or a history of directed head and neck radiation are strong predictors of difficult BMV.
- ***O***bstruction/***O***besity/***O***bstructive sleep apnea—Obstruction of the airway, particularly supraglottic obstruction, or presence of obesity, which results in redundant upper airway tissues, increased chest wall weight, and resistance of abdominal mass, similarly are predictors of difficult BMV.
- ***M***allampati/***M***ask seal/***M***ale—High Mallampati classification, inability to achieve a good mask seal (e.g., because of facial trauma or presence of a beard), and male gender all have associations with challenging rescue mask ventilation.
- ***A***ge—This refers to advanced age and is best judged by the physiologic appearance of the patient, but age older than 55 years increases risk.
- ***N***o *teeth*—Identifies the edentulous patient. Lack of teeth, which form a strut to support the mask for ventilation and also support the upper and lower lips, independently interferes with mask seal and hence successful BMV. The difficulty with BMV of the edentulous patient is the basis of the advice often cited for patients with dentures: "teeth out to intubate, teeth in to ventilate." Another approach involves placing the mask inside the patient's lower lip. This may limit air leaks in patients without teeth and eliminates the risk of aspiration associated with dental prosthetics or rolled gauze (Fig. 1.4).

Difficult BMV is common in the ED and out-of-hospital patients, but, with proper technique, BMV is usually successful. In patients undergoing elective anesthesia, impossible B MV is exceptionally rare (<0.5%) and is associated with the ROMAN mnemonic factors. The likelihood of difficult or impossible BMV increases proportionately to the number of these factors present.

Difficult Extraglottic Device Placement: RODS

Placement of an EGD, such as a laryngeal mask airway (LMA), Combitube, or similar upper airway device, often can convert a CI:CO situation to a "can't intubate, can oxygenate" situation, which allows time for rescue of a failed airway (see following section). Difficulty achieving placement or ventilation with an EGD can be predicted by the mnemonic *RODS* (see Box 1.3).

Fortunately, if the emergency clinician has already performed the LEMON and ROMAN assessments, only the *"D"* for distorted anatomy remains to be evaluated (see Box 1.3). EGDs are placed blindly and have a mask or balloon structure that, when inflated, obstructs the oropharynx proximally and esophageal inlet distally, permitting indirect ventilation. Distorted upper airway anatomy can result in a poor seal and ineffective ventilation. Short thyromental distance, the "S" in RODS, is identified as part of the 3-3-2 measurement during the LEMON assessment. Patients with receded mandibles have tongues that sit more posteriorly in the oral cavity creating an anatomic hurdle that the EGD must traverse to get to its final resting position relative to the glottis.[8]

Difficult Cricothyrotomy: SMART

Difficult cricothyrotomy can be anticipated whenever there is limited access to the anterior neck or the laryngeal landmarks are obscured. This can be assessed using the mnemonic *SMART* (Box 1.4). Prior surgery, hematoma, tumor, abscess, scarring (as from radiation therapy or prior injury), local trauma, obesity, edema, or subcutaneous air each has the potential to make cricothyrotomy more difficult. Perform an examination for the landmarks needed to perform cricothyrotomy as part of the preintubation difficult airway assessment of the patient. Point-of-care ultrasound can be used at the bedside to locate the cricothyroid membrane, thereby allowing the emergency clinician to mark the location on the surface of the neck in high-risk cases.[9] The emergency clinician should not avoid performing a rescue cricothyrotomy when necessary, even in the presence of predicted difficulty. Prediction of the difficulty and identification of the factors causing the difficulty help the clinician to work through the problem to achieve success.

Measurement and Incidence of Intubation Difficulty

The actual degree to which an intubation is difficult is highly subjective, and quantification is challenging. The CL system is the most widely used system for grading a laryngoscopic view of the glottis, which grades laryngoscopy according to the extent to which laryngeal and glottic structures can be seen (see Fig. 1.1). In grade 1 laryngoscopy, all or nearly all of the glottic aperture is seen; in grade 2, the laryngoscopist visualizes only a portion of the glottis (arytenoid cartilages alone or arytenoid cartilages plus part of the vocal cords), in grade 3 only the epiglottis is visualized, and, in grade 4, not even the epiglottis is visible.

Fewer than 1% of stable patients undergoing DL during elective anesthesia yield a grade 4 laryngoscopy, a finding associated with an extremely difficult intubation. Grade 3 laryngoscopy, which represents highly difficult intubation, is found in less than 5% of patients. Grade 2 laryngoscopy, which occurs in 10% to 30% of patients, can be subdivided further into grade 2a, in which the arytenoids and a portion of the vocal cords are seen, and grade 2b, in which only the arytenoids are

Fig. 1.4 Mask ventilation in edentulous patients can be performed by placing the lower rim of the mask on the inside of the patient's lower lip to improve mask seal. (Courtesy Dr. Tobias Barker.)

seen. Intubation failure occurs in up to two-thirds of grade 2b cases but in less than 1 in 20 grade 2a cases. Approximately 80% of all grade 2 laryngoscopies are grade 2a; the rest are grade 2b. First-attempt intubation success drops off significantly as the glottic view transitions from a grade 2a to 2b; however, a grade 1 view is associated with virtually 100% intubation success. Outside of the operating room, the rate of difficulty may be higher. In one review of emergency adult inpatient intubations, as many as 10% were considered difficult (grade 3 or 4 CL direct view or more than three attempts required).[1] The incidence of difficult ED intubations is unknown but is likely much higher. An alternative system of grading laryngeal view, percentage of glottic opening (POGO), also has been proposed and validated but has not been widely used or studied. The incidence of difficult intubation and the predictors thereof are primarily based on the use of conventional DL and do not apply to VL. In a single-center assessment of ED intubations at an academic ED using VL exclusively, 80% of intubations predicted to be difficult were managed with NBMAs, with a 90% first-attempt success (FAS) rate.[10] Thus predictors of difficult DL do not impact VL to the same degree. Nonetheless, a bedside assessment should still be performed in all patients so potential pitfalls can be identified and avoided.

Confirmation of Endotracheal Tube Placement

Immediately after intubation, the operator should apply an end-tidal carbon dioxide ($ETco_2$) detection device to the ETT and assess it through six manual ventilations. Disposable colorimetric $ETco_2$ detectors are highly reliable, convenient, and easy to interpret, indicating adequate CO_2 detection by color change (Figs. 1.5 and 1.6) and determining tracheal and esophageal intubation in patients with spontaneous circulation. The persistence of detected CO_2 after six manual breaths indicates that the tube is within the airway, although not necessarily within the trachea. CO_2 is detected with the tube in the mainstem bronchus, trachea, or supraglottic space. Correlation of $ETco_2$ detection with the depth markings on the ETT, particularly important in pediatric patients, confirms tracheal placement. Rarely, BMV before intubation or ingestion of carbonated beverages may lead to the release of CO_2 from the stomach after esophageal intubation, causing a transient false indication of tracheal intubation. Washout of this phenomenon universally occurs within six breaths.

Although colorimetric $ETco_2$ measurement is highly sensitive and specific for detecting esophageal intubation, caution is required for patients in cardiopulmonary arrest. In general, patients in early cardiopulmonary arrest (as long as cardiopulmonary resuscitation [CPR] is being performed) still produce sufficient CO_2 (2%) to cause a positive color change. Persistent color change is definitive evidence of correct ETT placement, and lack of color change is indicative of a misplaced (likely esophageal) tracheal tube. Although unlikely, insufficient gas exchange during prolonged cardiac arrest, or with inadequate CPR, might prevent CO_2 detection in the exhaled air, even when the tube is correctly placed within the trachea. However, the absence of color change (i.e., the absence of CO_2 in expired air), even if the patient is in complete or prolonged cardiac arrest, should prompt a careful evaluation to ensure that an esophageal intubation has not occurred. Newer resuscitation guidelines have suggested continuous quantitative measurement of $ETco_2$ during cardiac arrest to gauge the efficacy of CPR. This circumstance arises in approximately 25% to 40% of intubated cardiac arrest patients.

When $ETco_2$ detection is not possible, tracheal tube position can be confirmed using other techniques. One approach involves point-of-care ultrasound. In live patient and cadaver studies, ultrasonography performed over the cricothyroid membrane or upper trachea has accurately confirmed ETT position in the trachea, especially during intubation.[11]

Another method of tube placement confirmation is the aspiration technique, based on the anatomic differences between the trachea and esophagus. The esophagus is a muscular structure with no support within its walls and is therefore collapsible when negative pressure is applied. The trachea is held patent by cartilaginous rings and thus is less likely to collapse when negative pressure is applied. Vigorous aspiration of air through the ETT with the ETT cuff deflated results in occlusion of the ETT orifices by the soft walls of the esophagus, whereas aspiration after tracheal placement of the tube is easy and rapid. Although once quite common, these devices are now rarely used and generally only in austere environments.

A gum elastic bougie can be placed through the center of an ETT to further corroborate tube location. Passing the bougie deeply through the tube, with little or no resistance, suggests an esophageal intubation because the bougie has likely passed beyond the tube and into the esophagus and stomach. If the ETT is in the trachea, the tip of the bougie will encounter resistance after emerging only a couple of inches from the tracheal tube, as it abuts the wall of the right mainstem bronchus. Another technique involves sliding the bougie in an upward and downward motion over a few inches distal to the tracheal tube. A vibration from contact of the deflected tip of the bougie with the anterior tracheal rings may be transmitted to the operator's fingertips.

Quantitative or qualitative $ETco_2$ detection, with ultrasound or the bougie technique as backup, is the primary means of ETT placement

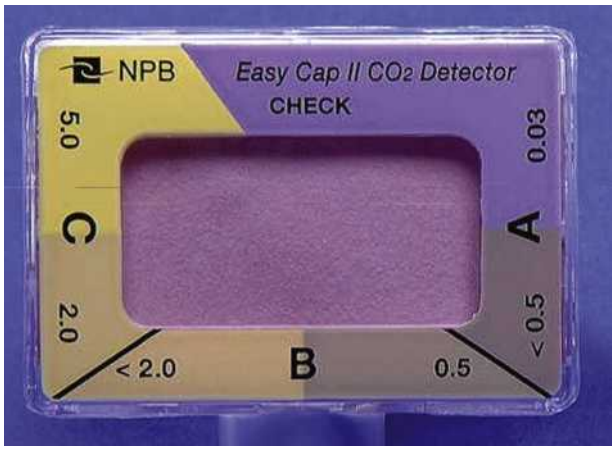

Fig. 1.5 End-Tidal CO_2 Detector Before Application. The indicator is *purple*, which indicates failure to detect CO_2. This also is the appearance when the esophagus is intubated.

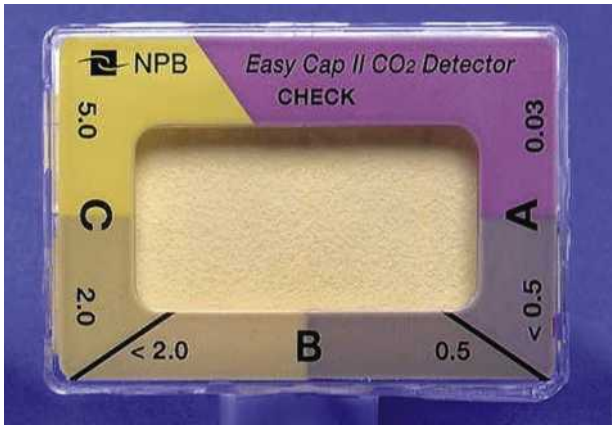

Fig. 1.6 Positive detection of CO_2 turns the indicator *yellow*, indicating tracheal placement of the endotracheal tube.

confirmation. Secondary means include physical examination findings, oximetry, and radiography. The examiner should auscultate both lung fields and the epigastric area but should not rely on these findings alone. Pulse oximetry is indicated as a monitoring technique in all critically ill patients, not just those who require intubation. Oximetry is useful in detecting esophageal intubation but may not show a decreasing oxygen saturation for several minutes after a failed intubation because of the oxygen reservoir (preoxygenation) created in the patient before intubation. Although chest radiography is universally recommended after ETT placement, its primary purpose is to ensure that the tube is well positioned below the cords and above the carina. Because the esophagus lies directly behind the trachea, a single anteroposterior chest radiograph is not sufficient to confirm tracheal intubation, although esophageal intubation may be detected if the ETT is clearly outside the air shadow of the trachea. In cases in which doubt persists, a fiberoptic scope can be passed through the ETT to identify tracheal rings, another "gold standard" for confirmation of tracheal placement.

MANAGEMENT

Decision Making

Algorithms for emergency airway management have been developed and provide a useful guide for planning intubation and rescue in case of intubation failure. The algorithms are applied after the decision to intubate, and the approach is predicated on two key determinations that are to be made before active airway management is initiated (Fig. 1.7).

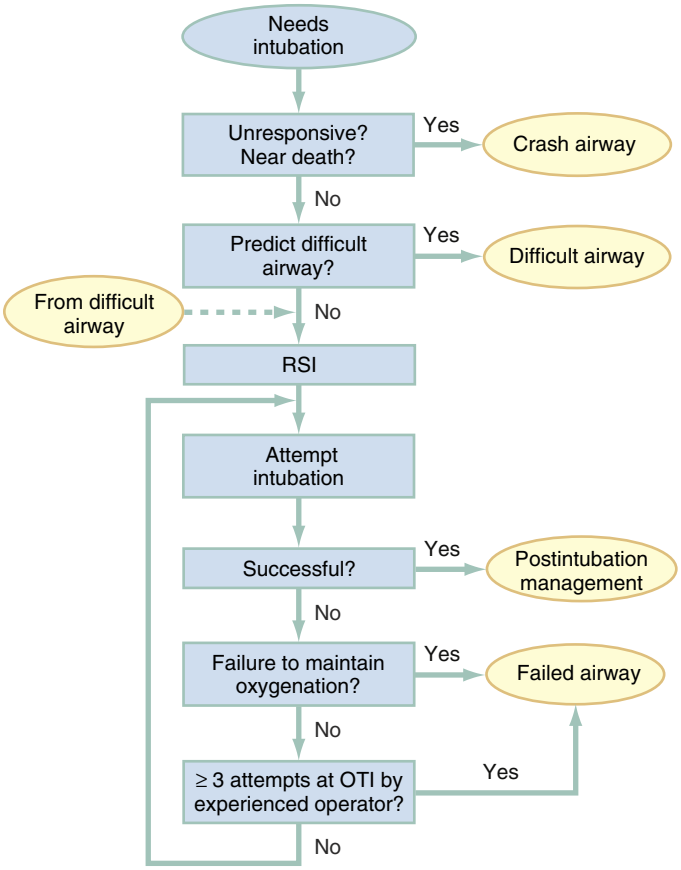

Fig. 1.7 Main Emergency Airway Management Algorithm. *OTI,* Orotracheal intubation; *RSI,* rapid sequence intubation. (Modified from Brown III CA, Mick NM, Sakles JC, editors. *The Emergency Airway Algorithms in the Walls Manual of Emergency Airway Management.* 5th ed. Philadelphia: Wolters Kluwer; 2018.)

The first determination is whether the patient is in cardiopulmonary arrest or a state of near arrest and is likely not to resist attempts at laryngoscopy. Such a patient—agonal, near death, in circulatory collapse—is deemed a "crash" airway patient for the purposes of emergency airway management and is treated using the crash airway algorithm by an immediate intubation attempt without use of drugs; this can be supplemented by a single large dose (2.0 mg/kg intravenous [IV]) of succinylcholine if the attempt to intubate fails and the patient is thought not to be sufficiently relaxed (Fig. 1.8). In a crash scenario, larger doses of succinylcholine are recommended because poor circulation impairs drug delivery, resulting in paralysis that may be slower in onset and incomplete. A higher dosing can help to compensate for this impaired distribution. If a crash airway is not present, the LEMON, ROMAN, RODS, and SMART evaluations are made to determine if a difficult airway is present, and, if so, the difficult airway algorithm is used (Fig. 1.9).

For patients who require emergency intubation but who have neither a crash airway nor a difficult airway, RSI is indicated. RSI provides the safest and quickest method of achieving intubation in such patients.[1] After administration of RSI drugs, intubation attempts are repeated until the patient is intubated or a failed intubation is identified. If more than one intubation attempt is required, oxygen saturation is monitored continuously and, if saturations decrease to 92% or

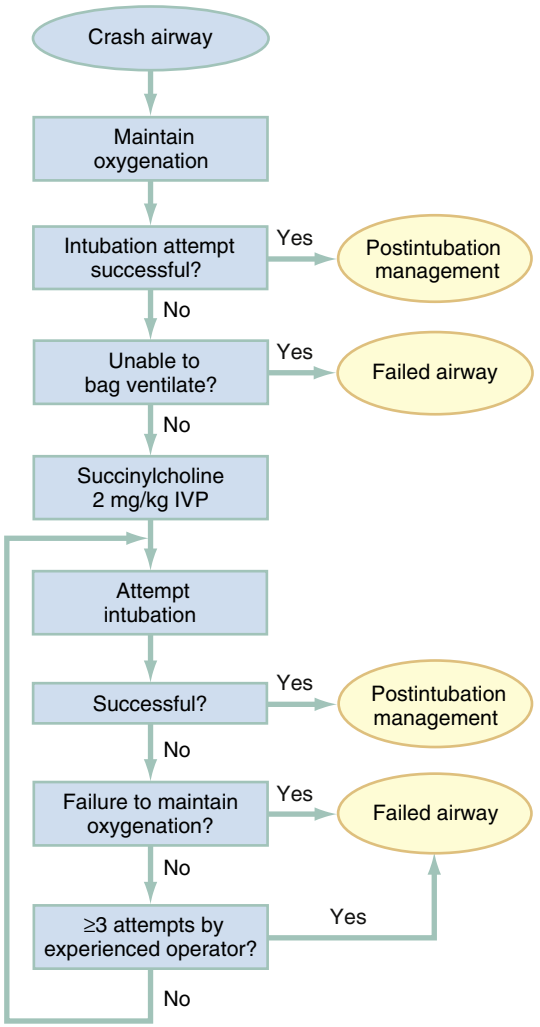

Fig. 1.8 Crash Airway Algorithm. *IVP,* Intravenous push. (Modified from Brown III CA, Mick NM, Sakles JC, editors. *The Emergency Airway Algorithms in the Walls Manual of Emergency Airway Management.* 5th ed. Philadelphia: Wolters Kluwer; 2018.)

less, the laryngoscopic attempt is aborted (unless the operator feels he or she is on the cusp of successful tube placement) and BMV is performed until saturation is sufficiently recovered for another attempt. If the oxygen saturation continues to fall, despite optimal use of BMV or EGD, a failed airway exists. This is referred to as a CI:CO type of failed airway. A second form of failed airway is present when there have been three unsuccessful "best attempts" at laryngoscopy, because subsequent attempts by the same clinician are unlikely to succeed. The three failed laryngoscopy attempts are defined as attempts by an experienced clinician using the best possible patient positioning, device, and technique. Three attempts by a trainee using a direct laryngoscope may not count as best attempts if an experienced emergency clinician is available or VL has not yet been attempted. In addition, the emergency clinician can identify a failed airway after even a single laryngoscopic attempt if it is judged that intubation likely will be impossible (e.g., grade 4 laryngoscopic view with DL, despite optimal patient positioning and use of external laryngeal manipulation) and no alternative device (e.g., videolaryngoscope, intubating LMA) is available. The failed airway is managed according to the failed airway algorithm (Fig. 1.10).

Difficult Airway

The perception of a difficult airway is relative, and many emergency intubations rightly are considered "difficult." Deciding whether to treat the airway as a typical emergency airway or whether to use the difficult airway algorithm is based on the degree of perceived difficulty, operator experience, armamentarium of airway devices, and individual circumstances of the case. The LEMON, ROMAN, RODS, and SMART assessments provide a systematic framework to assist in identifying the potentially difficult airway but are not meant to firmly determine whether any individual patient should, or should not, receive an NMBA.

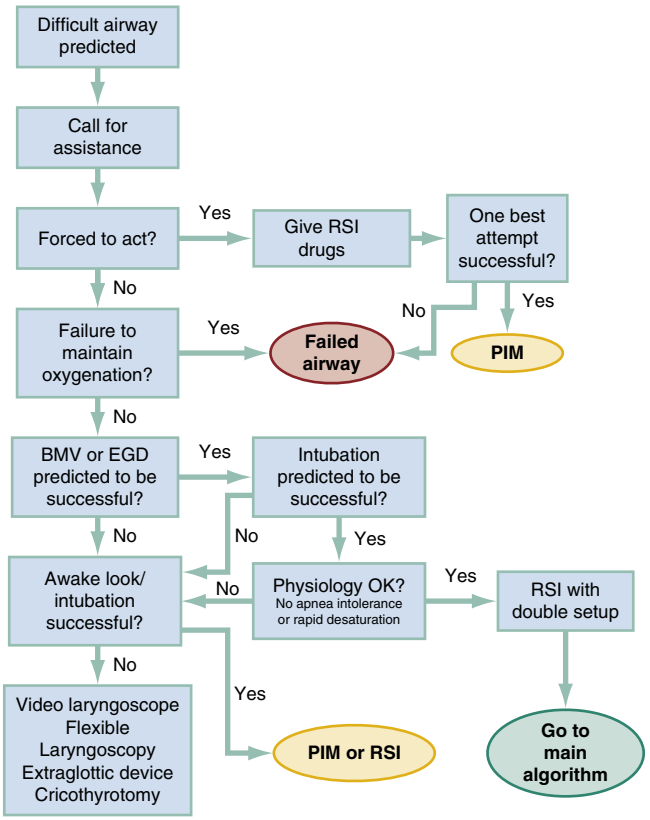

Fig. 1.9 Difficult Airway Algorithm. *BMV,* Bag-mask ventilation; *EGD,* extraglottic device; *PIM,* postintubation management; *RSI,* rapid sequence intubation. (Modified from Brown III CA, Mick NM, Sakles JC, editors. *The Emergency Airway Algorithms in the Walls Manual of Emergency Airway Management*. 5th ed. Philadelphia: Wolters Kluwer; 2018.)

When preintubation evaluation identifies a potentially difficult airway (see Fig. 1.9), the approach is based on the premise that NMBAs generally should not be used unless the emergency clinician believes that (1) intubation is likely to be successful, (2) oxygenation can be maintained via BMV or EGD should the patient desaturate during an intubation attempt, and (3) the patient will not experience cardiovascular catastrophe or arrest from precipitous desaturation or hemodynamic collapse following administration of RSI medications. This is particularly true when intubation is undertaken with a conventional laryngoscope which may result in prolonged laryngoscopy and a lower FAS, even if that attempt is augmented by laryngeal manipulation and use of a bougie.[12,13] In addition, anatomic features of a difficult airway should be considered in the context of deranged physiology, provider experience, and availability of VL. Patients with refractory hypoxemia, right heart failure, or severe metabolic acidosis may be best managed with an awake intubation, especially if anatomic challenges exist, because the possibility of prolonged or repeated laryngoscopy combined with rapid physiologic decline with the onset of hypopnea can result in rapid arrest and anoxic injury. In these cases, if RSI is still deemed the best approach, then all other elements should be optimized to increase FAS. This includes (ideally) use of VL, robust preoxygenation and cardiovascular optimization with fluids, blood, and pressor agents, as necessary. The one exception to this recommendation occurs in the "forced to act" scenario.

A forced to act imperative permits RSI, even in a highly difficult airway situation in which the operator is not confident of the success of laryngoscopy or of sustaining oxygenation. This usually occurs in the setting of a rapidly deteriorating patient with an obviously difficult airway and a presumed clinical trajectory of imminent arrest or airway obstruction. Although this is not yet a crash airway situation, the operator is forced to act—that is, there is a need to act immediately to intubate before orotracheal intubation quickly becomes impossible or the patient arrests. The patient retains sufficient muscle tone and voluntary effort (including combative behavior induced by hypoxia) to require administration of drugs before intubation can be attempted. Consider an agitated patient with rapidly advancing anaphylaxis or angioedema, a morbidly obese patient in severe, end-stage status asthmaticus, or an intensive care unit (ICU) patient with inadvertent or premature extubation, respiratory failure, and difficult airway. Within seconds to minutes, perhaps before a full difficult airway assessment can be done or preparations can be completed for an alternative airway approach (e.g., flexible endoscopy), the patient's rapid deterioration signals impending respiratory arrest. This is a unique situation in which the operator may be compelled to take the one best chance to secure the airway by rapidly administering RSI drugs, despite obvious airway difficulty, and attempting intubation before the airway crisis has advanced to the point that intubation is impossible or delay has caused hypoxic arrest. If laryngoscopy fails, the RSI drugs have optimized patient conditions for cricothyrotomy or insertion of an alternative airway device, depending on the operator's judgment.

Therefore, in the difficult airway algorithm, the first determination is whether the operator is *forced to act*. If so, RSI drugs are given, a best attempt at laryngoscopy is undertaken, and, if intubation is not successful, the airway is considered failed, and the operator moves immediately to the failed airway algorithm. However, in the vast majority of difficult airway situations, the operator is not forced to act, and the first step is to ensure that oxygenation is sufficient to permit a planned orderly approach to airway management. If oxygenation is inadequate,

oxygenation cannot be made adequate by supplementation with BMV, and anatomic challenges are significant, then the airway should be considered a failed airway. Although inadequate oxygenation should be defined on a case-by-case basis, oxygenation saturation decreasing to less than 93% is the accepted threshold, because this represents the point at which hemoglobin undergoes a conformational change, more readily releases oxygen, and increases the pace of further desaturation. Oxyhemoglobin saturations in the mid-80s, if holding steady, might be considered adequate in some circumstances, particularly if the patient is chronically hypoxemic. When oxygenation is inadequate or dropping, the failed airway algorithm should be used because the predicted high degree of intubation difficulty, combined with failure to maintain oxygen saturation, is analogous to the CI:CO scenario.

However, when oxygenation is deemed adequate, the next consideration is whether RSI is appropriate, on the basis of the operator's assessment of the likelihood of (1) successful ventilation with BMV or EGD in case intubation is unsuccessful, (2) the likelihood of successful intubation by laryngoscopy, and (3) the severity of physiologic derangement. If the operator is not confident of successful intubation or rescue oxygenation and time allows, an awake technique can be used. In this context, awake means that the patient continues to breathe and, although IV sedation and analgesia may be administered, can cooperate with caregivers. If the operator judges that anatomic challenges are minimal and would not significantly adversely affect laryngoscopy or rescue oxygenation, then the patient's physiologic vulnerability is considered. If the patient is deemed both hemodynamically stable and not at risk for immediate desaturation, then RSI is performed. However, if the patient is thought to be intolerant of apnea because of severe metabolic acidosis or anticipated precipitous desaturation or exhibits profound, refractory shock such that the vasoplegic effects of sedative/induction agents might precipitate circulatory collapse, then an awake technique is preferred. If RSI is performed on a patient with significant difficult airway attributes identified, then we recommend a double setup, with preparations simultaneously undertaken for rescue cricothyrotomy or another immediate rescue technique.

During an awake intubation, the patient is prepared by applying topical anesthesia with atomized or nebulized lidocaine, ideally preceded by a drying agent such as glycopyrrolate. Titrated doses of sedative and analgesic agents (or ketamine, which provides both actions) may be required for the patient to tolerate the procedure. Once this is accomplished, any of a number of different devices can then be used to attempt glottic visualization, with device selection most often dictated by patient anatomy and pathology. Regardless of the route taken to the airway (nasal or oral), VL, whether flexible or rigid, is preferable to DL. If the glottis is adequately visualized, the patient can be intubated at that time or, in a stable difficult airway situation, the emergency clinician may proceed with planned RSI, now assured of intubation success. If the awake laryngoscopy is unsuccessful, the patient can be intubated with any of numerous techniques shown in the last box in Fig. 1.9. For each of these methods, the patient is kept breathing but is variably sedated and anesthetized. The choice among these methods depends on clinician experience and preference, device availability, and patient attributes.

Failed Airway

Management of the failed airway is dictated by whether the patient can be oxygenated. If adequate oxygenation cannot be maintained with rescue BMV, the rescue technique of first resort is cricothyrotomy (see Fig. 1.10). Multiple attempts at other methods in the context of failed oxygenation only delay cricothyrotomy and place the patient at increased risk for hypoxic brain injury. However, if an alternative device (i.e., an EGD such as an LMA or King LT airway) is readily available and the operator judges it to be an appropriate device for the patient's anatomy, a single attempt can be made to use it simultaneously with preparations for immediate cricothyrotomy as long as initiation of cricothyrotomy is not delayed. If early indications are that the EGD is effective and oxygenation improves, cricothyrotomy can wait; however, the operator must continuously reassess EGD function and oxygenation status. If the EGD subsequently fails, cricothyrotomy must begin without delay.

If adequate oxygenation is possible, several options are available for the failed airway. In almost all cases, cricothyrotomy is the definitive rescue technique for the failed airway if time does not allow for other approaches (i.e., oxygenation cannot be maintained) or if they fail. We distinguish the difficult and failed airway as follows: the difficult airway is something one anticipates; the failed airway is something one experiences. The fundamental difference in philosophy between the difficult and failed airway is that the difficult airway is planned for, and the standard is to place a definitive airway (cuffed ETT) in the trachea. The failed airway is not planned for, and the standard is to achieve any airway that provides adequate oxygenation to avert hypoxic brain injury. Some devices used in the failed airway (e.g., EGDs) are temporary and do not provide definitive airway protection, so are not generally used in the planned management of the difficult airway.

Methods of Intubation

Although many techniques are available for intubation of the emergency patient, four methods are the most common, with RSI being the most frequent approach.[1,14]

Rapid Sequence Intubation

RSI is the cornerstone of emergency airway management and is defined as the nearly simultaneous administration of a potent sedative (induction) agent and NMBA, after a period of preoxygenation and cardiopulmonary optimization, for tracheal intubation. This approach

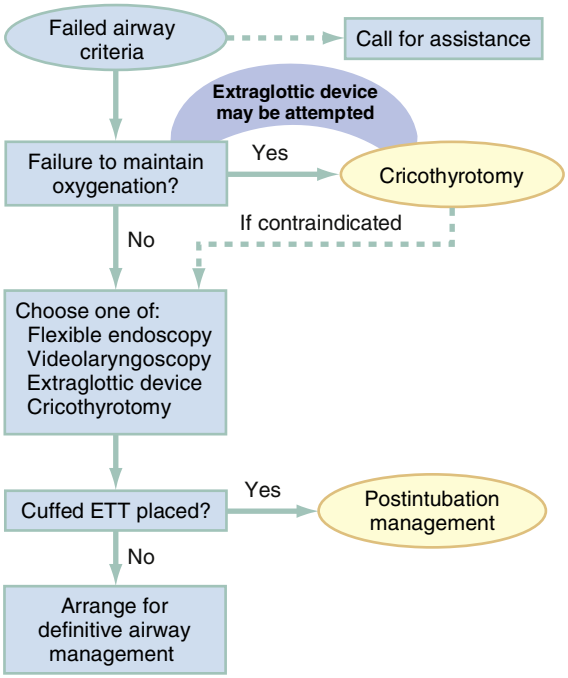

Fig. 1.10 Failed Airway Algorithm. *ETT,* Endotracheal tube. (Modified from Brown III CA, Mick NM, Sakles JC, editors. *The Emergency Airway Algorithms in the Walls Manual of Emergency Airway Management.* 5th ed. Philadelphia: Wolters Kluwer; 2018.)

provides optimal intubating conditions and was initially developed to safely and effectively intubate patients while minimizing the risk of aspiration of gastric contents. There is not compelling evidence that RSI mitigates aspiration risk, although its designed avoidance of BMV during intubation would seem to reduce the likelihood of gastric insufflation and resultant regurgitation of gastric contents. RSI is the most widely used technique for emergency intubation of patients without identifiable difficult airway attributes, with recent large registry data showing that it is used in 85% of all ED intubations.[1,13,14]

The central concept of RSI is to take the patient from the starting point (e.g., conscious, breathing spontaneously) to a state of unconsciousness with complete neuromuscular paralysis and then to achieve intubation without interposed assisted ventilation. The risk of aspiration of gastric contents is thought to be significantly higher for patients who have not fasted before induction and, if adequately preoxygenated, would have a sufficient period of safe apnea such that bagging would not be required. Application of positive pressure ventilation can cause air to pass into the stomach, resulting in gastric distention and increasing the risk of regurgitation and aspiration. For patients considered at high risk for desaturation during RSI, use of careful, controlled mask ventilation between induction and intubation is a reasonable approach as long as the patient is not believed to be at high risk for aspiration (i.e., active upper gastrointestinal bleeding, emesis prior to intubation). A multicenter trial of ICU patients intubated for hypoxic respiratory failure randomized patients to bagging versus no bagging during RSI.[15] The bagging cohort had significantly fewer episodes of desaturation and higher oxygen nadirs when desaturation occurred, compared with the no bagging group. Similar rates of either witnessed aspiration or infiltrate on follow-up chest x-rays were observed between the two groups. Patients who were excluded were more likely to have been fasted, high-risk aspirators, and there was no standardized preoxygenation strategy; therefore these results cannot be broadly extrapolated to emergency airway management. However, balancing risk and consequence of desaturation against risk and consequence of aspiration may appropriately lead to a decision to perform gentle, measured manual ventilation during RSI. As a general rule, RSI is performed without positive pressure ventilation until the ETT is placed correctly in the trachea, with the cuff inflated. This requires a preoxygenation phase, during which mixed alveolar gases (mostly nitrogen) within the lungs' functional residual capacity (FRC) are replaced with oxygen, permitting at least several minutes of apnea (see later discussion) in a healthy normal body habitus adult before oxygen desaturation to less than 90% ensues (Fig. 1.11).

Use of RSI ensures the patient is unaware of the procedure and facilitates successful endotracheal intubation by causing complete relaxation of the patient's musculature, allowing better access to the airway. In patients suffering from a hypertensive emergency such as intracranial hemorrhage, RSI permits administration of sympatholytic agents used to mitigate further spikes in blood pressure and heart rate that might worsen the patient's disease process. RSI is a series of discrete steps, and every step should be planned (Box 1.5).

Preparation. In the initial phase, the patient is assessed for intubation difficulty and abnormal physiology unless this has already been done, and the intubation is planned, including determining dosages and sequence of drugs, tube size, and laryngoscope type, blade, and size. Drugs are drawn up and labeled. All necessary equipment is assembled. All patients require continuous cardiac and pulse oximetry monitoring. At least one and preferably two good-quality IV lines should be established. Redundancy is always desirable in case of equipment or IV access failure. Most importantly, a rescue plan for intubation failure should be developed at this time and made known to the appropriate members of the resuscitation team.

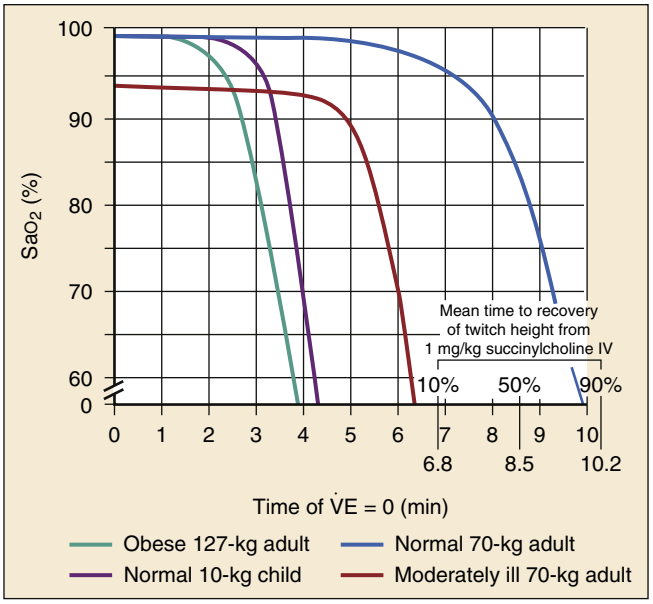

Fig. 1.11 Extrapolated Desaturation Time for Apneic, Fully Preoxygenated Patients. Children, patients with comorbidity, and obese patients desaturate much more rapidly than healthy normal adults. The box on the lower right side of the graph depicts time to recovery from succinylcholine, which in almost all cases exceeds safe apnea time. Note also the precipitous decline of oxygen saturation from 90% to 0% for all groups. *VE,* Expired volume. (Modified from Benumof JL, Dagg R, Benumof R. Critical hemoglobin desaturation will occur before return to unparalyzed state following 1 mg/kg intravenous succinylcholine. *Anesthesiology.* 1997;87:979–982.)

Preoxygenation. The goal of preoxygenation is denitrogenation of the alveoli and formation of an oxygen-rich reservoir within the lung's FRC. The FRC is an untapped potential space, approximately 30 mL/kg in the average adult, that can be used to create an oxygen reserve from which the pulmonary circulation can continue to use even after the patient is rendered apneic. The traditional method for preoxygenation involved having the patient breathe, for 3 minutes at normal tidal volumes, 100% oxygen at 15 L/min flow through a nonrebreather mask. Inevitable room air entrainment resulted in a fraction of inspired oxygen (Fio_2) of only 65% and an end-tidal oxygen level (ETo_2) of only 50% to 60% with this approach. Administration of flush-rate oxygen (40 to 70 L/min) has been shown to significantly increase both the Fio_2 and ETo_2 by outcompeting room air entrainment around the margin of the mask and should be used as the default preoxygenation flow rate whenever possible.[16,17] Flush rate oxygen flow is accomplished by fully opening the oxygen valve at the base of the wall oxygen regulator. The maximum flow rate will vary depending on the size and manufacturer of each unit but is approximately 50 L/min on average. When preoxygenation is performed effectively, the patient may have as much as 6 to 8 minutes

of safe apnea before oxygen desaturation to less than 90% occurs (see Fig. 1.11). Real-time measurement of ETo_2 using a simple bedside gas analyzer can quantify denitrogenation and better ensure that maximal preoxygenation has been accomplished.[18] The time to desaturation to less than 90% in children, obese adults, late-term pregnant women, and patients who are acutely ill or injured is considerably shorter. Desaturation time also is reduced if the patient does not inspire 100% oxygen or has significant intrapulmonary shunting or dead space. Patients with infiltrative lung disease, pulmonary edema, or ARDS may never achieve adequate preoxygenation despite maximal ambient pressure supplemental oxygen. If saturations remain at 93% or less despite these efforts, then the patient should be transitioned to BiPAP to increase alveolar recruitment, reduce shunting, and increase ETo_2. With this approach, adequate preoxygenation usually can be obtained to permit minutes of safe apnea. If time is insufficient for a full 3-minute preoxygenation phase, eight vital capacity breaths (the largest breaths the patient can take with greatest effort) with high-flow oxygen can achieve oxygen saturations and apnea times that match or exceed those obtained with traditional preoxygenation. Apneic oxygenation (ApOx) takes advantage of a physiologic principle termed *aventilatory mass flow,* by applying continuous oxygen flow during the apneic phase of RSI. Even though there is no ventilatory activity by the patient, circulation is unaltered. The constant diffusion of alveolar oxygen into the pulmonary circulation creates a natural downward gradient promoting passive oxygen movement from the patient's upper airway into the gas-exchanging portions of the lungs. Desaturation time in obese patients can be prolonged by preoxygenating with the patient in a head-up position and by continuing supplemental oxygen (via nasal cannula at a flow rate of 5 to 15 L/min) after motor paralysis and during laryngoscopy until the ETT is successfully placed. In obese patients without preexisting lung disease, ApOx extends the time to desaturation to 95% from 3 to 5 minutes. A randomized trial of ED patients undergoing RSI challenged the use of ApOx when it reported no observable reduction in desaturation events or nadir oxygen levels with apneic nasal oxygen. However, in the study, the vast majority of patients were intubated in less than 2 minutes, thereby removing the possibility of an observable benefit from ApOx.[19] Subsequent meta-analyses, including one focused on pediatric patients, revealed that ApOx significantly reduces the risk of hypoxia.[20–22] A meta-analysis of randomized controlled trials including both ICU and preoperative patients found no reduction in severe desaturation (<80%) or peri-intubation adverse events from the use of high-flow nasal cannula (HFNC) applied during intubation; however, only one of the included trials reported the number of intubation attempts, the type of device used, total intubation time, or glottic view.[23] Patients with prolonged laryngoscopic attempts may be the group most at risk for peri-intubation hypoxia and garner the most benefit from ApOx. On balance, ApOx is noninvasive, cheap, and likely beneficial during emergency airway management. We recommend that oxygen by nasal cannula, be continued at a minimum of 5 L/min, up to 15 L/min, throughout emergency RSI attempts until tracheal intubation is achieved.

Preintubation optimization. Airway management can be made more complex by unstable hemodynamics and impaired patient physiology. Although shock states, severe myocardial depression, or an inability to preoxygenate do not necessarily make the act of laryngoscopy and tracheal tube placement more difficult, they can increase patient morbidity by drastically shortening the time available to safely intubate or by placing the patient at risk for hypoxic injury or peri-intubation circulatory collapse. Preintubation optimization is designed to identify and address areas of physiologic concern that may complicate resuscitative efforts, even if tracheal intubation goes quickly and smoothly. When time permits, abnormal hemodynamic parameters should be improved to the extent possible prior to intubation. Patient outcomes can be compromised in those with hypotension or shock caused by bleeding, dehydration, sepsis, and primary cardiac pathology, even if tube placement is smooth, fast, and successful. Vasoplegia from induction agents can potentiate peripheral vascular dilation and exacerbate hypotension. Patients who present with low intravascular volume, right heart disease, or poor vascular tone can suffer circulatory collapse after RSI drugs are administered, particularly after positive pressure ventilation is initiated. Isotonic fluids, blood products, and pressor agents (typically norepinephrine) may be used, time permitting, to support blood pressure and increase pharmacologic options for RSI. We recommend a balance of fluid or blood product replacement, as indicated, complemented by pressors, optimal oxygenation, and control of any exacerbating factors, such as external hemorrhage.

Paralysis with induction. In this phase, a potent sedative agent is administered by rapid IV push in a dose capable of producing unconsciousness rapidly. This is immediately followed by rapid administration of an intubating dose of an NMBA, either succinylcholine at a dose of 1.5 mg/kg IV or rocuronium at a dose of 1.2 mg/kg IV. An analysis of more than 5000 patients from the National Emergency Airway Registry (NEAR) database revealed that the glottic view obtained, rates of FAS, and adverse events were equivalent between the two drugs when these, or higher doses, were used.[14]

Positioning. The patient should be positioned for intubation as consciousness is lost. Usually, positioning involves head extension, often with flexion of the neck on the body. Although simple extension may be adequate, a full sniffing position with cervical spine extension and head elevation is optimal if DL is used.[7] There is no difference in FAS rates between supine and nonsupine patient positioning regardless of airway difficulty.[24] The Sellick maneuver—application of firm, backward pressure over the cricoid cartilage with the goal of obstructing the cervical esophagus and reducing the risk of aspiration—had long been recommended to minimize the risk of passive regurgitation and hence aspiration but is no longer recommended. The Sellick maneuver is incorrectly applied by a variety of operators, making laryngoscopy or intubation more difficult in some patients, and aspiration often occurs despite use of the Sellick maneuver. In many patients, the cervical esophagus is positioned lateral to the cricoid ring in a relationship that is exaggerated by posterior pressure, rarely resulting in esophageal obstruction. Accordingly, we do not recommend use of the Sellick maneuver. After administration of an induction agent and NMBA, although the patient becomes unconscious and apneic, BMV should not be initiated unless the oxygen saturation falls to 92%.

Placement of tube. Approximately 45 to 60 seconds after administration of the NMBA, the patient is relaxed sufficiently to permit laryngoscopy. This is assessed most easily by moving the mandible to test for mobility and absence of muscle tone. Place the ETT during glottic visualization with the laryngoscope. Confirm placement, as described earlier. If the first attempt is unsuccessful but oxygen saturation remains high, it is not necessary to ventilate the patient with a bag and mask between intubation attempts. If the oxygen saturation is approaching 92%, the patient may be ventilated briefly with a bag and mask between attempts to reestablish the oxygen reservoir.

Postintubation management. After confirmation of tube placement by $ETco_2$, obtain a chest radiograph to confirm that mainstem intubation has not occurred and to assess the lungs. If available, place the patient on continuous capnography. In general, long-acting NMBAs (e.g., pancuronium, vecuronium) are avoided; the focus is on optimal management using opioid analgesics and sedative agents to facilitate mechanical ventilation. An adequate dose of a benzodiazepine (e.g., midazolam, 0.1 to 0.2 mg/kg IV) and opioid

TABLE 1.1 Sample Rapid Sequence Intubation Using Etomidate and Succinylcholine.

Time	Step
Zero minus 10 min	Preparation
Zero minus 5 min	Preoxygenation—100% oxygen for 3 min or 8 vital capacity breaths
Zero minus 3 min	Preintubation optimization—as indicated
Zero	Paralysis with induction • Etomidate, 0.3 mg/kg • Succinylcholine, 1.5 mg/kg
Zero plus 30 s	Positioning—Sellick maneuver optional
Zero plus 45 s	Placement • Laryngoscopy and intubation • End-tidal carbon dioxide confirmation
Zero plus 2 min	Postintubation management • Sedation and analgesia as indicated • Initiate mechanical ventilation • NMBA only if needed after adequate sedation, analgesia

NMBA, Neuromuscular blocking agent.

analgesic (e.g., fentanyl, 0.5 to 1 μg/kg IV, or morphine, 0.2 to 0.3 mg/kg IV) is given to improve patient comfort and decrease sympathetic response to the ETT.

Propofol infusion (0.05 to 0.1 mg/kg/min IV) with supplemental analgesia is an effective method for managing intubated patients who do not have hypotension or ongoing bleeding. It is especially helpful for the management of neurologic emergencies because its clinical duration of action is very short (<5 minutes), allowing frequent neurologic examinations. An NMBA is added only if appropriate use of sedation and analgesia fail to control the patient adequately or when ventilation is challenging because of muscular activity. Table 1.1 presents a sample RSI protocol using etomidate and succinylcholine. Zero refers to the time at which the induction agent and succinylcholine are pushed.

Delayed Sequence Intubation

Delayed sequence intubation (DSI) is a technique proposed to maximize preoxygenation in preparation for intubation. Agitation, delirium, and confusion can confound attempts at preoxygenation when a patient is unable to comply with conventional modes of supplemental oxygenation, such as a face mask or BiPAP. DSI considers preoxygenation a procedure and uses dissociative doses of ketamine (1 to 2 mg/kg IV bolus) as procedural sedation to accomplish this. A small, ED- and ICU-based multicenter observational study showed post-DSI oxygen saturations significantly higher than pre-DSI levels. There were no noted adverse outcomes or desaturations when intubation eventually took place in this limited case series.[25] A prehospital investigation that studied the routine use of DSI as part of a multi-interventional bundle (which also included preoxygenation targets and upright patient positioning) to prevent desaturation during airway management showed a 10-fold reduction in rates of peri-intubation desaturation without increased adverse events.[26] However, this approach is not without some risk, as there have been reports of ketamine-induced apnea during DSI.[27] On balance, more investigation is required to determine the possible indications for and safety of DSI when performed in various emergency settings.

Awake Oral Intubation

Awake oral intubation is a technique in which sedative and topical anesthetic agents are administered to permit management of a difficult airway without neuromuscular blockade. Sedation and analgesia are achieved in a manner analogous to that for painful procedures in the ED. Topical anesthesia may be achieved by topically applied anesthetic paste, spray, nebulization, or local anesthetic nerve block. Various sedative agents can be used, but ketamine, which provides dissociative anesthesia, analgesia, maintenance of protective airway reflexes, and minimal respiratory depression, is often the best choice (see later, "Pharmacologic Agents"). Ketamine-induced apnea has been reported, so close observation is required, especially in patients with partial airway obstruction.[28] Starting with small aliquots at doses of 0.25 to 0.5 mg/kg IV every 10 minutes, titrated to the desired level of sedation and procedural tolerance, ketamine anesthesia is an effective method for awake intubation. Dexmedetomidine (Precedex), a centrally acting alpha receptor blocker, has been used successfully, alone or in combination with benzodiazepines, for awake airway evaluations. A typical dose is 1.0 mg/kg IV infused over 5 to 10 minutes. After the patient is sedated, and topical anesthesia has been achieved, gentle flexible or rigid VL is performed to determine whether the glottis is visible and intubation possible. If the glottis is visible, the patient may be intubated during initial laryngoscopy, or the operator, confident that the glottis can be visualized, may opt to perform RSI to benefit from pretreatment, induction, and paralysis, as might be the case in a patient with a head injury.

Awake oral intubation is distinct from the practice of oral intubation with a sedative or opioid agent to obtund the patient for intubation without neuromuscular blockade. This latter technique can be referred to as intubation with sedation alone or, paradoxically, nonparalytic RSI. Intubating conditions and FAS achieved even with deep anesthesia are significantly inferior to what is achieved when neuromuscular blockade is used.[1] In general, the technique of administering a potent sedative agent to obtund the patient's responses and permit intubation in the absence of neuromuscular blockade is ill advised and inappropriate for endotracheal intubation in the ED, unless performed as part of an awake intubation (see earlier), during which different agents and lower amounts are typically used.

Oral Intubation Without Pharmacologic Agents

The arrested or near-death patient may not require pharmacologic agents for intubation, but even an arrested patient may retain sufficient muscle tone to render intubation difficult. If the glottis is not adequately visualized, administration of a single dose of succinylcholine alone may facilitate laryngoscopy (see earlier, "Decision Making"). Success rates for intubating unconscious, unresponsive patients are variable but approach those achieved with RSI, presumably because the patient is in a similar physiologic state (i.e., muscle relaxation, no ability to react to laryngoscopy or tube insertion).[1] This does not apply to patients who are unconscious from neurologic catastrophe or trauma and those who have overdosed or have other medical causes of coma who warrant an induction agent and are intubated with standard RSI procedures (see earlier).

Pharmacologic Agents

Neuromuscular Blocking Agents

NMBAs are highly water-soluble, quaternary ammonium compounds that mimic the quaternary ammonium group on the acetylcholine (ACh) molecule. Their water solubility explains why they do not readily cross the blood-brain barrier or placenta. NMBAs are divided into two main classes, depolarizing and nondepolarizing agents. The depolarizing agent succinylcholine exerts its effects by binding noncompetitively with ACh receptors on the motor end plate, causing sustained

depolarization of the myocyte while preventing transmembrane potentials from reforming and resisting further stimulation from ACh. The other major class of NMBA comprises the competitive, or nondepolarizing, agents, which bind competitively to ACh receptors, preventing access by ACh and preventing muscular activity. The competitive agents are of two pharmacologically distinct types, steroid-based agents (aminosteroid compounds) and benzylisoquinolines. Each of these basic chemical types has distinct properties, but only aminosteroid compounds are used in the ED.

Succinylcholine. Succinylcholine is a combination of two molecules of ACh. Succinylcholine is rapidly hydrolyzed by plasma pseudocholinesterase to succinylmonocholine, which is a weak NMBA, and then to succinic acid and choline, which have no NMBA activity. Pseudocholinesterase is not present at the motor end plate and exerts its effects systemically before the succinylcholine reaches the ACh receptor. Only a small amount of the succinylcholine administered survives to reach the motor end plate. Succinylcholine is active at the motor end plate until it diffuses away. Decreased plasma pseudocholinesterase activity can increase the amount of succinylcholine reaching the motor end plate, prolonging succinylcholine block, but this is of little significance in the emergency setting because the prolongation of action rarely is significant, reaching only 23 minutes at the extreme.

Uses and dosing. Succinylcholine is rapidly active, typically producing intubating conditions within 45 seconds of administration by rapid IV bolus injection. The clinical duration of action before spontaneous respiration is 6 to 10 minutes (see Fig. 1.11). Full recovery of normal neuromuscular function occurs within 15 minutes. The combination of rapid onset, complete reliability, short duration of action, and absence of common serious side effects has kept succinylcholine as the drug of choice for most ED intubations. Time-trended surveillance of ED intubation practices has suggested that succinylcholine is slowly being replaced by rocuronium, with use of the agents approximately equal in a large multicenter assessment of NMBA use during adult ED intubations.[14] There is high, site-specific variation, suggesting that local culture is the primary driver for drug selection. The appropriate dose of succinylcholine for emergency airway management is 1.5 mg/kg IV. Although the effective dose at which paralysis is achieved in 95% of patients (ED_{95}) for succinylcholine paralysis is much lower (0.3 mg/kg), the onset of muscle paralysis is excessively long at these lower doses and is not compatible with emergency intubation. Excellent intubating conditions are best achieved when succinylcholine is dosed at 1.5 mg/kg. Although hydrophilic, multiple studies have confirmed that the dose of succinylcholine is based on the patient's total body weight (TBW) and is not adjusted (downward), regardless of the degree of obesity because pseudocholinesterase activity increases with body habitus.

Cardiovascular effects. As an ACh analogue, succinylcholine binds to ACh receptors throughout the body, not just at the motor end plate. It is difficult to separate the effects of succinylcholine on the heart caused by direct cardiac muscarinic stimulation from those caused by stimulation of autonomic ganglia by succinylcholine and from the effects induced by autonomic responses to laryngoscopy and intubation. Succinylcholine can be a negative chronotrope, especially in children, and sinus bradycardia may ensue after succinylcholine administration. Sinus bradycardia is treated with atropine, if necessary, but is usually self-limiting. Some pediatric practitioners recommend pretreatment with atropine for children younger than 1 year, but there is no evidence for benefit, and we do not agree with this recommendation. Uncommonly, adults may develop bradycardia if succinylcholine is readministered, but bradycardia in the context of intubation should be considered to be caused by hypoxemia until that cause is excluded. Other cardiac dysrhythmias, including ventricular fibrillation and asystole, have been reported with succinylcholine, but it is impossible to distinguish the effects of the drug itself from those caused by the intense vagal stimulation and catecholamine release that accompany laryngoscopy and intubation. In addition, many of these catastrophic complications occur in critically ill patients, further confounding attempts to identify whether the illness or any particular drug or procedure is the cause.

Fasciculations. The depolarizing action of succinylcholine results in fine chaotic contractions of the muscles throughout the body for several seconds during the onset of paralysis in more than 90% of patients. Muscle pain occurs in approximately 50% of patients who receive succinylcholine. Although it has been thought that muscle pains are reduced or abolished by prior administration of a defasciculating dose of a competitive NMBA, the evidence is not conclusive. Use of 1.5 mg/kg of succinylcholine results in less fasciculation and less myalgia than occur with 1 mg/kg.

Hyperkalemia. Succinylcholine has been associated with severe fatal hyperkalemia when administered to patients with specific predisposing clinical conditions (Table 1.2). The mechanism of severe hyperkalemia is related to receptor upregulation on the postsynaptic muscle membrane. When a muscle is deprived of ACh stimulation for as little as 3 days, receptor upregulation begins, causing an increase in receptor density and a change of receptor subtypes on the muscle surface. ACh receptors are primarily K^+ ion channels, and at-risk patients can have an immediate massive efflux of potassium as these newly recruited receptors are depolarized by succinylcholine. This occurs predominantly at the site of injury but may also occur in tissue remote from the original insult. Although the hyperkalemia occurs within minutes after administration of succinylcholine and may be severe or fatal, the patient's vulnerability to succinylcholine-induced hyperkalemia starts as early as 3 days but does not become significant until more than 5 days after the inciting injury or burn, because receptor upregulation and production of protein subunits takes time to develop.

Succinylcholine remains the agent of choice for RSI in acute burn, trauma, stroke, and spinal cord injury if intubation occurs earlier than 5 days after onset of the condition. If doubt exists regarding the onset time, succinylcholine should be replaced with rocuronium. Degenerative neuromuscular disorders, denervation syndromes, or primary myopathies (e.g., multiple sclerosis, amyotrophic lateral sclerosis, Duchenne muscular dystrophy) can be particularly troubling because the risk begins with the onset of the disease and continues indefinitely, regardless of the apparent stability of the symptoms. In patients with denervation caused by a sudden discreet injury or ischemic insult (e.g., stroke, spinal cord injury), the upregulated receptors eventually regress, and the patient can safely receive succinylcholine beginning 6 months after the original insult.

TABLE 1.2 Conditions Associated With Hyperkalemia After Succinylcholine Administration.

Condition	Period of Concern
Burns >10% BSA	>5 days after injury until wounds are healed
Crush injury	>5 days after injury until wounds are healed
Denervation (stroke, spinal cord injury)	>5 days until 6 months postinjury
Neuromuscular disease (ALS, MS, MD)	Indefinitely
Intraabdominal sepsis	>5 days until infection resolves

ALS, Amyotrophic lateral sclerosis; *BSA,* body surface area; *MD,* muscular dystrophy; *MS,* multiple sclerosis.

Potassium release does not occur to any significant extent in the general population. Succinylcholine is not contraindicated in renal failure but should be avoided in patients with known or presumed hyperkalemia (often in the setting of missed dialysis) sufficient to be manifest on the electrocardiogram (ECG). Treatment for succinylcholine-induced hyperkalemia is the same as for any other hyperkalemic emergency.

Masseter spasm. Succinylcholine has rarely been reported to cause masseter spasm, primarily in children and young adults. The clinical significance of this phenomenon is unclear, but administration of a competitive NMBA terminates the spasm. Severe persistent spasm should raise suspicion of malignant hyperthermia.

Malignant hyperthermia. Succinylcholine has been associated with malignant hyperthermia, a perplexing and exceptionally rare syndrome of rapid temperature rise and rhabdomyolysis. Malignant hyperthermia occurs in genetically predisposed individuals who receive certain volatile anesthetic agents or succinylcholine. The condition is extremely rare and has not been reported in the context of ED intubation. Treatment consists of cessation of any potential offending agents, administration of dantrolene (1 to 2.5 mg/kg IV every 5 minutes, to a maximum dose of 10 mg/kg IV), and attempts to reduce body temperature by external means. A national malignant hyperthermia hotline is available for emergency consultation at 1-800-644-9737 (then dial 0).

Competitive agents. Competitive NMBAs are classified according to their chemical structure. The aminosteroid agents include pancuronium, vecuronium, and rocuronium. Vecuronium neither releases histamine nor exhibits cardiac muscarinic blockade and is an excellent agent for the maintenance of neuromuscular blockade when this is desirable. Rocuronium is the best agent for use in RSI as an alternative to succinylcholine or when succinylcholine is contraindicated. When dosed appropriately, rocuronium and succinylcholine are clinically equivalent.[14]

Rocuronium. When a patient has a contraindication to succinylcholine, rocuronium is the paralytic agent of choice. At a dose of 1.2 mg/kg IV, rocuronium achieves intubating conditions similar to those of succinylcholine in approximately 60 seconds and lasts approximately 45 minutes. Onset of paralysis is dose dependent and can be as fast as 30 seconds at doses of 1.5 mg/kg IV. For emergency airway management, there is little additional risk in administering more, rather than less, rocuronium. There are no adverse effects to a larger dose of rocuronium other than prolongation of clinical action. A longer clinical duration of action would not unnecessarily place a patient in jeopardy when, even at lower doses, one can expect at least 45 minutes of neuromuscular blockade, and, in any case, rocuronium is fully reversible by sugammadex. The specter of a partially paralyzed difficult airway makes erring on a lower-dose regimen unwise. There are no absolute contraindications to rocuronium. In the ED, dosing in morbidly obese patients should be based on actual TBW. Although adequate intubating conditions can be obtained when ideal body weight (IBW) is used, this concept is pertinent only to the anesthesiologist who may be titrating neuromuscular blockade to a short anesthetic time. Regardless of which weight-based dosing regimen is used, paralysis is of sufficient duration that the emergency clinician needs to manage the airway successfully before spontaneous respirations return. The potential for inferior intubating conditions using IBW dosing makes this approach undesirable. In the subset of critically ill patients who require frequent, serial, neurologic examinations, a longer duration of paralysis with rocuronium may make it less desirable than succinylcholine; however, in patients who must be reversed, sugammadex can be administered and results in faster muscle twitch recovery than neostigmine.[28] However, sugammadex should not be considered a rescue option for a CI:CO failed airway when rocuronium is used. It is not readily available outside of the operating room, and even if it is immediately ready to administer, the speed and completeness of recovery of spontaneous ventilation is variable and does not address the effects of the induction dose of the sedative agent that may contribute to ongoing hypopnea and hypoxia. The approach to the CI:CO failed airway is in the failed airway algorithm—a rescue EGD can be attempted followed quickly by surgical rescue if efforts to oxygenate fail.

Paralysis after intubation. After intubation, prolonged paralysis may be desired to optimize mechanical ventilation; however, current management is based on use of deep sedation and analgesia, with neuromuscular paralysis used only when necessary to maintain ventilatory control. If neuromuscular blockade is required, vecuronium (0.1 mg/kg IV) can be given. However, longer-term neuromuscular blockade is not to be undertaken without ensuring appropriate sedation and analgesia of the patient and a means to ensure that ongoing sedation and analgesia are adequate. Prolonged paralysis without adequate sedation occurs in up to 20% of patients following RSI in the ED. Risk factors for not receiving sedation after intubation include head injury and use of rocuronium.[29] A sedating dose of a benzodiazepine, such as midazolam (0.1 mg/kg IV), combined with an opioid analgesic, such as fentanyl (0.5 to 1 μg/kg IV) or morphine (0.1 to 0.2 mg/kg IV bolus), is required to improve patient comfort and decrease sympathetic response to the ETT. A sedative strategy using propofol (0.1 mg/kg/min IV) is common, especially in head-injured patients, because of its beneficial cerebroprotective profile and rapid resolution of anesthesia that allows frequent neurologic reassessments. With appropriate attention to achieving optimal sedation and analgesia, ongoing use of an NMBA usually is not necessary. We recommend the use of a standardized sedation scale to ensure that adequate sedation is achieved, both for patient comfort and to optimize physiology.

Induction Agents

A patient with any degree of clinical responsiveness, including reactivity to noxious stimuli, should receive a sedative or induction agent at the time of administration of any NMBA. Patients who are deeply unconscious and unresponsive may require only a reduced dose of an induction agent if the unconscious state is caused by drugs or alcohol, which are themselves general anesthetic agents. Patients who are unconscious because of a central nervous system insult should receive a full induction dose of an appropriate agent to attenuate adverse responses to airway manipulation. Induction agents also potentiate the effect of the NMBA and improve intubation conditions because the intubation is often initiated on the leading edge of paralysis, and the relaxation effects of the induction agent are additive to those of the NMBA.

Etomidate. Etomidate is an imidazole derivative that has been in use since 1972. Its activity profile is similar to that of thiopental, with rapid onset, rapid peak activity, and brief duration, but it is remarkable in its lack of adverse hemodynamic effects. Emergency clinicians have high confidence in etomidate, which is used in up to 90% of all ED intubations.[1] The induction dose is 0.3 mg/kg IV. Because etomidate is able to decrease intracranial pressure (ICP), cerebral blood flow (CBF), and cerebral metabolic rate without adversely affecting systemic mean arterial blood pressure (MAP) and cerebral perfusion pressure (CPP), it is an excellent induction agent for patients with elevated ICP, even in cases of hemodynamic instability. Etomidate may cause brief myoclonus, but this is of no clinical significance when administered for RSI. A single dose of etomidate has been shown to reduce serum cortisol levels transiently and blunt the adrenal response to adrenocorticotropic hormone (ACTH) by reversibly inhibiting 11β-hydroxylase, a key

synthetic enzyme in the glucocorticoid pathway. Since discovering this mechanism, much debate has emerged regarding etomidate's impact on survival in sepsis patients. Data from retrospective studies are conflicting, but a large meta-analysis of 18 prospective observational and controlled trials has shown no mortality effect from a single dose of etomidate in septic patients.[30] Ironically, much of the original criticism of etomidate arose from the hypothesis that the adrenocortical response to exogenous corticotropin predicts outcome in patients with septic shock, a theory that has since been discredited. Pending a properly constructed, prospective, randomized clinical trial, there is not sufficient evidence to support the recommendation that etomidate be avoided in patients with septic shock. In fact, etomidate's superior hemodynamic profile makes it an excellent choice in these and other unstable patients, and in a recent large observational cohort of ED patients intubated for sepsis, etomidate was less likely to precipitate peri-intubation hypotension than ketamine.[31]

Ketamine. Ketamine, a phencyclidine derivative, has been widely used as a general anesthetic agent since 1970. After an IV dose of 1.5 mg/kg ketamine produces loss of awareness within 30 seconds, peaks in approximately 1 minute, and has a clinical duration of 10 to 15 minutes. As a dissociative anesthetic agent, ketamine induces a cataleptic state rather than a true unconscious state. The patient has profound anesthesia but may have her or his eyes open. Protective airway reflexes and ventilatory drive usually are preserved.

The principal uses of ketamine in emergency airway management are as a sedative agent for awake intubation (e.g., flexible bronchoscope) and as the induction agent during RSI for patients with acute severe asthma or hemodynamic instability. Because of its hemodynamic profile, ketamine can be considered as a second line agent to etomidate for a hemodynamically unstable patient, such as a patient with sepsis or multiple traumas. Although ketamine generally supports blood pressure, the rate of peri-intubation hypotension may be higher than etomidate.[31,32] However, all sedative induction agents, including ketamine, can provoke further hypotension or cardiovascular collapse in patients with profound refractory shock or those with depressed myocardial contractility and catecholamine depletion. In these settings, dosages are reduced to 50% of the usual dose. Close monitoring for respiratory compromise is necessary when using ketamine as a procedural sedative to facilitate oxygenation (see DSI earlier) as reports of unanticipated apnea have emerged.[27] In patients with status asthmaticus, ketamine may be preferred as an induction agent given its bronchodilatory effects, although no outcome studies have clearly demonstrated its superiority.

Ketamine can also be useful for intermittent administration as part of sedation for mechanical ventilation in patients with severe asthma.

Controversy exists regarding the use of ketamine in patients with elevated ICP because it may increase the cerebral metabolic rate, ICP, and CBF. The evidence that ketamine can produce harm in this way is conflicting and may be outweighed in trauma patients because of its overall favorable hemodynamic profile. Ketamine does not appear to increase the likelihood of an adverse outcome compared with other induction agents in patients with elevated ICP.[33] Ketamine also does not appear to be harmful in children when given in procedural doses to patients with known elevated ICP and may actually lower ICP.

Because it may cause release of catecholamines and increase blood pressure, ketamine should be avoided in traumatic brain injury (TBI) patients with elevated blood pressure. However, we recommend the use of ketamine or etomidate during RSI for induction of patients with TBI and hypotension or risk factors for hypotension. Ketamine may produce unpleasant emergence phenomena, especially disturbing or frightening dreams in the first 3 hours after awakening. These reactions, which are more prominent in adults than in children, in women than in men, in patients receiving larger doses, and in certain personality types, may be mitigated by benzodiazepine administration. Patients who undergo RSI with ketamine should receive a benzodiazepine (e.g., lorazepam, 0.05 mg/kg, or midazolam, 0.1 mg/kg) as part of postintubation management.

Propofol. Propofol is a highly lipophilic alkylphenol with γ-aminobutyric acid (GABA) receptor stimulation activity. Its primary use in the emergency setting has been for postintubation sedation in head-injured patients; however, it increasingly has been used as an induction agent during RSI.[1] It reduces ICP and cerebral oxygen use and is indicated for patients with elevated ICP caused by a medical or traumatic emergency. Because of the propensity of propofol to cause hypotension through vasodilation and direct myocardial depression, the dosage is reduced, or the drug is avoided altogether, in hemodynamically compromised patients. The usual induction dose of propofol is 1.5 mg/kg IV, but reduced dosages should be used in older patients or those with hemodynamic compromise or poor cardiovascular reserve. Propofol is delivered in a soybean oil and lecithin vehicle and should not be used for patients with allergies to these substances. Although propofol has traditionally been avoided in patients with egg allergy, it is likely safe unless a history of anaphylaxis to egg protein exists. Propofol causes pain at the site of administration in as many as 60% of patients. Using a proximal (antecubital) vein in lieu of a distal venous injection site is the most important preventive measure. Pretreatment with IV lidocaine, coadministration of lidocaine mixed with propofol, and pretreatment with opioids or ketamine can limit this common adverse reaction.

Other induction agents. Given the widespread acceptance and familiarity with etomidate, propofol, and ketamine, other drug classes such as barbiturates and benzodiazepines are infrequently used as induction agents for RSI. In North America, nearly all emergency intubations are performed with one of those three agents.[1] Of the benzodiazepines, only midazolam is used as an induction agent. Notably, it is inferior to other, more commonly used agents, such as etomidate and propofol. The usual induction dose for midazolam is 0.2 to 0.3 mg/kg IV. At a dose of 0.3 mg/kg IV, midazolam produces loss of consciousness in approximately 30 seconds (but may take up to 120 seconds) and has a clinical duration of 15 to 20 minutes. Midazolam is a negative inotrope and should be used with caution in hemodynamically compromised and older patients, for whom the dose can be reduced to 0.1 or 0.05 mg/kg. Onset is slower at these reduced doses.

Dexmedetomidine (Precedex) has gained popularity as a solo agent, or in combination with benzodiazepines, for procedural sedation and awake intubation but is not used for induction during RSI given its slow loading rate. The typical loading dose is 1 mg/kg IV over 5 to 10 minutes. At therapeutic levels, it has a minimal effect on the respiratory drive or protective airway reflexes, but its use is limited by bradycardia and hypotension.

Special Clinical Circumstances

This section will discuss several specific clinical scenarios that often warrant modification of the airway management plan. Pediatric airway management is discussed in Chapter 156.

Status Asthmaticus

RSI is the recommended technique for intubation of a patient in status asthmaticus. Difficult airway considerations are complex in an asthmatic patient because of impending respiratory arrest and the patient's inability to tolerate attempts at awake intubation. When a difficult airway is identified, intubation preparation should begin early, so that awake methods, such as flexible endoscopic intubation, may be retained as options. We recommend, when possible, to preoxygenate with BiPAP because the reductions in work of breathing may improve

respiratory dynamics and oxygenation and stave off, temporarily, a precipitous respiratory arrest. Anxiety and air hunger in asthmatic patients may make them resistant to having any mask placed—continuous reassurance, encouragement, and coaching may help. However, even when a difficult airway is identified in an asthmatic patient, RSI usually is the intubation method of choice. Ventilation with a BMV or EGD may be difficult because of high airway resistance, and the technique should be optimized with the use of a low tidal volume and respiratory rate, with a high inspiratory flow rate. Appropriate use of IV epinephrine, often a continuous epinephrine drip, and long-term neuromuscular blockade, may be required to permit adequate ventilation. Reducing the respiratory rate to allow for adequate exhalation, even at the expense of retaining CO_2, is recommended to prevent the development of auto-PEEP (positive end-expiratory pressure), known as breath stacking, which can compromise ventilation and cause barotrauma.

The asthmatic patient has highly reactive airways, and steps should be taken to minimize any additional bronchospasm that may occur during intubation. The bronchoconstriction that occurs with ETT placement is thought to be neurally mediated, and local anesthetics, particularly lidocaine, have been studied as a way to blunt this airway reflex. There have been no high-level human studies supporting its use during RSI, and we do not recommend use of lidocaine for this purpose. High-dose, inhaled β-agonists, such as albuterol, provide maximal protection against reactive bronchospasm during intubation and are indicated for asthmatics with or without active bronchospasm. Ketamine has bronchodilatory properties and may mitigate bronchospasm in patients who are not intubated and in patients who are already intubated and are not improving with mechanical ventilation. Although studies to date have been limited, ketamine is also a reasonable induction agent for the emergency intubation of patients with status asthmaticus (Table 1.3).

TABLE 1.3 Rapid Sequence Intubation for Status Asthmaticus.

Time	Step
Zero minus 10 min	Preparation
Zero minus 5 min	Preoxygenation (as possible) • Continuous albuterol nebulizer • 100% oxygen at flush rate by NRB mask or BiPAP for 3 min.
Zero minus 3 min	Preintubation optimization—albuterol, 2.5 mg nebulized, IV epinephrine or subcutaneous terbutaline
Zero	Paralysis with induction • Ketamine, 1.5 mg/kg • Succinylcholine, 1.5 mg/kg
Zero plus 30 s	Positioning
Zero plus 45 s	Placement • Laryngoscopy with intubation • End-tidal carbon dioxide confirmation
Zero plus 2 min	Postintubation management • Sedation and analgesia • NMBA only if required after adequate sedation, analgesia • In-line albuterol nebulization, terbutaline, epinephrine, magnesium • Additional ketamine as indicated

BiPAP, Bilevel positive airway pressure; *IV,* intravenous; *NMBA,* neuromuscular blocking agent; *NRB,* non-rebreather.

Hemodynamic Consequences of Intubation

Laryngoscopy and intubation are potent stimuli for the reflex release of catecholamines. This reflex sympathetic response to laryngoscopy (RSRL) produces a modest increase in blood pressure and heart rate and is of little or no consequence in otherwise healthy patients. The RSRL is of potential clinical significance in two settings, acute elevation of ICP and certain hypertensive cardiovascular emergencies (e.g., intracerebral hemorrhage, subarachnoid hemorrhage, aortic dissection or aneurysm, ischemic heart disease). In these settings, the reflexive release of catecholamines, increased myocardial oxygen demand, and attendant rise in MAP and heart rate may produce deleterious effects. The synthetic opioids (e.g., fentanyl) and β-adrenergic blocking agents (e.g., esmolol) are capable of blunting the RSRL and stabilizing heart rate and blood pressure during intubation. In patients at-risk from acute blood pressure elevation, administration of fentanyl (3 μg/kg) during the preintubation optimization phase of RSI attenuates the heart rate and blood pressure increase. The full sympatholytic dose of fentanyl is much higher, but limiting the dose minimizes the likelihood of precipitating or worsening hypoventilation. Because fentanyl reduces sympathetic tone, it should not be given to patients with hemodynamic compromise (e.g., bleeding, volume depletion, sepsis). The administration of 3 μg/kg is safer than larger doses and can be supplemented with an additional 3 μg/kg immediately after intubation if greater sympathetic blockade is desired or hypertension and tachycardia persist. Fentanyl should be given over 60 seconds and the patient observed for hypoventilation or apnea.

Elevated Intracranial Pressure

When the ICP is elevated as a result of head injury or acute intracranial catastrophe, there are two considerations—maintaining CPP (by avoiding excessive hypotension) and minimizing supranormal surges in the MAP, which can increase ICP. Normally, cerebrovascular autoregulation maintains a constant CBF over a wide range of systemic blood pressures, but this action may be lost in conditions that elevate ICP. Maintenance of the systemic MAP at 100 mm Hg or higher supports CPP and reduces the likelihood of secondary injury. Therefore the RSI induction agent for a patient with suspected elevated ICP should be selected and dosed to minimize the likelihood of exacerbation of hypotension. In patients with suspected or documented elevation of ICP, control of RSRL is desirable to avoid further elevation of ICP. Fentanyl (3 μg/kg) given as a pretreatment drug is the best choice for this purpose in the emergency setting.

In emergency patients who may have elevated ICP, the emergency clinician should choose an induction agent that balances a favorable effect on cerebral dynamics and ICP with a stable systemic hemodynamic profile. We recommend etomidate, although propofol is also a good option when there is no hemodynamic compromise (Table 1.4).

Hypotension and Shock

In critically ill and injured patients, induction agents have the potential to exaggerate preexisting hypotension and, in some cases, precipitate circulatory collapse. Peri-intubation cardiac arrest, typically pulseless electrical activity (PEA), complicates up to 4% of emergency RSIs and is more likely in elderly patients with preexisting cardiac disease and those who present with an elevated shock index (>0.8). In patients with profound shock, all induction agents have the potential to exacerbate hypotension. Shock-sensitive RSI hinges on three primary optimization principles—volume resuscitation with isotonic fluid or blood prior to induction (if time permits), reduced dose of a hemodynamically stable induction agent, and titration of peri-intubation pressor agents (Table 1.5).

TABLE 1.4 Rapid Sequence Intubation for Elevated Intracranial Pressure.

Time	Step
Zero minus 10 min	Preparation
Zero minus 5 min	Preoxygenation (as possible)—100% oxygen for 3 min or eight vital capacity breaths
Zero minus 3 min	Preintubation optimization—fentanyl, 3 mcg/kg (slowly)
Zero	Paralysis with induction • Etomidate, 0.3 mg/kg or Propofol 1.5 mg/kg • Succinylcholine, 1.5 mg/kg[a]
Zero plus 30 s	Positioning
Zero plus 45 s	Placement • Laryngoscopy with intubation • End-tidal carbon dioxide confirmation
Zero plus 2 min	Postintubation management—sedation and analgesia; consider propofol to permit frequent reexamination NMBA only if required after adequate sedation, analgesia

NMBA, Neuromuscular blocking agent.
[a]May substitute rocuronium, 1 mg/kg, for succinylcholine.

TABLE 1.5 Rapid Sequence Intubation for Hypotension and Shock.

Time	Step
Zero minus 10 min	Preparation—adequate IV access, possibly central venous access with a volume cordis
Zero minus 5 min	Preoxygenation—100% oxygen at flush rate (40–70 L/min) for 3 min by NRB mask
Zero minus 3 min	Preintubation optimization—Blood and isotonic fluid Norepinephrine infusion at 5–10 mcg/min IV (if still hypotensive after IVFs or blood)
Zero	Paralysis with induction • Ketamine, 0.5–0.75 mg/kg OR Etomidate, 0.1–0.15 mg/kg • Succinylcholine, 1.5 mg/kg IV
Zero plus 30 s	Positioning
Zero plus 45 s	Placement • Laryngoscopy with intubation • End-tidal carbon dioxide confirmation
Zero plus 2 min	Postintubation management—continued volume resuscitation, pressor agents as needed

IV, Intravenous; *IVF,* intravenous fluids; *NRB,* non-rebreather.

When time allows, patients with hypotension should receive isotonic fluid boluses or packed red blood cells (PRBCs) to maximize preload, increase blood pressure, and allow more pharmacologic options during RSI. Norepinephrine should be initiated early (5 to 10 mcg/min IV) and titrated quickly upward by reassessing the patient's blood pressure every 3 to 5 minutes and escalating the norepinephrine by 5 mcg/min if the MAP remains at or less than 60 mm Hg. In addition, induction agent selection should be limited to etomidate or ketamine and the dose should be reduced by 50% for patients who do not respond appropriately to volume and pressor agents. Attention to these details can reduce the incidence of cardiovascular peri-intubation adverse events.

Potential Cervical Spine Injury

Historically, most patients with suspected blunt cervical spine injury were intubated orally by DL with in-line cervical spine immobilization, whether done as an awake procedure or with neuromuscular blockade. However, with this approach, glottic views can be inadequate, and excessive lifting force often is required. Patients with known cervical spine fractures are optimally managed with a flexible bronchoscope to minimize cervical spine motion; however, in the emergency setting, a videolaryngoscope should be used and, if not available, a direct laryngoscope also can be used. A videolaryngoscope, especially one with a hyperangulated blade shape (GlideScope or C-MAC d-blade), provides superior laryngeal views without excessive lifting force or cervical spine movement and has higher intubation success rates when compared with conventional DL.

The intubating laryngeal mask airway (I-LMA) also may result in less cervical spine movement during intubation than DL, although the need for blind intubation devices has greatly diminished with the advent of VL.[1] The Airtraq, King Vision, and Pentax Airway Scope are curved intubation devices that integrate an ETT channel and either a viewing lens or a video screen to facilitate intubation. All three devices have shown high levels of intubation success and minimal cervical spine motion compared with DL. A trial of 135 patients with cervical spine immobilization randomized in the operating room to either a standard geometry C-MAC, a C-MAC d-blade, or King Vision revealed that the three devices exhibited clinical equipoise with glottic view. In addition, all had FAS rates greater than 93%, with the traditionally shaped C-MAC having a 100% FAS.[34] In the absence of a coexistent blunt traumatic mechanism or a neurologic examination indicating spinal cord injury, cervical spine immobilization for intubation of patients with penetrating head and neck trauma rarely is indicated. It is not proven whether patients with gunshot or shotgun injuries to the head or neck are at risk of exacerbation of cervical cord injury during intubation, and there is no report of such a patient, with or without clinical evidence of spinal cord injury, who was injured by intubation. In addition, cervical spine immobilization in patients with penetrating neck injuries may be harmful resulting in delayed transport and patient assessment, added difficulty for airway procedure and an increase likelihood of death.

Airway Devices and Techniques

Direct Laryngoscopy Versus Videolaryngoscopy

The inherent limitations of DL make adequate glottic visualization less likely when compared with video instruments. VL offers the ability to visualize the glottis without creating a direct line of sight, thus making irrelevant many of the issues that complicate DL. Although DL remains a valid technique for tracheal intubation, there is mounting evidence of the clear superiority of modern video devices while DL is increasingly relegated to use as a back-up device or when VL is unavailable. The most recent data from the national emergency airway registry, encompassing 2016 to 2018, show that two-thirds of all first attempts in adult patients in participating centers are now performed with a videolaryngoscope.[14,24] This number has nearly doubled since the last multicenter NEAR report.[1]

Videolaryngoscopes

Modern laryngoscopes incorporate video imaging into specially designed laryngoscope blades to provide glottic visualization superior to that of a direct laryngoscope, without the need to create a straight-line visual axis through the mouth. Videolaryngoscopes can be separated into two large groups based on shape—those that use traditional laryngoscope geometry complemented by a video viewing device (which also can be used as direct laryngoscopes), and those with specially curved or angulated blades, designed specifically for use in a video system and not suitable for DL. In ED intubations, regardless of blade shape, VL has been shown to provide superior glottic views, reduce the rate of esophageal intubations, and facilitate greater

first-pass success when compared with direct laryngoscopes.[13,35–37] If a direct laryngoscope is used and glottic visualization is poor, it can be augmented in real time through external laryngeal manipulation, use of a bougie, and changes to patient positioning (ramping). Criticism of the various ED-based VL studies focused on the fact that VL had not been compared with "optimized" DL. However, a subsequent NEAR analysis of more than 11,000 adult ED intubations showed that first attempt intubation success was more likely with VL compared with DL with any combination of optimization maneuvers. The superiority was greatest for VL with hyperangulated blade designs.[13]

In contrast, recent ICU-based studies have not shown as clear a benefit. In one multicenter randomized trial of ICU intubations, there was no difference in FAS comparing DL with a McGrath Mac VL despite significantly better glottic visualization with VL. However, the majority of patients were intubated by rotating internal medicine interns or junior trainees with poorly defined oversight.[38] A meta-analysis of 12 RCTs including both ED and ICU patients also found no difference in FAS between VL and DL.[39] Three studies were prehospital investigations with one assessing a nonvideo device (Airtraq) to DL, and, most importantly, three-quarters of the studies excluded patients with predicted difficult airways, the exact patient population whom VL is most likely to benefit. Therefore design, sampling, and analytic flaws make these findings hard to extrapolate to ED populations. Since ED intubations are by definition emergent and cannot be rescheduled, operator experience varies, and airways are often difficult, VL is currently the predominant device for emergency intubations. We recommend use of a video laryngoscope for all emergency intubations, unless the operator identifies a specific reason not to do so.

The GlideScope videolaryngoscope system (GVL; Verathon, Seattle) uses a modified Macintosh blade with a straightened, angulated, and elongated tip enclosing a proximally placed camera to provide a wide-angle view of the glottis and surrounding anatomy, even in patients with difficult airways. Video images are transmitted to a high-resolution display that can record still pictures and video clips. Handle and blade sizes range from neonate to obese adult. A variety of GVLs have been developed over the years, including the GVL Ranger, an ultraportable version of the device, and the Cobalt, a version with sleeves designed for a single use, without the need for cleaning. The Cobalt consists of a flexible video wand insert that fits inside a disposable, single-piece transparent blade called a stat and comes in sizes and shapes comparable to those for the standard GVL. The newest generation GVL handles are made of lightweight titanium, with a narrower side profile and come in reusable and single-use varieties (Fig. 1.12). The placement of the camera distally along the blade to create a viewing field essentially negates the obstructive potential of the tongue, so GlideScope laryngoscopy and most other hyperangulated VL is performed with the blade introduced in the midline of the mouth and advanced around the tongue, with minimal lifting. A stylet must be used when intubating using a video laryngoscope. A proprietary rigid, preformed stylet is available for use with GVL systems, or a standard, malleable stylet can be shaped to match the exaggerated curve of the GVL blade. The rigid stylet is less likely to deform during intubation attempts and allows the operator better ETT control on the video screen. Either stylet may be used, although the rigid stylet helps to facilitate tube passage by maintaining its shape despite operator manipulation. The Walls method is to use a four-step technique to use the video laryngoscope and the viewing screen in combination to achieve intubation. The four steps are: (1) look in the mouth directly to insert the scope; (2) look at the screen to position the videolaryngoscope to obtain the best glottic view; (3) look in the mouth directly to insert the (stylet loaded) tracheal tube and align it with the blade of the laryngoscope; and (4) look at the screen to maneuver the tube tip through the vocal cords. Retaining "tip control" of the ETT on the video screen improves FAS and should be used whenever a hyperangulated VL is chosen and the tube needs to be manually passed into the trachea. Hyperangulated VL universally improves glottic visualization compared with DL and, consequently, enhances FAS and reduce peri-intubation adverse events. Given the low clearance profile and acute deflection offered by the blade shape, they can be particularly helpful in patients with reduced mouth opening and cervical spine immobilization.

The C-MAC videolaryngoscope (Fig. 1.13; Karl Storz Endoscopy, Tuttlingen, Germany) incorporates a complementary metal oxide semiconductor (CMOS) video chip into a range of laryngoscope blades to enhance glottic views. Images are displayed on a high-resolution monitor, with image- and video-saving capabilities. The traditionally

Fig. 1.12 GlideScope titanium handles incorporate similar video elements in a lightweight titanium blade with a narrower side profile. Connection to the video display is made by a USB-style cord. (Courtesy Verathon, Seattle, WA.)

Fig. 1.13 The C-MAC videolaryngoscope (Karl Storz Endoscopy, Tuttlingen, Germany) uses an integrated complementary metal oxide semiconductor (CMOS) video chip to capture a video image from near the distal tip of an otherwise conventional laryngoscope blade. The image is conveyed to a video screen, where it is viewed by the intubator. (Modified from Brown III CA, Mick NM, Sakles JC, editors. *The Walls Manual of Emergency Airway Management*. 5th ed. Philadelphia: Wolters Kluwer; 2018.)

shaped C-MAC blade can be used as a direct laryngoscope by a trainee while a supervisor observes the video output, providing an excellent tool for teaching DL. A hyperangulated version, the d-blade, is available and both single use and reusable versions are manufactured. The C-MAC has been extensively studied and, like other VLs, improves glottic exposure and FAS. It has also been shown to outperform DL when rescuing a failed first attempt using DL.[1,36] In a single-center analysis of patients with anticipated difficult airways, C-MAC use was associated with a 90% FAS rate with RSI.[10] The C-MAC can also be augmented by use of a bougie. A randomized trial of bougie versus stylet-in-tube during C-MAC intubations of patients with at least one difficult airway characteristic showed that use of a bougie resulted in a FAS of 96% compared with 82% when a stylet-in-tube was used.[40] The results of this single-site study may not be generalizable as the study site operators were highly skilled with bougie-assisted intubations. Nevertheless, the study showed promise for the routine use of a bougie with standard geometry VL for ED intubations. The King Vision videolaryngoscope (King Systems, Noblesville, IN) is a single-use, lightweight device with a detachable (and reusable) screen that sits on top of a disposable video blade (Fig. 1.14). There are two blade types, one with an integrated tube channel and one without; the latter requires the operator to place the ETT manually. A newer version that consists of a flexible video wand covered by a single-use plastic blade is now in use. The McGrath Mac is a cordless videolaryngoscope with an integrated screen and handle configuration. It has a hybrid blade that is more akin to a standard geometry laryngoscope blade.

There are several other models of videolaryngoscopes with various sizes and features, such as disposable sheaths or blades, at various price points. Individual evaluation of these devices is important in selecting the best videolaryngoscope for an individual practitioner or practice group. Overall, VL has transformed laryngoscopy and has the potential to render DL obsolete.

Flexible Intubating Scopes

Intubation using a flexible endoscope is an important option for certain difficult airways, particularly in those with distorted upper airway anatomy, such as angioedema or blunt anterior neck trauma. These scopes long relied on fiberoptic technology, but this has largely been supplanted by miniaturized, high-quality video systems in both reusable and single-use versions (Fig. 1.15). After appropriate patient preparation, the endoscope is passed through the vocal cords under continuous visualization, serving as an introducer for an ETT, which is then placed through the glottis. Flexible endoscopic examination also is used for airway assessment to determine whether intubation is needed, such as for patients with smoke inhalation or supraglottitis. Intubation of morbidly obese patients, those with distorted airway anatomy (e.g., penetrating or blunt anterior neck injury), or those with a fixed cervical spine deformity can be achieved with the flexible endoscope with topical anesthesia and judicious sedation, thus preserving the patient's ability to breathe until intubation has been achieved. Flexible scopes also have been used successfully to intubate through a wide array of LMA-type supraglottic airways.

There is a significant learning curve for flexible endoscopic intubation, and proficiency with this device requires training and practice. Fortunately, endoscopic examination of the upper airway to the level of the vocal cords is a similar skill set as that needed to maneuver the scope through the cords to intubate. This is an important alternative method to obtain real-life experience with insertion and manipulation of the scope. Approximately 1% of ED patients are managed with a flexible bronchoscope, possibly reflecting reluctance to select this instrument if the operator does not feel sufficiently trained or competent. The most common indications for flexible bronchoscopic intubation are airway obstruction and angioedema. In the hands of emergency physicians, first-attempt and ultimate intubation success are approximately 50% and 75%, respectively.[1,41] The role of flexible endoscopic intubation in the ED will likely expand as obesity increases in the population and, increasingly, difficult airways are handled in the ED without backup. The transition from

Fig. 1.14 King Vision videolaryngoscope integrates a single-use, curved video blade attached to a top-mounted display. The blades come in two versions, those with endotracheal tube channels, for advancing the endotracheal tube, and those without. (Courtesy Calvin A. Brown III, MD.)

Fig. 1.15 New video flexible bronchoscopes are now available and integrate fully with the C-MAC high-resolution display. (Courtesy Karl Storz Endoscopy, Tuttlingen, Germany.)

fiberoptic to video technology will make these flexible scopes more durable and less prone to fogging, both desirable attributes for emergency intubation. Although the cost required to purchase and maintain a flexible endoscope can make it challenging for some EDs, single-use flexible videoscopes, such as the Ambu aScope (Ambu, Columbia, MD) and the Karl Storz (Tuttlingen, Germany) FIVE-S (Flexible Intubation Video Endoscope), provide less costly options (Figs. 1.16 and 1.17). Emergency clinicians should have immediate access to flexible endoscopes and should acquire training and regular practice in their use.

Extraglottic Devices

Laryngeal mask airways. LMAs collectively include a number of commercially available ovoid, silicone mask devices designed to seal above the glottis and permit ventilation through a central channel with a standard bag. They are used as a primary airway device in elective surgery cases and rarely during difficult airway management in the operating room.[42] There are several models available, and attributes differ among the models, but use and success rates are very similar. The historical standard is the original LMA. Although it is not often used in the ED, all modern LMA-type devices derive from this common ancestor. Reusable and single-use configurations, conventional and intubating formats, are offered by several manufacturers. Most modern LMA-type devices are "second generation" that offer more robust leak pressures through use of thicker plastic material. In addition, they integrate an orogastric tube channel for stomach decompression after being placed. The mask is inserted blindly into the pharynx and then inflated, providing a seal that permits ventilation of the trachea with minimal gastric insufflation. In elective anesthesia, the LMA has an extremely high insertion success rate and low complication rate, including a low incidence of tracheal aspiration. Evaluations of LMA insertion by experienced and inexperienced personnel consistently have shown ease of insertion, high insertion success rates, and successful ventilation. The LMA may be a viable alternative to endotracheal intubation for in-hospital or out-of-hospital treatment of cardiac arrest, particularly when responders are inexperienced airway managers. At a minimum, the device can serve a temporizing role when BMV is difficult or prolonged ventilation is anticipated. In general, all LMAs are safe to be left in place for up to 4 hours without the risk of mucosal injury. They also serve a prominent role as conduits to facilitate either blind or flexible bronchoscopic intubations. The LMA Supreme (Teleflex Inc., Morrisville, NC) is a more robust LMA with a rigid angled tube, similar to an I-LMA; as a second generation LMA, it offers an orogastric tube channel and higher seal pressures than the standard LMA. This is likely the best version for general ED use.

A noninflatable LMA, the i-Gel (Intersurgical, Berkshire, England), has a viscous gel cuff and does not require inflation (Fig. 1.18). Once in place, the warmth and humidity of the hypopharynx allows the gelatinous material to become more fluid and conform to the recesses over the glottis, creating a trapped gas space for oxygenation and ventilation. It is available in a variety of sizes for adult, pediatric, and neonatal patients. The device is placed blindly, and insertion depths are marked

Fig. 1.16 The Ambu aScope is a new, fully disposable video flexible bronchoscope with an integrated suction port and working channel for suctioning and instillation of local anesthetic. Airway images are viewed via a reusable digital display. (Courtesy Calvin A. Brown III, MD.)

Fig. 1.17 The i-gel mask airway (Intersurgical, Berkshire, England) does not have an inflatable cuff and is available in sizes from infant to adult. (Courtesy Dr. Calvin A. Brown, III, MD.)

Fig. 1.18 The intubating laryngeal mask airway is modified to facilitate insertion of an endotracheal tube after placement and ventilation have been achieved. The epiglottic elevator *(arrowhead)* lifts the epiglottis to allow passage of the special endotracheal tube *(arrow)*.

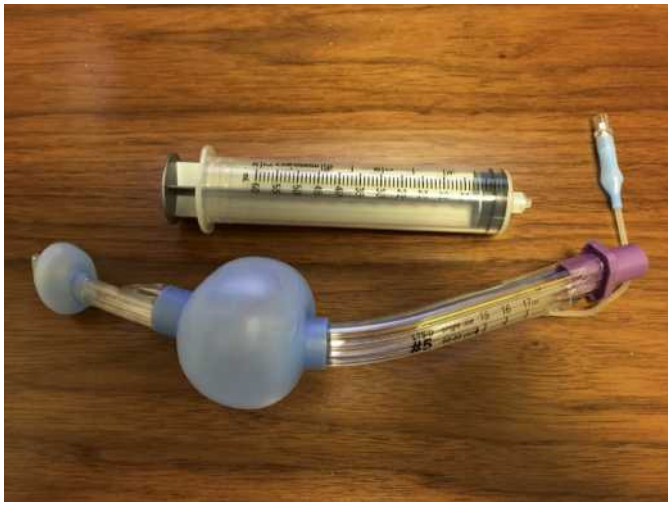

Fig. 1.19 King laryngeal tube incorporates two cuffs but inflates with a single bolus of air. There is a channel in the back for passage of an orogastric tube. It is available in a variety of adult and pediatric sizes.

on the side of the device. It has an integrated bite block and channel for passage of an orogastric tube. Initial experience with the device, even with minimally trained novice users, has been promising, with high insertion success rates and shorter insertion times when compared with the LMA or laryngeal tube airway. They also serve as functional conduits for flexible endoscopic intubation.[43]

The Fastrach LMA or I-LMA is designed to facilitate blind intubation through the mask after correct placement (Fig. 1.19). It differs from the LMA in two main ways. First, the mask is attached to a rigid, stainless steel ventilation tube curved almost to a right angle, and the mask incorporates an epiglottic elevator at its distal end. Placement of the I-LMA results in successful ventilation in almost 100% of cases and successful subsequent blind intubation in approximately 75% to 80% of cases. The I-LMA can also be used for ventilation and intubation in obese patients, with similarly high success rates. The I-LMA has a special ETT and stabilizer rod to remove the mask over the ETT after intubation has been accomplished.

The I-LMA is a better device than the standard LMA for use in the ED because it facilitates rescue ventilation and intubation. When the I-LMA is placed, intubation can be performed blindly or guided by a flexible bronchoscope. The I-LMA comes only in sizes 3, 4, and 5 and so is not suitable for use in patients weighing less than approximately 30 kg (66 lb). For smaller patients, the standard LMA, which has sizes down to size 1 (infant), should be used. Intubation can be achieved through the standard LMA, but the success rate is significantly less than with the I-LMA. Newer LMA-style devices, the Ambu air-Q and Aura-I, can act as standard LMAs for ventilation and oxygenation but can facilitate blind intubation with standard adult ETTs. Both work well intubating a difficult airway, especially when augmented by flexible endoscopy.[44]

In the ED, the primary use of the LMA or I-LMA is as a rescue technique to provide a temporary airway when intubation has failed, BVM ventilation is satisfactory, and the patient has been paralyzed and may require prolonged ventilation. In the "can't intubate, can't ventilate" situation, cricothyrotomy is indicated, but an ILMA may be placed rapidly in an attempt to achieve ventilation (converting the situation to "can't intubate, can ventilate"), as long as this is done in parallel with preparations for cricothyrotomy and does not delay initiation of a surgical airway. Patients may arrive from the field with an EGD in place. The primary technique for managing a prehospital EGD is to first decompress the stomach, deflate the device, remove the EGD, and reintubate using VL.[45]

Other extraglottic devices. In addition to LMAs, which sit above the glottis, there are other types of EGDs that travel behind the laryngeal inlet with the distal tip of the device sitting in the cervical esophagus. These are inserted blindly to provide oxygenation and ventilation through side ports while inflatable balloons occlude the pharynx above and the esophageal inlet below. Because of their positioning behind the larynx, these often are called retroglottic devices. The prototype for these devices was the esophagotracheal Combitube. These are rarely, if ever, used and will not be discussed further.

The King laryngeal tube airway (King LT; King Systems) has a single port through which distal and proximal low-pressure balloons are inflated as a single step (see Fig. 1.19). The distal balloon, when seated correctly, obstructs the cervical esophagus, and the larger proximal balloon obstructs the hypopharynx, preventing regurgitation of air. A newer version of the King LT has a posterior channel that accepts a nasogastric tube, which can be passed through the device into the stomach for aspiration of gastric contents. The King LT is disposable, rapidly placed, easy to use by operators of various skill levels and has seal pressures similar to those of standard LMAs. As mentioned, all EGDs can be safely left in place for 4 hours without mucosal pressure damage. All retroglottic devices are primarily a substitute for endotracheal intubation for non–ETT-trained personnel but are also used by advanced airway managers as a way to oxygenate and ventilate patients during crash and failed airway scenarios. These devices should be considered temporary measures, do not protect against aspiration, and should be exchanged for a definitive airway as soon as possible.

Surgical Airway Management

Needle Cricothyrotomy with Transtracheal Jet Ventilation

With the advent of newer airway devices, especially videolaryngoscopes, surgical airway management, which always has been distinctly uncommon, is required even less frequently.[1] Needle cricothyrotomy, which involves the insertion of a large needle (ideally, a large catheter designed for this purpose) through the cricothyroid membrane into the airway for transtracheal ventilation, may have a limited role in pediatric airway management (see Chapter 156). It is rarely, if ever, the right choice for an adult airway emergency and will not be discussed further here.

Cricothyrotomy

Cricothyrotomy is the creation of an opening in the cricothyroid membrane through which a 6-mm internal diameter ETT, is inserted to permit ventilation. The techniques and variations thereof have been well described elsewhere.[46] When surgical airway management is required, cricothyrotomy is the procedure of choice in the emergency setting, where it is faster, more straightforward, and more likely to be successful than tracheotomy.

Cricothyrotomy is indicated when oral or nasal intubation is impossible or fails and when BMV or EGD cannot maintain adequate oxygen saturation (the can't intubate, can't ventilate situation). ED-based intubation surveillance has suggested that the rate of salvage cricothyrotomy—a surgical airway performed after another technique was attempted first—has dropped and is now approximately 0.3%.[1] Cricothyrotomy is relatively contraindicated by distorted neck anatomy, preexisting infection in the neck, and coagulopathy; however, these contraindications are relative, and establishment of the airway takes precedence over all other considerations. The procedure should be avoided in infants and young children, in whom anatomic limitations make it exceedingly difficult. Studies have suggested that approximately five practice cricothyrotomies on a simulator or animal model are sufficient to achieve at least baseline capability with the procedure, although training intervals for skill maintenance have not been well defined.

The recommended technique for emergency cricothyrotomy is the knife-bougie-scalpel technique. It is simple to perform, requires only a few pieces of readily available equipment, and has been shown to be faster and more successful than other techniques. This approach is

supported by the latest recommendations from the Difficult Airway Society's guidelines on management of the failed airway.[47] After landmark identification, a vertical skin incision is followed by a horizontal incision into the cricothyroid membrane. A bougie is then placed through the opening followed immediately by a 6-0 ETT over the bougie. Percutaneous, needle-guided, or Seldinger technique cricothyrotomies are more likely to result in paratracheal tube placement, especially in patients with indistinct landmarks, and are no longer recommended.

OUTCOMES

The NEAR classification system characterizes potentially adverse occurrences during intubation as adverse events. In the NEAR study, the overall rate of adverse events was 12%, with recognized esophageal or mainstem intubation and hypotension being the most common.[1] Phase III of the NEAR project has reported on more than 17,500 adult ED intubations over an 11-year period (2002 to 2012).[1] The latest data from this multicenter registry have revealed the majority of intubations are now performed with VL with an overall FAS of 91%.[13] Emergency clinicians continue to manage 95% of all patients, and more than 99% were successfully intubated within three attempts. Peri-intubation adverse event rates are between 11% and 12% and are similar regardless of laryngoscope type; however, esophageal intubation is significantly less likely when VL is used. Hypoxia, recognized esophageal intubation, and hypotension are most common. The incidence of cricothyrotomy continues to drop with the rate of rescue cricothyrotomy currently at 0.3%.

CHAPTER 1: QUESTIONS AND ANSWERS

1. Which of the following is considered unreliable for assessing the need to establish an artificial airway?
- **a.** Absence of a gag reflex
- **b.** Absence of swallowing on command
- **c.** Level of consciousness
- **d.** Patient's ability to phonate
- **e.** Pooling of secretions in the oropharynx

Answer: a. The gag reflex can be absent in up to 25% of normal adults. Moreover, there is no evidence that the presence or absence of a gag reflex corresponds to a patient's ability to protect his or her airway. Therefore it should not be used as an indicator of the need for intubation.

2. Which of the following is the most reliable overall method for confirmation of correct tube placement after endotracheal intubation?
- **a.** Chest and gastric auscultation
- **b.** Chest radiography
- **c.** Detection of colorimetric or quantitative end-tidal carbon dioxide ($ETCO_2$)
- **d.** Measurement of exhaled volume

Answer: c. Detection of $ETCO_2$ after endotracheal intubation is the most reliable of the options listed for the confirmation of tube placement. (A fiberoptic scope passed through the endotracheal tube, with visualization of the tracheal rings, is the gold standard but is not generally required.) Limitations of colorimetric CO_2 detection should be appreciated in cardiac arrest patients. In these situations, a bulb aspiration device may provide helpful information, even though this technique is generally not as reliable as $ETCO_2$ detectors. The other listed options, traditional as they may be, are prone to failure and should not be relied on for confirmation of tube placement.

3. During rapid sequence intubation (RSI) of a hypotensive blunt abdominal trauma patient, which of the following will mitigate the risk of circulatory collapse during emergency airway management if performed before medications are administered?
- **a.** Central venous access
- **b.** Choosing propofol instead of ketamine for induction
- **c.** Resuscitating with packed red cells
- **d.** Obtaining an abdominal computed tomography (CT) scan to better characterize the degree of bleeding

Answer: c. Before induction and paralysis, the preintubation optimization step of RSI suggests that volume resuscitation with either isotonic fluids or blood in a hemodynamically unstable patient should be performed, if time allows, to reduce the chance of cardiac arrest during or immediately after intubation.

4. In which of the following conditions is succinylcholine contraindicated?
- **a.** Acute burn <5 days
- **b.** Acute head injury secondary to motor vehicle accident
- **c.** Acute spinal cord injury <5 days
- **d.** Renal failure with a serum potassium level of 4.7 mEq/L
- **e.** Multiple sclerosis

Answer: e. Succinylcholine has been associated with severe fatal hyperkalemia when administered in specific clinical circumstances. The risk of succinylcholine-induced hyperkalemia in patients with denervation syndromes begins with the onset of disease and continues indefinitely. With respect to acute burns, trauma, stroke, spinal cord injury, and intra-abdominal sepsis, the risk of hyperkalemia with succinylcholine use becomes evident 5 days after the onset of injury or disease process. Succinylcholine is not contraindicated in renal failure; however, known elevations in the potassium level may warrant use of another neuromuscular blocking agent.

5. Which of the following provides the highest ETO_2 after 3 minutes of ambient pressure tidal volume breathing?
- **a.** Nonrebreather mask with oxygen flow at 15 L/min
- **b** High-flow nasal cannula
- **c.** Nonrebreather facemask at flush rate oxygen (40 to 90 L/min)
- **d.** Venturi mask

Answer: c. Flush flow rate oxygen using a nonrebreather mask provides an ETO_2 of 85%. This is in comparison with an ETO_2 level in the mid-50s with a nonrebreather mask at 15 L/min flow. The increased inflow rate outcompetes room air entrainment around the margin of the mask and increases the fraction of inspired oxygen (FiO_2) resulting in better nitrogen washout.

6. Until how long after an acute burn is succinylcholine considered safe to use for RSI?
- **a.** 30 minutes
- **b.** 12 hours
- **c.** 24 hours
- **d.** 48 hours
- **e.** 5 days

Answer: e. Succinylcholine can produce severe (and fatal) elevations in serum potassium levels after administration in patients with burns. However, this vulnerability to succinylcholine-induced hyperkalemia is not clinically significant until at least 5 days after the acute burn. As a result, succinylcholine remains the paralytic of choice if rapid sequence intubation occurs less than 5 days after the burn.

2

Mechanical Ventilation and Noninvasive Ventilatory Support

Todd A. Seigel and Nicholas J. Johnson

KEY CONCEPTS

- Noninvasive positive-pressure ventilation (NPPV) is often adequate for reversal of impending respiratory failure due to a rapidly reversible cause, and should be considered as the first-line therapy for patients with exacerbations of chronic obstructive pulmonary disease (COPD) and acute cardiogenic pulmonary edema (ACPE) in whom immediate intubation is not required.
- NPPV should generally be avoided for definitive management of patients with pneumonia or acute respiratory distress syndrome (ARDS) unless the patient is clearly improving or has a do-not-intubate status. Otherwise, endotracheal intubation and mechanical ventilation are preferred.
- For patients in need of ventilatory support, bilevel positive airway pressure (BiPAP) and continuous positive airway pressure (CPAP) have clinical equipoise. BiPAP should begin with an inspiratory pressure setting of 10 cm of H_2O and expiratory pressure of 5 cm of H_2O and be evaluated frequently for tolerance and need to titrate up or down.
- Pressure-controlled ventilation (PC) delivers breaths at a predetermined pressure but with variable volume, while volume-controlled ventilation (VC) delivers a predetermined inspiratory volume but variable pressures.
- Assist-control ventilation (A/C) delivers a required number and volume of breaths per minute while synchronized intermittent-mandatory ventilation (SIMV) synchronizes mandatory breaths with spontaneous breaths. Either mode can be PC or VC.
- Invasive mechanical ventilation requires dynamic, ongoing monitoring. After intubation, blood gas analysis should be performed to confirm appropriate ventilation and provide correlation with noninvasive monitoring of oxyhemoglobin saturation and end-tidal CO_2.
- Positive pressure can have adverse hemodynamic consequences.
- Plateau pressure should be maintained below 30 cm H_2O.
- Elevation in ventilation pressures suggests ventilator circuit obstruction, bronchospasm, mainstem intubation, tension pneumothorax or hemothorax, decreased chest wall compliance or increased chest wall rigidity.
- Inappropriately low ventilation pressures, particularly in conjunction with hypoxia, indicates ventilator circuit leak or a faulty connection, endotracheal tube cuff leak, accidental extubation, or esophageal intubation.
- The Richmond Agitation Sedation Score (RASS) or a similar scoring system should be used to manage sedation and analgesia of the mechanically ventilated patient. Avoid unnecessary use of prolonged neuromuscular blockade. When RASS is used, a target score of –2 to 0 avoids both over and under sedation.

FOUNDATIONS

Invasive and noninvasive ventilation are often essential components of a successful resuscitation in critically ill patients. Some patients require support for respiratory failure or as part of comprehensive management of critical illness, whereas other patients require assistance primarily for airway protection. The reasons for initiating ventilatory support are varied and will influence ventilation strategy, hemodynamics, sedation strategy, and subsequent clinical course.

The decision to intubate is discussed in Chapter 1 and in other chapters throughout this text in the context of individual conditions. This chapter describes the modalities and techniques of noninvasive and invasive mechanical ventilation.

Physiology of Positive-Pressure Breathing

A typical respiratory cycle in spontaneously breathing patients begins with negative intrathoracic pressure created by contraction and relaxation of the diaphragm in concert with the intercostal muscles. This elevates the lateral ribs in a bucket-handle fashion, increasing the intrathoracic volume and resulting in a pressure gradient between intra- and extra-thoracic airspaces and net airflow into the lungs. Relaxation of the diaphragm and recoil of the chest wall decreases intrathoracic volume, increases pressure in the chest cavity, and results in passive exhalation. The amount of force required to generate adequate inspiration is influenced by the work of breathing. When the work of breathing increases, patients may be unable to generate enough negative force to sustain successful respiration and require ventilatory support.

Unlike spontaneous breathing, invasive and noninvasive mechanical ventilation are based on the delivery of humidified air with positive pressure. The amount of positive pressure required for adequate ventilation is dependent on the patient's respiratory effort, ranging from mild assistance to full support. Inhalation occurs by driving air into the lungs under positive pressure; air is passively exhaled when the chest wall recoils.

Transition from negative-pressure breathing to positive-pressure breathing affects cardiovascular and pulmonary physiology and can have significant clinical consequences. Pressure changes in the thoracic cavity directly affect pressures in the chambers of the heart. During spontaneous inspiration, decreased intrathoracic pressure augments venous return and preload. Cardiac output is increased, and there is an increased pressure gradient between the left ventricle and aorta. With the initiation of positive-pressure ventilation (PPV), the opposite occurs: venous return is diminished, cardiac output falls, and there is a decreased pressure gradient between the left ventricle and aorta. Hypotension can occur after ventilatory support has been initiated and may be exaggerated in patients with clinical hypovolemia or vasodilatory states.

Invasive Mechanical Ventilation: Control Variable and Ventilator Mode

The primary considerations when initiating mechanical ventilation relate to how gas is delivered to the lungs. This includes the volume,

duration, and frequency of each breath, and the degree of interaction the patient has with the ventilator.

How the ventilator delivers gas to the lungs is referred to as the *control variable*. The amount of air delivered in each breath is either set directly as a specific volume or indirectly as a specific amount of pressure. These are referred to as volume-controlled ventilation (VC) and pressure-controlled ventilation (PC), respectively. The amount of time over which the breath is delivered is defined as the inspiratory time, and the speed at which air travels through the circuit is defined as inspiratory flow rate. The term "cycle" refers to how the ventilator terminates delivery of a breath.

With VC, a breath is defined by delivery of a set tidal volume to the lungs. Inspiratory volume and flow rate are set by the clinician, and the ventilator cycles once a preset tidal volume has been delivered. The inspiratory time is a function of the set flow rate. Lung pressures—peak inspiratory pressures (PIPs) and end-inspiratory alveolar pressures—vary based on respiratory system resistance and compliance, as well as set tidal volume. The main benefit to the use of VC is the ability to control tidal volume and minute ventilation, but in scenarios of impaired respiratory system compliance, delivery of desired tidal volume may result in dangerously high airway pressures and barotrauma.

In PC, a set amount of pressure is applied to the airway to expand the lungs for a specified amount of time. During PC, the inspiratory pressure is set by the clinician, whereas the delivered tidal volume and inspiratory flow rate vary as functions of dynamic lung compliance and airway resistance. An inspiratory time is also set, after which the ventilator cycles by terminating delivery of the set inspiratory pressure. Ability to control the pressure delivered to the lungs is particularly useful to prevent barotrauma, which is described in more detail below. In addition, because inspiratory flow is not fixed, PC may improve ventilator synchrony in intubated patients with a high respiratory drive. A significant disadvantage of PC is that tidal volume can neither be guaranteed nor limited as it changes with acute changes in lung compliance.

The choice between volume-controlled ventilation and pressure-controlled ventilation is driven by the underlying physiology of the condition for which mechanical ventilation is needed, and for patients who do not require strict control of pressure or volume, safe and effective ventilation can be achieved with either strategy (Table 2.1). Volume-controlled ventilation should be used when strict control of tidal volume is mandated. Specifically, this includes patients with known acute respiratory distress syndrome (ARDS), in whom low tidal volume strategies have been proven to reduce mortality. In addition, patients with markedly decreased chest wall compliance should be placed on VC to ensure that adequate tidal volume is delivered. This includes patients with morbid obesity or severe chest wall burns. Conversely, PC offers advantages over VC in clinical conditions in which control of airway pressure is strictly mandated. This includes patients with the potential to develop dynamic hyperinflation and intrinsic positive end-expiratory pressure (PEEP) such as those with severe asthma or chronic obstructive pulmonary disease (COPD).

Notably, while both VC and PC can have specific advantages, patients with acute derangements in pulmonary mechanics may be difficult to optimize regardless of the ventilator control variable used. Newer ventilators have attempted to address this dynamic interdependence by delivering breaths that combine volume and pressure strategies, referred to as dual-control ventilation. A common dual-control method of ventilation is pressure-regulated volume control (PRVC). A variation of volume control, PRVC is set to deliver a specific tidal volume while simultaneously minimizing airway pressure. In contrast to strict volume control, pressure is measured and modulated by the ventilator with each breath to ensure the delivery of the preset tidal volume. In addition, a pressure limit is set, and the ventilator sounds an alarm when that pressure has been exceeded. Theoretically, this combines the advantages of pressure and volume control to ensure the delivery of a specific tidal volume while the airway pressure is monitored. That said, because the ventilator is set to deliver a specific tidal volume, the disadvantages of volume-controlled ventilation persist. In addition, elevations in airway pressure are still possible and must be addressed if changes in respiratory system compliance occur. The efficacy of PRVC has not been compared to traditional PC or VC but likely does not offer significant advantage over traditional volume- or pressure-controlled ventilation, particularly if strict parameters for airway pressure are desired.

The term *ventilator mode* refers specifically to the amount of respiratory support provided by the ventilator and how often the ventilator initiates a breath for the patient. These can be divided broadly into assist-control mechanical ventilation (A/C), intermittent mechanical ventilation (IMV), and continuous spontaneous ventilation (CSV). The key difference is that A/C and IMV are intended to provide patients with a specific minimum number of preset breaths as defined by the ventilator and can be delivered via pressure or volume control methods. Conversely, in CSV, no mandatory breaths are delivered to a patient; the size and rate of the breaths are determined by the effort of the patient and are augmented with applied pressure or volume to the airway. These methods are compared in Table 2.2. Other, more complex modes of ventilation include proportional assist ventilation (PAV) and airway pressure release ventilation (APRV), although these are rarely used in the emergency department (ED).

A/C is intended to provide full ventilatory support for patients with little or no spontaneous respiratory activity by continuous delivery of breaths at a preset rate. However, if a patient generates respiratory effort while on A/C, that breath will also be assisted by the ventilator. Patients

TABLE 2.1 Features of Pressure Control Versus Volume Control

	Set Parameters	Variable Parameters	Clinical Implications	Clinical Conditions
Pressure-controlled ventilation (PC)	Pressure target, inspiratory time, RR, PEEP	Tidal volume, inspiratory flow rate	Controls airway pressure, but tidal volume becomes a function of lung compliance (no guaranteed tidal volume or minute ventilation). Allows estimation of end-inspiratory alveolar pressure based on ventilator settings. Variable inspiratory flow helpful for patients with high respiratory drive	Severe asthma, COPD, salicylate toxicity
Volume-controlled ventilation (VC)	Tidal volume, RR, inspiratory flow pattern, inspiratory time	PIP, end-inspiratory alveolar pressure	Guaranteed delivery of tidal volume, but may result in high or injurious lung pressures. End-inspiratory alveolar pressure cannot be reliably estimated and must be measured (plateau pressure)	ARDS, obesity, severe burns

ARDS, Acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease; *PIP,* peak inspiratory pressure; *PEEP,* positive end-expiratory pressure; *RR,* respiratory rate.

can trigger a breath at any rate but will always receive at least the preset number of breaths, hence the nomenclature of "assist-control." This is the most useful initial mode of mechanical ventilation in ED patients, because most patients are initially paralyzed and sedated and do not interact with the ventilator.

In A/C mode, breaths can be volume-controlled (AC/VC) or pressure-controlled (AC/PC) as detailed previously. For the promotion of ventilator synchrony, a spontaneous patient-initiated breath will take priority over a preset breath, meaning that if the ventilator is set to deliver 12 breaths/min, a breath is provided every 5 seconds in the absence of spontaneous inspiratory effort. When the patient makes a spontaneous effort, the ventilator provides an additional breath and the timer resets for another 5 seconds. One of the biggest challenges with A/C ventilation, however, is that patient-initiated breaths are not proportional to patient effort; when inspiratory effort is detected, a full-sized breath is delivered. Clinically, this requires adequate sedation of patients when ventilated in the A/C mode to prevent spontaneous respiratory efforts that will result in hyperventilation, air trapping, hypotension, and poor ventilator synchrony.

Intermittent mandatory ventilation provides intermittent ventilatory support to patients by delivering both mandatory and spontaneous breaths. In this mode, mandatory breaths are given at a preset rate, but the breath is synchronized as much as possible with spontaneous patient effort. For this reason, it is most commonly known as synchronized IMV or SIMV. Similar to A/C, the patient will receive at least the minimum number of preset mandatory breaths; if the patient provides no effort, the preset number of breaths will be given. If a patient has a rate of spontaneous respirations lower than the set rate, the ventilator will provide the preset number of full breaths but will deliver as many as possible in synchrony with patient effort. In these scenarios, there is little difference between A/C and SIMV. If a patient has a higher spontaneous respiratory rate than the preset rate, the patient receives all preset full breaths at the set rate. In contrast to A/C, additional breaths generated by the patient will be volume or pressure-supported breaths commensurate with the patient's respiratory effort. This attenuates the effects of air trapping and hyperventilation potentially seen with A/C and is one advantage of SIMV in less sedated patients.

CSV, in contrast to A/C or SIMV, provides no mandatory breaths and only augments a patient's spontaneous respiratory effort. On a ventilator, the most common way to eliminate mandatory delivery of preset breaths is via pressure-supported ventilation (PSV) and is designed to support patients' spontaneous respiratory effort by delivering an applied pressure to the airway on the trigger of a breath. The amount of pressure required to support a full breath is variable and depends on the patient's ability to overcome the work of breathing. When inspiratory flow slows to a prespecified fraction of maximal inspiratory flow (often 25%), this signals the end of inhalation. At this point, pressure support ceases and exhalation is allowed to proceed spontaneously. The level of pressure support is the only set parameter in PSV; inspiratory flow, inspiratory time, and tidal volume are determined by patient effort. This mode of ventilation most closely resembles normal spontaneous breathing and, for this reason, promotes patient control and comfort. In the ED, PSV is rarely used for intubated patients because most patients who require intubation are unable to breathe spontaneously and effectively and may have failed noninvasive support before intubation. PSV may prove to be most useful in awake and interactive patients who have been intubated for temporary airway protection rather than for respiratory failure. If PSV is used, careful monitoring and ventilatory alarms are needed to ensure against undetected hypoventilation or apnea.

TABLE 2.2 Selecting Ventilator Strategy: Features of Potential Options

Mode	Parameters Set by Clinician	Clinical Scenario
Assist-Control Ventilation		
Assist-control volume control (AC-VC)	Tidal volume, inspiratory flow, PEEP, RR	Paralyzed or deeply sedated patient, sedated patients with intermittent spontaneous respiratory effort. Can lead to hyperventilation
Assist-control pressure control (AC-PC)	Target pressure, inspiratory time, PEEP, RR	
Intermittent Mandatory Ventilation (IMV)		
Synchronized intermittent mandatory ventilation (SIMV)	Pressure or volume control, PEEP, RR (backup rate)	Patients with regular but poor spontaneous respiratory effort; if used in deeply sedated patients, set RR will need to be higher
Continuous Spontaneous Ventilation (CSV)		
Pressure-support ventilation (PSV)	Level of pressure support, PEEP	Spontaneously breathing patients with good respiratory effort requiring minimal ventilatory support
Continuous positive airway pressure (CPAP)	Level of CPAP	Alert, spontaneously breathing patients with immediately reversible causes of respiratory distress; COPD and ACPE are classic indications for noninvasive ventilation
Bi-level positive airway pressure (BL-PAP)	IPAP and EPAP	Similar to CPAP

ACPE, acute cardiogenic pulmonary edema; *COPD,* chronic obstructive pulmonary disease; *EPAP,* expiratory positive airway pressure; *IPAP,* inspiratory positive airway pressure; *PEEP,* positive end-expiratory pressure; *RR,* respiratory rate.

Positive End-Expiratory Pressure

Regardless of the ventilatory mode chosen, PEEP is often used during invasive mechanical ventilation. PEEP refers to the maintenance of positive airway pressure after the completion of passive exhalation. During acute respiratory failure, the application of PEEP increases functional residual capacity (FRC), improves oxygenation, and decreases intrapulmonary shunting by preventing alveolar collapse. The use of PEEP also reduces portions of nonaerated lung that may contribute to the development of ventilator-induced lung injury (VILI). PEEP is most effective in diffuse parenchymal lung disease, such as the ARDS. In focal processes, such as lobar pneumonia, it may simply over-distend well-aerated lung units, resulting in worse ventilation-perfusion matching. Notably, by increasing intrapulmonary and intrathoracic pressures, PEEP can also deleteriously affect pulmonary and cardiovascular physiology by reducing venous return, decreasing cardiac output, and creating lung overdistention or pneumothorax.

Applied PEEP must be specifically differentiated from intrinsic PEEP (iPEEP, or auto-PEEP), which may result from improper assisted ventilation when adequate time is not allowed between breaths for complete exhalation (see below).

Noninvasive Techniques

Noninvasive positive-pressure ventilation (NPPV) is the delivery of CSV via sealed mask rather than endotracheal tube. As with PSV, the ventilator is set to provide a defined level of pressure when a patient

takes a breath; inspiratory flow and inspiratory time are completely patient-mediated. The most common types of noninvasive ventilation in the ED are continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BL-PAP). BiPAP, a term commonly used for BL-PAP, is the proprietary name of a portable device that uses this method of noninvasive ventilation rather than a term for the ventilation itself (Philips Respironics, Murrysville, PA). CPAP provides constant positive pressure throughout the respiratory cycle, whereas BL-PAP alternates between higher pressure during inspiration (IPAP) and lower pressure during expiration (EPAP). Although, strictly speaking, CPAP applies positive pressure to the airway during inspiration, the amount of inspiratory assistance is minimal. Conversely, just as with invasive mechanical ventilation, IPAP augments patient respiratory effort by decreasing the work of breathing during inspiration, whereas EPAP acts as PEEP to maintain FRC and alveolar recruitment. Notably, although PEEP, CPAP, and EPAP all represent positive airway pressure at the end of expiration, PEEP, by convention, refers to pressure applied during invasive mechanical ventilation, whereas CPAP is the application of positive pressure (invasively or noninvasively) during spontaneous breathing. The terms are occasionally used interchangeably.

In addition to NPPV, noninvasive oxygen supplementation can also by achieved with high-flow nasal cannula (HFNC). HFNC and other high-flow oxygen delivery devices are specially designed to use high-pressure oxygen and air, a gas blender, humidifier, and large-diameter tubing to deliver oxygen at flow rates often exceeding 60 L/min. The theoretical benefits are as follows: (1) high flow rates more closely match patients' inspiratory flow and volume demands, so more inspired gas comes from the device than ambient air increasing the fraction of inspired oxygen (Fio_2); (2) the high flow washes out anatomic dead space and replaces it with oxygen; (3) Fio_2 and flow rate can be titrated independently (classically, Fio_2 is titrated for hypoxemia and flow rate for dyspnea); (4) many devices deliver a small amount of PEEP (1 to 3 cm H_2O); (5) gas is humidified and heated, which makes the high flow rate more tolerable; and (6) the large nasal prongs on the cannula devices often occlude the entire nares, reducing entrainment of ambient air during closed-mouth breathing. HFNC supplementation is indicated for acute hypoxemic respiratory failure without significant hypercarbia, and in patients for whom supplementary intrathoracic pressure would not be necessary. HFNC cannot be used in patients without a patent upper airway. Other relative contraindications include depressed mental status, facial injury, inability to manage secretions, or respiratory arrest.

MANAGEMENT

Decision Making: Noninvasive Versus Invasive Ventilation

The decision to intubate carries significant implications for patients, including complications related to invasive airway management, the use of neuromuscular blocking agents (NMBAs), and the risk of prolonged mechanical ventilation in the intensive care unit (ICU). NPPV is an appealing option for patients requiring ventilatory assistance with rapidly reversible conditions or for those with "do-not-intubate" directives. Relative contraindications include decreased level of consciousness, lack of respiratory drive, increased secretions, hemodynamic instability, and conditions such as facial trauma that would prevent an adequate mask seal. Although the need for emergent intubation is generally a contraindication to treatment with noninvasive ventilation, noninvasive ventilation may improve preoxygenation prior to intubation when compared to standard methods of oxygen delivery. If NPPV is initiated, patients should be reassessed frequently for progress of therapy, tolerance of the mode of support, and any signs of clinical deterioration that would indicate a need for intubation.

Patients most likely to respond to NPPV in the ED are those with more readily reversible causes of respiratory distress such as COPD exacerbation or cardiogenic pulmonary edema in which fatigue is a significant factor. Robust evidence has supported the use of NPPV for both conditions. In patients with acute COPD exacerbations, NPPV decreases the need for intubation by 65%, decreases hospital length of stay, and improves mortality with NNT of 12 when compared with standard therapy.[1] Treatment failure, defined as a subsequent need for intubation, is predicted by a Glasgow Coma Scale score of less than 11, sustained arterial pH less than 7.25, and tachypnea greater than 35 breaths/min. Several studies highlighted the need for appropriate patient selection in that a failed trial of NPPV was associated with higher mortality when compared to those who received immediate intubation.

In patients with acute cardiogenic pulmonary edema (ACPE), NPPV reduces the work of breathing while simultaneously improving cardiac output. The application of NPPV causes elevations in intrathoracic pressure that decrease left ventricular (LV) ejection pressure and LV transmural pressure, which results in afterload reduction. In addition, decreases in right ventricle (RV) preload may improve LV compliance via ventricular interdependence. Compared with standard therapy, NPPV has been shown to reduce mortality with number needed to treat (NNT) 17 and reduce rates of endotracheal intubation by 50% for patients with ACPE.[2] Benefits were found to be independent of whether patients received CPAP or BL-PAP and, despite suggestions from early clinical data, no increased rate of acute myocardial infarction occurred in patients receiving any form of NPPV. Specific predictors of failure of NPPV in those with congestive heart failure (CHF) have not been systematically examined.

Evidence regarding the use of NPPV in other patients with respiratory compromise, including asthma and pneumonia, is limited. Several small studies have suggested that NPPV may be beneficial for patients with acute asthma exacerbations by improving lung function, decreasing bronchodilator requirements, and shortening overall hospital length of stay, suggesting a potential role for NPPV in these patients (see Chapter 59). Studies have failed to establish a definitive role for NPPV in pneumonia, and the presence of pneumonia has been shown to be an independent risk factor for failure of noninvasive ventilation. In addition, the duration of NPPV prior to intubation has been associated with in-hospital mortality, suggesting that early intubation is preferable for patients who do not rapidly improve on noninvasive therapy.

A recent randomized, controlled trial compared HFNC, standard oxygen therapy, and NPPV in patients with acute hypoxemic respiratory failure.[3] While the trial found no difference in the proportion of patients intubated at day 28 (the primary outcome), there was a mortality benefit favoring HFNC. HFNC has also been trialed post-extubation and after cardiothoracic surgery with favorable results.[4–6] Another trial in immunocompromised patients showed no difference compared with standard oxygen delivery devices.[7] In light of potential mortality benefit, HFNC should be considered early in the treatment of hypoxemic respiratory failure.

Approach to Initial Ventilator Settings

Noninvasive Ventilation

Initial settings for noninvasive ventilation should be determined by the amount of ventilatory assistance required by the patient, as well as patient comfort and cooperation with therapy. The first consideration in the use of NPPV is whether to provide support in the form of CPAP or BL-PAP. As described earlier, there is no clear benefit of one over the other. Support may be provided by a full-face (oronasal) mask or nasal mask; this choice is determined by patient comfort,

ability of the patient to cooperate, and the need for the patient to cough effectively or speak. Notably, nasal masks have been associated with higher leak rate and decreased patient comfort; therefore, a full-face mask as the first method of NPPV is recommended. In the case of BL-PAP, inspiratory support (IPAP) is initiated at 10 cm H_2O and expiratory support (EPAP) at 5 cm H_2O. Subsequent titration of these parameters is based on the patient's clinical response, particularly pressure tolerance, respiratory rate, and oxygen saturation. Although blood gas analysis is confirmatory, improvements in the patient's clinical condition can be observed by decrease in work of breathing, good patient-ventilator synchrony, increased oxygen saturation, and a positive subjective patient report. If required, IPAP and EPAP can be adjusted by 1 to 2 cm H_2O at a time based on the clinical response. Changes in IPAP will predominantly impact ventilation and work of breathing by modulating tidal volume and minute ventilation, whereas EPAP (acting as PEEP) will impact oxygenation by combating atelectasis and promoting alveolar recruitment. IPAP greater than 20 cm H_2O should be avoided, because it can be uncomfortable and cause gastric insufflation.

High-Flow Nasal Cannula

For patients with acute hypoxemic respiratory failure without significant hypercarbia, HFNC or other high-flow oxygen devices may be applied. After positioning the cannula or face mask, a blend of oxygen and air is delivered at flow rates of up to 80 L/min. These devices typically use high-pressure oxygen and air, which is routed to the gas blender, a humidifier, then to the patient interface via large-bore tubing. The nasal prongs are large diameter, which reduces the amount of ambient air entrained around them. Face mask and tracheostomy tube interfaces also exist. Typical initial settings are Fio_2 of 50% and flow rate of 40 L/min, with maximum values of Fio_2 of 100% and 60 liters per minute. Fio_2 should be titrated to achieve the goal Spo_2, and flow can be titrated both for hypoxemia and relief of dyspnea. Recent data suggest that risk of dispersion of potentially infectious respiratory droplets and aerosols is low with these devices.[8,9] Close monitoring is required. An index (termed ROX, and defined as the ratio of (Spo_2 / Fio_2) to respiratory rate) has been derived and validated to predict risk of HFNC failure (defined as need for endotracheal intubation) and success, and may be used as an adjunct to clinical evaluation.[10] A value less than 3.85 indicates a high risk of HFNC failure, and values ≥ 4.88 measured at 2, 6, or 12 hours after HFNC initiation are associated with lower risk of intubation.

Mechanical Ventilation of the Intubated Patient

For the intubated patient, initial ventilator settings should facilitate ventilation that improves gas exchange, promotes ventilator synchrony, and minimizes the potential for complications. For an apneic or paralyzed patient, full ventilatory support is required; therefore, A/C is the recommended mode of initial ventilation for emergent patients. Specific required settings depend on whether the patient is receiving PC or VC, but the principles underlying the selection of settings are similar. Typical initial ventilator settings include a tidal volume of 6 to 8 mL/kg of estimated ideal body weight (IBW) with a rate of 12 to 14 breaths/min or one that matches the patient's pre-intubation respiratory rate. If VC is used, tidal volume can be set directly and, if PC is used, tidal volume is determined by adjusting the targeted pressure to be delivered. Regardless of VC or PC, initial pressure targets should ideally not exceed 30 cm H_2O. The initial Fio_2 should be set at 1.0 and titrated down to maintain an oxygen saturation of 88% to 94%. PEEP is routinely set initially at 5 cm H_2O. Settings for specific clinical conditions such as status asthmaticus are discussed later.

Ongoing Management

Mechanical ventilation requires monitoring and regular adjustment to ensure appropriate gas exchange, safe delivery of desired tidal volume, and prevention of acid-base derangement. Changes to ventilator settings are guided dynamically by multiple factors, including pulse oximetry, end-tidal carbon dioxide ($ETco_2$) measurement, ventilation pressures, and blood gas levels. Blood gases should be measured 15 to 20 minutes after the initiation of ventilatory support to determine pH and adequacy of gas exchange.

Overall, while venous blood gases (VBGs) can be used to titrate ventilator settings, venous blood samples should be interpreted with several caveats. First, while the pH of venous blood samples generally correlates well with the pH of arterial samples, the correlation of Pco_2 between venous and arterial samples is less reliable. In addition, although there is variation in agreement between capnography and blood gas values, capnography generally correlates better with the Pco_2 of arterial samples. Lastly, an arterial sample is required to assess the relationship between the Fio_2 and Pao_2, a key indicator of the severity of hypoxemia in ARDS. For these reasons, arterial blood gases are more useful when adjusting initial ventilator settings.

Once an initial correlation has been established, noninvasive modalities can be used for further adjustment. Data have confirmed the importance of continuous capnography, demonstrating a decrease in the use of blood gases and resultant, significant cost savings.[11] If capnography is difficult to perform or otherwise noncorrelative, arterial blood gas determination remains the definitive test for evaluating Pao_2 and Pco_2.

Pco_2 should be adjusted by changing the minute ventilation, or the volume of air cycled in one minute. Minute ventilation is determined by the tidal volume and respiratory rate. As such, adjustment of these, as indicated by the scenario, can be used to affect the Pco_2.

To avoid oxygen toxicity, Fio_2 should be reduced at the earliest opportunity to the lowest level that provides acceptable oxygen saturation (>90%) as hyperoxemia has been associated with worse outcomes. In a recent cohort study of ED patients, hyperoxemia (defined as Pao_2 >120 mm Hg) was an independent predictor for hospital mortality.[12] In many cases, increases in PEEP will allow better oxygenation for a given Fio_2 but may worsen hypotension or increase intrathoracic pressure.

In addition to maintaining adequate gas exchange, care should be taken to ensure that pressure in the ventilator circuit (including the lungs) is appropriate. The two main measurements are the peak inspiratory (PIP) and plateau (Pplat) pressures. The PIP measures the maximum amount of pressure in the ventilator circuit during a breath cycle. It reflects both respiratory system compliance (including the lungs, pleural spaces, chest wall, and abdomen) and respiratory system resistance (including resistance in the ventilator circuit itself). In PC ventilation, because pressure limits are preset, the PIP is the sum of the set pressure target and PEEP. In this case, PIP also reflects the maximum amount of pressure in the alveoli, an important determinant in the development of VILI. In VC ventilation, PIP can be influenced greatly by airway resistance and therefore is not reflective of the maximal alveolar pressure. Rather, maximal alveolar pressure is determined on the ventilator at the end of inspiration by means of an inspiratory hold, referred to as plateau pressure (Pplat). At the end of inspiration, flow in the circuit stops; therefore, there is no pressure from resistance in the circuit.

Increases in measured pressure indicate increased airway resistance or changes in compliance of the respiratory system and can indicate potentially dangerous clinical deterioration. Sudden increased airway resistance or decreased lung compliance would result in increased airway pressure during VC and reduced tidal volume during PC

ventilation. Decreases in lung pressure, conversely, indicate decreased resistance or decreased airflow in the ventilatory circuit and should prompt investigation of the ventilator circuit for leaks. Large or sudden decreases in pressure suggest disconnection of the ventilator circuit or unintended extubation. For patients with underlying respiratory failure secondary to increased airway resistance such as in asthma or COPD, gradual decreases in PIP indicate clinical improvement.

Pharmacology: Analgesia and Sedation of the Ventilated Patient

Analgesia and sedation are critical in the care and comfort of mechanically ventilated patients. Intubation, mechanical ventilation, and paralysis are a significant cause of pain and anxiety for patients, and analgesia and sedation are required to promote patient comfort and ventilator synchrony.

Analgesia and sedation should be titrated to comfort and therapeutic goals, treating pain and anxiety while avoiding over or under sedation. A large body of ICU literature has documented an association between deep sedation, delirium, prolonged mechanical ventilation, and mortality. Recent data suggest that early deep sedation is common in the ED, carries on to the ICU, and may be associated with worse outcomes.[13,14] The desired level of sedation will differ based on patient tolerance and the clinical scenario; assuming that comfort is maintained, lighter sedation is reasonable for most patients. Deep sedation is required for any patient who has recently received neuromuscular blockade or is undergoing procedures or diagnostic studies.

Multiple validated tools are used to guide appropriate levels of sedation for mechanically ventilated patients. These include the Critical Care Pain Observation Tool (CPOT) and Richmond Agitation-Sedation Scale (RASS). Both allow nurses and clinicians to target analgesia and sedation to specific goals. CPOT uses variables such as facial expression, body movement, muscle tension, and ventilator compliance to allow for titration of analgesia to achieve preselected goals. The RASS is a commonly used scale of +4 to −5. A +4 patient is combative with staff, a 0 is alert and calm, and −5 is unarousable to physical stimulation (Table 2.3). Sedation should be maintained at the highest RASS score at which the patient is comfortable (between 0 and −5) and frequently reassessed. Any patient who has recently received neuromuscular blockade should remain deeply sedated as RASS cannot be obtained in a paralyzed patient. ED-based data have demonstrated that the use of rocuronium during rapid sequence intubation (RSI) is associated with increased time to adequate sedation, as well as decreased overall dose of sedation, when compared to patients intubated with succinylcholine.[15] This is likely because emergency clinicians wrongly ascribe the patient's inability to move or respond to adequate sedation, rather than to the paralysis. When rocuronium is used for RSI, additional sedation should be immediately administered after intubation confirmation.

TABLE 2.3 Richmond Agitation-Sedation Scale

Score	Term	Description
+4	Combative	Overtly combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s), aggressive
+2	Agitated	Frequent nonpurposeful movement, fights ventilator
+1	Restless	Anxious, but movements not aggressive or vigorous
0	Calm	Alert and calm
−1	Drowsy	Not fully alert, but has sustained awakening (>10 s)
−2	Light sedation	Briefly awakens with eye contact to voice (<10 s)
−3	Moderate sedation	Movement or eye opening to voice but no eye contact
−4	Deep sedation	No response to voice but movement or eye opening with physical stimulation
−5	Unarousable	No response to voice or physical stimulation

Adapted from Ely EW, Truman B, Shintani A, et al. Monitoring sedation status over time in ICU patients: reliability and validity of the Richmond Agitation-Sedation Scale (RASS). *JAMA*. 2003;289:2983–2991.

After RSI, additional NBMAs should generally not be used unless ventilator dyssynchrony interferes with adequate oxygenation or ventilation despite adequate sedation and analgesia. While NMBAs were previously recommended for patients with moderate-to-severe ARDS, a recent trial demonstrated no benefit when they were given universally to this population.[16] NMBAs still may be used as a rescue strategy for refractory hypoxemia or ventilator dyssynchrony in ARDS. With proper sedation and analgesia, however, NMBAs are usually not required. If needed, single doses of longer-acting agents such as rocuronium and vecuronium may be used; note that impaired hepatic or renal function may increase duration of paralysis. An infusion of cisatracurium may also be used for patients requiring prolonged NMBA and is generally preferred over other agents as its metabolism is independent of organ function.

Analgesia is achieved with opioids; fentanyl and morphine remain the most commonly used agents for analgesia in critically ill patients. Opioids are associated with dose-dependent respiratory depression, a side effect that may be particularly beneficial for patients experiencing ventilator dyssynchrony. Morphine (0.5 to 1 mg/kg IV push) and fentanyl (weight-based, 0.5 to 1 mcg/kg IV push) can be used for analgesia, although dosage requirements will vary based on tolerance and drug metabolism. Sedation and analgesia should therefore be titrated with a standard sedation scale, as discussed earlier. Notably, the active metabolite of morphine (morphine-6-glucuronide) is cleared renally and has potent sedative effects. For this reason, fentanyl may be preferred in patients with renal insufficiency. Fentanyl has a context-sensitive half-life; its duration of action is short when administered as a bolus or low-dose infusion. Because it is lipophilic, large or prolonged doses may dissolve in adipose tissue, leading to drug accumulation and prolonged effect. Remifentanil is an ultra–short-acting opiate that is metabolized by nonspecific plasma esterases. Adjunct non-opioid analgesic agents, such as acetaminophen, gabapentin, ketamine, tricyclic antidepressants, and regional anesthesia may also be useful in patients with coexisting painful conditions or opioid tolerance.

Sedation after intubation can be accomplished via multiple pharmacologic modalities. In the ICU, benzodiazepines had been a common choice for sedation, but data suggest they are associated with increased delirium and prolonged ventilation, so they are falling out of favor. Other agents, such as propofol and dexmedetomidine, are commonly used. A recent, multicenter study of ED sedation practices revealed that propofol was the most commonly used sedative, followed by midazolam and lorazepam.[13] Notably dexmedetomidine does not provide deep sedation and should not be used as a single agent in patients who received long-acting NMBAs.

Propofol is highly lipophilic, rapidly penetrates the blood-brain barrier, and distributes into peripheral resulting in a short duration of its clinical effect. Propofol exerts dose-dependent clinical effects by binding γ-aminobutyric acid (GABA) receptors, first producing anxiolysis and then sedation and hypnosis. Propofol clearance is only minimally impacted by organ dysfunction in critically ill patients. Propofol can precipitate hypotension by increasing venous capacitance and suppressing myocardial contractility, a side effect that is exaggerated in hypovolemic patients. Thus, propofol should be given as an

infusion rather than as a bolus, initiated at low doses (0.1 mg/kg/min) and titrated to the desired level of sedation. In comparison to benzodiazepines, continuous infusions of propofol have been demonstrated to decrease the duration of mechanical ventilation. A rare but potentially deadly propofol infusion syndrome can occur in patients receiving prolonged or high-dose infusion and is characterized by metabolic acidosis, rhabdomyolysis, renal and liver injury, and cardiovascular collapse.

Like propofol, benzodiazepines also bind GABA receptors. Benzodiazepines also cause respiratory depression, which is potentiated by concomitant opioid administration. Therefore, a sedation regimen of opioids and benzodiazepines may improve ventilator dyssynchrony while providing anxiolytic and amnestic effects. Benzodiazepines can be administered as repeated boluses or by continuous infusion although, in critically ill patients, benzodiazepines have altered pharmacokinetics that result in tissue accumulation and prolonged sedation. This is particularly true in obese patients and patients with renal or hepatic insufficiency. For this reason, sedation with benzodiazepines should be first attempted with intermittent bolus administration before a continuous infusion is used. The most commonly used benzodiazepines are midazolam (0.01 to 0.05 mg/kg IV push) and lorazepam (0.02 to 0.04 mg/kg IV push).

Other medications for the sedation of ventilated patients in the ED include dexmedetomidine, ketamine, and haloperidol. Dexmedetomidine is a centrally acting α_2-agonist with sedative and analgesic properties, largely distinguished from other sedative agents by a negligible impact on respiratory drive, even with simultaneous opioid administration. It is administered as a continuous infusion (0.2 to 1.5 mcg/kg/min), and can precipitate bradycardia, transient hypertension, and hypotension in an idiosyncratic fashion. Several multicenter trials demonstrated that dexmedetomidine was associated with a shorter duration of mechanical ventilation as well as decreased sedation-associated delirium compared with continuous infusions of benzodiazepines.[17] A large, multinational trial compared dexmedetomidine with usual care, which consisted mainly of continuous infusions or propofol and occasionally benzodiazepines, and demonstrated no difference in mortality, but more adverse hemodynamic events in the dexmedetomidine arm.[18] Although not systematically studied in ventilated ED patients, dexmedetomidine has emerged as an alternative sedation strategy for critically ill patients and may be considered as an alternative to traditional modalities in clinical settings in which agitation or anxiety limit therapeutic goals.

Ketamine has emerged as a popular agent for sedation and analgesia in the ED for a variety of indications and may have a role for ongoing sedation and analgesia in mechanically ventilated patients. In addition to its main property as a dissociative anesthetic, binding the N-methyl-D-aspartate (NMDA) receptors, it also acts on opioid receptors, monoaminergic receptors, muscarinic receptors, and voltage sensitive calcium ion channels. It has a moderate analgesic effect and may be effective in patients with opioid tolerance. Although data in critically ill patients are limited, it is used widely as an opioid-sparing analgesic agent for postoperative pain, in combat settings, and in the developing world as an anesthetic agent. It has a beneficial side effect profile and is generally safe, but may cause tachycardia, hypertension, and emergence reactions. Ketamine may be administered as IV boluses of 1 to 2 mg/kg or as a continuous infusion (0.5 to 1 mg/kg/h).

Haloperidol and other antipsychotics may be used as an adjunct to traditional sedation regimens in mechanically ventilated patients. Haloperidol may be particularly useful for patients who remain acutely agitated after receiving large doses of other sedative medications, especially because it does not affect hemodynamics. However, haloperidol does not have analgesic or amnestic properties and cannot be used as a single agent for sedation in critically ill patients. Notably, antipsychotics have not been shown to prevent or reduce the duration or severity of delirium in critically ill patients.[19]

Ventilator-Associated Pneumonia Prevention

Ventilator-associated pneumonia (VAP) is a common complication of mechanical ventilation and is associated with poor outcome. Approximately 50% of all cases of VAP occur within the first 4 days of mechanical ventilation. A number of strategies can be initiated in the ED to help prevent VAP later on in the patient's clinical course.

Management of secretions, which is necessary not only for VAP prevention but also patient comfort, is achieved via regular endotracheal suctioning, recognizing a balance between secretion clearance and the disruption of ventilation. Ideally, suctioning occurs using a sterile, enclosed, in-line endotracheal catheter. In addition, a nasogastric or orogastric tube should be placed for gastrointestinal decompression. Finally, evidence has demonstrated that placing the patient in the semi-recumbent position by elevating the head of the bed to at least 30 degrees can also reduce rates of VAP. This can be accomplished in patients undergoing spinal immobilization by placing them in the reverse Trendelenburg position.

The use of VAP care bundles, including elevation of the head of the bed, daily sedation vacations and assessment of extubation readiness, peptic ulcer disease prophylaxis, oral decontamination, gastrointestinal decompression, and other interventions, have decreased the incidence of VAP in the ICU. One study of patients with ARDS demonstrated that an ED ventilator protocol, which included head elevation, was feasible and associated with improved mortality and ventilator-free days.[20]

Endotracheal tube design and management may also affect VAP incidence. A meta-analysis has also demonstrated a decrease in the incidence of VAP with continuous aspiration of subglottic secretions.[21] Several studies also demonstrated reduced incidence of VAP in patients treated with silver-coated endotracheal tubes. Maintenance of endotracheal tube cuff pressure at 20 to 30 cm H_2O may prevent leakage of secretions around the cuff into the lower respiratory tract, though this approach has not been consistently demonstrated to prevent VAP.

Troubleshooting the Ventilator

When a patient's condition suddenly deteriorates during mechanical ventilation, a systematic approach should be applied to assess for life-threatening conditions (Fig. 2.1). The first step in evaluating the ventilated patient who has a change in clinical status is to assess vital signs. Patients with acute, severe hemodynamic compromise, such as profound hypotension or cardiac arrest, should be removed from the ventilator and bagged manually on 100% oxygen. Tension pneumothorax, increased iPEEP, and accidental extubation are the most life-threatening concerns in this situation and must be expeditiously addressed. While the patient is bagged, the chest should be examined to ensure bilateral breath sounds. Changes in breath sounds may indicate a pneumothorax or migration of the endotracheal tube. Clinical examination, oxygen saturation, correlation between set and exhaled tidal volumes, and $ETCO_2$ monitoring can be used to assess tube placement, but suspicion of inadvertent extubation should prompt immediate laryngoscopy or endoscopic evaluation of the location of the endotracheal tube. Acute hypotension can be precipitated by extreme elevations in intrathoracic pressure; compromise from iPEEP will improve once the patient has been disconnected from the ventilator, whereas hypotension from a tension pneumothorax will not be relieved. If the patient's condition remains unstable after she or he has been disconnected from the ventilator circuit, a tension pneumothorax should be treated presumptively with needle decompression or finger thoracostomy and eventual chest tube placement. If the patient remains

TABLE 2.4 Troubleshooting the Ventilator: Potential Causes of Acute Respiratory Distress

With Hemodynamic Compromise: Immediately Discontinue Mechanical Ventilation and Manually Bag with 100% Oxygen	
Increased intrinsic positive end-expiratory pressure (iPEEP)	
Tension pneumothorax	
Massive pulmonary embolus	
Without Hemodynamic Compromise: Search for Underlying Cause	
Mechanical	Physiologic
Endotracheal tube migration into bronchus	Worsening lung compliance
Endotracheal tube obstruction	Worsening airway obstruction
Endotracheal tube cuff leak	Abdominal distention
Inadvertent extubation	Pulmonary embolus
Discontinuity in ventilator circuit	Pain or inadequate sedation

unstable after chest decompression, other causes should be pursued. However, decompensation on the ventilator can often be averted by close attention to pressure alarms and waveforms and monitoring for the development of iPEEP in at-risk patients.

Acute distress without hemodynamic changes can be precipitated by multiple factors, mechanical and physiologic (Table 2.4). The initial evaluation should begin by confirming the position and patency of the endotracheal tube before other diagnoses are investigated, including evaluation of the tracheal balloon. Once tube placement has been confirmed, the next step in the evaluation of ventilator-related causes of distress should focus on airway pressures. Acute decreases in PIP indicate discontinuity in the ventilator circuit, which could include inadvertent extubation or disconnection from the circuit. Patients with increased PIP can be considered in two categories—those with concomitant increases in Pplat and those with unchanged Pplat. If both PIP and Pplat acutely increase, this suggests decreased compliance of the respiratory system. Elevated PIP with unchanged Pplat indicates problems with increased airway resistance in the lungs or ventilator circuit. Specific conditions that cause decreased respiratory system compliance or increased airway resistance are detailed in Fig. 2.1.

Special Clinical Circumstances

Although generalizations can be made regarding ventilator management in the ED, certain clinical circumstances merit specific discussion.

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Strategies for managing intubated patients with COPD focus on improving gas exchange while minimizing iPEEP. Reduction of iPEEP is achieved by decreasing airway resistance with bronchodilators and corticosteroids, as well as ensuring adequate expiratory time during mechanical ventilation. Adequate expiratory time is achieved by decreasing respiratory rate, tidal volume, and inspiratory time. Adequate oxygenation (saturation of 88%) is achieved while minimizing barotrauma by deliberately reducing minute ventilation, so-called permissive hypercapnia. While many clinicians select PC in COPD, no data have suggested the advantage of PC over VC, and either method can be used. The ideal ratio of inspiratory-to-expiratory time (I/E ratio) is variable, but should initially be set at 1:4. Studies in asthmatics have suggested that expiratory times longer than 4 seconds have minimal impact on airflow. iPEEP can also result in poor patient-ventilator synchrony, causing ineffective breath triggering. Unlike in patients with acute asthma (see following section), applied PEEP should be used in patients with COPD; it can be set initially at 5 cm H_2O, and may be increased to match iPEEP in the case of ineffective triggering. Initially, deep sedation and analgesia (and sometimes neuromuscular blockade) are required to prevent ventilator asynchrony and permit effective ventilation.

Status Asthmaticus

Management principles for ventilating the acute asthmatic generally parallel those for patients with COPD, with some notable differences.

In acute asthma, respiratory failure is a result of airway obstruction and airway inflammation. Furthermore, unlike COPD, airway obstruction is much less dynamic and occurs predominantly in the large airways. In addition, acute inflammatory changes throughout the lung contribute to decreased lung compliance, which has a direct impact on lung pressures during ventilation. Strategies should focus on low respiratory rates, with emphasis on maximizing expiratory time. The use of PEEP has been debated and is largely thought to contribute to increased lung pressure. Although no studies have definitively supported VC over PC, decreased lung compliance and potential iPEEP may make the delivery of adequate tidal volumes with PC difficult. This is especially problematic for patients with severe, acute respiratory acidosis, for whom adequate ventilation is essential. Recommendations for ventilator settings include VC with tidal volumes of 6 to 8 mL/kg IBW, respiratory rate of 8 to 12 breaths/min, and low PEEP of 3 to 5 cm H_2O in most circumstances. The PEEP should then be further titrated to match approximately 80% of the iPEEP. Decreased inspiratory time allows greater expiratory time and, in VC, is achieved by increasing the inspiratory flow rate. Increases in inspiratory flow rate, however, will increase airway pressures, emphasizing the interplay of inspiratory time, tidal volume, and airway pressure. Like in COPD, a low set respiratory rate matters little if the patient is tachypneic and triggering the ventilator frequently, so analgesia, deep sedation, and occasionally neuromuscular blockade may be necessary.

Acute Respiratory Distress Syndrome

ARDS represents a spectrum of inflammatory lung disease characterized by heterogeneous noncardiogenic pulmonary edema, hypoxemia, reduced lung compliance, and diffuse alveolar injury. The severity of ARDS is classified as mild, moderate, or severe and is defined by the ratio of arterial oxygen concentration to the fraction of inspired oxygen (Pao_2/Fio_2). ARDS can be caused by pulmonary or extrapulmonary insult, including VILI.

Data from cohorts of ventilated ED patients with sepsis suggest that ARDS may be present in 7% to 25% of cases and development of ARDS after ED admission is common.[22] The development of VILI has been associated with lung overdistention and alveolar injury, and attention to ventilation strategy in the ED is warranted. Studies have confirmed that decreased tidal volumes are of clear benefit in the management of patients with ARDS. Most studies examining low tidal volume ventilation strategies, including the landmark ARMA trial conducted by the ARDSnet in 2000, used 4 to 6 mL/kg tidal volumes based on IBW. A meta-analysis of these data has concluded that tidal volumes below 7 mL/kg and Pplat less than 31 cm H_2O confer mortality benefit in patients with ARDS, although more recent work has suggested that low tidal volume ventilation may improve outcome for patients without lung injury as well, including halting progression to ARDS.[22,23] The level of PEEP in patients with ARDS continues to be actively researched and, although higher levels of PEEP have been demonstrated to improve oxygenation, they have not reduced mortality. Therefore, in patients with ARDS ($Pao_2/Fio_2 < 300$), a low tidal volume (≤6 mL/kg of IBW) and low plateau pressure (≤ 30 cm H_2O) ventilation strategy should be used.

Although observational data across multiple settings, including the ED, suggest that ventilation with tidal volumes greater than 8 mL/kg IBW before onset of ARDS is associated with development of ARDS, a randomized trial showed no benefit of lower tidal volume ventilation among patients without ARDS.[23] However, given low risk of harm with protective strategies and potential benefit, we recommend ventilation with tidal volumes of 6 mL/kg IBW in patients with ARDS and 6 to 8 mL/kg IBW in patients at risk for ARDS. Observational data have suggested that adherence to lung-protective ventilation strategies in the ED is just over 50%.[22] Several studies have demonstrated that ED mechanical ventilation protocols that include low-tidal volume ventilation are associated with improved outcomes.[20,22,24]

OUTCOMES

Because of the heterogeneity of ventilation strategies and clinical reasons for respiratory failure, no studies have clearly shown the superiority of one ventilation method over another; considerations in initiating mechanical ventilation are individualized and serially reevaluated. Nonetheless, certain conclusions regarding outcomes can be made. Data have clearly indicated the effectiveness of NPPV in preventing intubation for patients with COPD and ACPE, and these benefits have resulted in decreased admission to the ICU and decreased mortality. In addition, increased alveolar volumes and pressures have been shown to contribute to VILI and increase mortality in patients with ARDS. Although the benefit of low tidal volume ventilation on the prevention of lung injury in patients with normal lungs has not been definitively proven, data suggest that strategies of mechanical ventilation in the ED can improve the subsequent clinical course of critically ill patients.

Finally, although the treatment of mechanically ventilated patients usually extends beyond the ED, delays in ICU admission can have significant implications on ED management of the critically ill ventilated patient because the role of emergency clinicians extends beyond acute stabilization and can include ongoing clinical management. In addition, because of "therapeutic momentum" clinical interventions implemented in the ED are likely to be continued through hospitalization. Finally, when boarding times are long, patients intubated solely for airway protection may be candidates for extubation in the ED if the initial insult has been reversed.

Complications

Although initiated as a lifesaving intervention, mechanical ventilation carries the risk of significant complications. As highlighted earlier, the initiation of mechanical ventilation leads to elevated intrathoracic pressure, which can reduce preload, raise pulmonary vascular resistance, and reduce cardiac output.

Mechanical ventilation can also injure the lungs; this is termed VILI. VILI may be caused by alveolar overdistention and volutrauma due to high tidal volumes. Trauma related to elevated lung inflation pressures can manifest overtly as barotrauma leading to alveolar rupture, pneumothorax, or pneumomediastinum. Biotrauma, characterized by ventilator-induced inflammatory mediator release, and atelectrauma, caused by shearing of alveoli during opening and closing, may also contribute to VILI. VILI is mitigated by limiting pathologic stretch on the alveoli; studies have supported that maximum safe end-inspiratory alveolar pressures are 30 to 32 cm H_2O. Recent studies have demonstrated that minimizing driving pressure, the difference between the end-inspiratory pressure during a pause (or plateau pressure) and PEEP, may be a better target to reduce VILI.[25]

Another potential complication of PPV is the development of intrinsic PEEP (iPEEP or auto-PEEP). Particularly problematic in patients with obstructive lung disease, iPEEP is the accumulation of end-expiratory volume and end-expiratory pressure that occurs when exhalation cannot be fully completed. In patients with obstructive lung disease, expiratory flow is limited by small airway obstruction, dynamic airway collapse, and diminished elastic recoil. The time required for full exhalation may be significantly longer than normal, and, in patients receiving mechanical ventilation, exhalation may not

be complete before the next delivered breath. This phenomenon, often termed *breath stacking*, results in dynamic hyperinflation. iPEEP leads to high PIPs, difficulty triggering breaths, hypotension, and potential circulatory collapse. Ventilation difficulty caused by iPEEP can be improved by decreasing the respiratory rate or inspiratory time, or increasing the inspiratory flow rate, all of which facilitate increased time for exhalation. Increasing set PEEP to match the level of iPEEP may also improve a patient's ability to trigger breaths.

CHAPTER 2: QUESTIONS AND ANSWERS

1. Which of the following is the most important consideration in the decision to initiate noninvasive positive-pressure ventilation (NPPV)?

a. Degree of acidosis
b. Degree of respiratory distress
c. Hemodynamic profile
d. Level of consciousness

Answer: b. Although NPPV will be helpful for many patients in distress, the need for emergent intubation is an absolute contraindication to NPPV. Both hemodynamic profile and level of consciousness are important determinants in the decision to implement NPPV, but both are relative (rather than absolute) contraindications to its use. Patients with chronic obstructive pulmonary disease (COPD), acute cardiogenic pulmonary edema (ACPE), and asthma are more likely to show benefit with NPPV than patients with pneumonia, but NPPV can be initiated for any patient with respiratory distress. Patients with hypoxia or hypercarbia may be acidemic, but the decision to initiate NPPV will be predicated on mental status and work of breathing rather than on degree of acidosis alone.

2. Which of the following is a potential adverse effect of intubation and positive-pressure ventilation?

a. Decreased mean intrathoracic pressure
b. Decreased ventilation/perfusion ratio
c. Increased cardiac output
d. Increased work of breathing

Answer: d. Positive-pressure ventilation (PPV) is associated with several complications. Some of these can quickly become life-threatening. This reality underscores the importance of familiarization with the common problems that arise as a result of PPV. Most complications result from changes in thoracic physiology when positive pressure is present for part or all of the respiratory cycle. Potential adverse effects of PPV include an increased work of breathing because of asynchrony or improperly set triggers, an increase in intrathoracic pressure,

decreased venous return to the heart and decreased cardiac output, an increased ventilation/perfusion ratio, air trapping and intrinsic positive end-expiratory pressure, barotrauma, decreased renal blood flow and glomerular filtration rate with fluid retention, nosocomial infections of the lungs and sinuses, respiratory alkalosis, and agitation and increased respiratory distress.

3. What is the primary physiologic effect of applying positive end-expiratory pressure (PEEP) during mechanical ventilation?
   - **a.** Decrease cardiac output
   - **b.** Decrease intrapulmonary shunting
   - **c.** Decrease ventilation/perfusion mismatch
   - **d.** Increase functional residual capacity (FRC)

Answer: d. Although all of these effects can be attributed to the application of PEEP, its primary physiologic effect is to increase FRC by maintaining patency of injured or flooded alveoli that would otherwise collapse at the end of exhalation. Increasing the FRC may improve both oxygenation and lung compliance. PEEP increases Pao_2 at a constant fraction of inspired oxygen (Fio_2) by decreasing intrapulmonary shunting and ventilation/perfusion mismatch. One of the potential adverse effects to PEEP is decreased cardiac output.

4. Regarding a patient who develops acute distress on mechanical ventilation, which of the following is the most accurate?
   - **a.** Accidental extubation is a common cause of increased airway pressure.
   - **b.** Anaphylaxis would cause immediate increases in both peak inspiratory pressure (PIP) and plateau pressure (Pplat).
   - **c.** All patients in distress should be immediately removed from the ventilator and bagged.
   - **d.** Compared to patients with restrictive lung disease, patients with obstructive lung disease and asthma are more likely to decompensate without an appropriate expiratory time.

Answer: d. One of the most life-threatening complications of mechanical ventilation is loss of adequate cardiac output because of elevated intrathoracic pressure from intrinsic PEEP (iPEEP). Intrinsic PEEP can be precipitated by a respiratory rate that is too high, which does not allow patients to fully exhale before the delivery of another breath. Patients with obstructive lung disease such as COPD or acute asthma are particularly sensitive to this phenomenon, also known as "breath stacking." Although patients with restrictive lung disease may develop iPEEP with an inappropriate respiratory rate, this is much more likely to occur in patients with obstructive conditions. If patients are not hemodynamically unstable, they do not need to be removed from the ventilator, and in hemodynamically unstable patients, pneumothorax should only be presumptively treated if removing the patient from the ventilator does not improve the situation. Accidental extubation is a common cause of decreased airway pressures, and although anaphylaxis would cause increases in PIP, it would not typically cause increases in Pplat.

3

Shock

Michael A. Puskarich and Alan E. Jones

KEY CONCEPTS

- Shock can occur with normal arterial blood pressure and not all patients with arterial hypotension have shock.
- A base deficit more negative than –4 mEq/L or a serum lactate level greater than 4.0 mmol/L warrants a presumptive diagnosis of shock.
- Urine output is a reliable index of vital organ perfusion in patients with suspected shock. Normal urine output is 1.0 mL/kg/h. Output less than 0.5 mL/kg/h indicates severe renal hypoperfusion in patients without preexisting disease.
- A combination of a worsening base deficit, increasing lactate level, and low urine output represents persistent or worsening shock.
- Hemorrhagic shock is preferentially treated with blood products, using a balanced transfusion approach of packed red blood cells, fresh frozen plasma, and platelets.
- Early initiation of balanced fluid resuscitation, vasopressor support, and prompt antimicrobial therapy improve outcomes in patients with septic shock.

FOUNDATIONS

Background and Importance

In philosophic terms, shock can be viewed as a transition between life and death. Whether shock results from hemorrhage, sepsis, or cardiac failure, mortality rates exceed 20%. Shock results from the widespread failure of the circulatory system to oxygenate and nourish the body adequately. At the cellular level, shock alters mitochondrial energy transfer and evokes the production and accumulation of toxic chemicals. The emergency clinician identifies shock by linking the qualitative clinical impression, synthesized from the patient's history of present illness, age, health status, and general appearance, to quantitative data, including vital signs, laboratory tests, urine output, and measurements of systemic oxygenation. When the clinical impression and quantitative data suggest widespread organ hypoperfusion, emergent resuscitation is used to restore tissue oxygenation and substrate delivery to prevent deterioration into a vicious cycle of systemic inflammation, organ dysfunction, and death. Anaphylaxis and its treatment are discussed in Chapter 106.

For years, shock has been classified into four broad categories—distributive, hypovolemic, cardiogenic, and obstructive. This basic organization scheme is useful for discussions of pathophysiology and formation of a differential diagnosis. However, for discussions of management, a system based on the requisite treatment response is more clinically useful. Box 3.1 outlines five categories of shock that generally have specific mechanisms and treatments. The epidemiology of shock in the emergency department (ED) is diverse and evolving. Traumatic, cardiogenic, or septic shock are diagnosed in fewer than 3% of ED patients. Our understanding of the metabolic, systemic, and inflammatory responses that occur in all types of shock and the specific pathophysiology of the major causes of shock has led to dramatic increases in the early identification and treatment of these states, with resultant improvement in outcomes.

Anatomy, Physiology, and Pathophysiology

At the subcellular level, shock first affects the mitochondria. Mitochondria function at the lowest oxygen tension in the body, but they consume almost all the oxygen used by the body. More than 95% of aerobic chemical energy comes from mitochondrial combustion of fuel substrates (fats, carbohydrates, ketones). These substrates combine with oxygen and are converted into carbon dioxide and water. Mitochondria have therefore been referred to as the canaries in the coal mine because they are affected first in conditions of inadequate tissue perfusion. When mitochondria have inadequate oxygen, the cell catabolizes fuels to lactate, which accumulates and diffuses into the blood. In the setting of hypoxia, mitochondria are unable to provide sufficient energy to maintain cellular processes and, at a certain point, an irreversible series of intracellular cascades leads to cellular dysfunction, organ failure, and ultimately death.

Specific Causes

Hemorrhagic Shock

Hemorrhagic shock results from a rapid reduction in intravascular blood volume from any cause. Rapid hemorrhage generally causes an increase in the strength of cardiac contraction and heart rate (HR), followed by baroreceptor activation and peripheral vasoconstriction. Typically, an initial slight increase in the diastolic blood pressure (BP) with a narrowing of the pulse pressure progresses to a decrease in ventricular filling and cardiac output, causing a reduction in systolic BP. This response varies considerably with cardiopulmonary status, age, and presence of vasoactive medications. The responses of HR and BP are therefore notoriously variable in hemorrhage, so no firm conclusion can be made at the bedside about the presence, absence, or degree of hemorrhagic shock by simple evaluation of the HR and BP.

Even before the cardiac output begins to decline, blood flow is directed away from noncritical organs and tissues, and their cells produce and release lactic acid. Consequently, acidemia often precedes any significant decrease in cardiac output. However, the blood contains bicarbonate ions that buffer the blood pH, keeping it near neutral, even as lactic acid accumulates. The base deficit—amount of strong base that would have to be added to 1 L of blood to normalize the pH—represents an index of how far the bloodstream has dipped into this reserve. A normal base deficit is more positive than –2 mEq/L. The arterial and venous blood base deficit can become more negative early in hemorrhage, even while blood pH and BP remain normal. The base deficit, therefore, crudely represents the physiologic endpoint that distinguishes trivial blood loss from clinically significant hemorrhage. In

BOX 3.1 Five Categories of Shock According to Primary Treatment of Causes and Problems

Primarily Infusion of Volume

Hemorrhagic shock
- Traumatic
- Gastrointestinal
- Body cavity

Hypovolemia
- Gastrointestinal losses
- Dehydration from insensible losses
- Third-space sequestration from inflammation

Volume Infusion and Vasopressor Support

Septic shock
Anaphylactic shock
Central neurogenic shock
Drug overdose

Improvement in Pump Function by Infusion of Inotropic Support or Reversal of the Cause of Pump Dysfunction

Myocardial ischemia
- Coronary artery thrombosis
- Arterial hypotension with hypoxemia

Cardiomyopathy
- Acute myocarditis
- Chronic diseases of heart muscle (ischemic, diabetic, infiltrative, endocrinologic, congenital)

Cardiac rhythm disturbances
- Atrial fibrillation with rapid ventricular response
- Ventricular tachycardia
- Supraventricular tachycardia

Septic shock with myocardial failure (hypodynamic shock)
Overdose of negative inotropic drug
- Beta blocker
- Calcium channel antagonist

Structural cardiac damage
- Traumatic (e.g., flail mitral valve)
- Ventriculoseptal rupture
- Papillary muscle rupture

Immediate Relief from Obstruction to Cardiac Output

Pulmonary embolism
Cardiac tamponade
Tension pneumothorax
Valvular dysfunction
- Acute thrombosis of prosthetic valve
- Critical aortic stenosis

Congenital heart defects in newborn (e.g., closure of patent ductus arteriosus, with critical aortic coarctation)
Critical idiopathic subaortic stenosis (hypertrophic obstructive cardiomyopathy)

Specific Antidotes Due to Cellular or Mitochondrial Poisons

Carbon monoxide
Methemoglobinemia
Hydrogen sulfide
Cyanide

addition to chemical buffering, the body responds to small reductions in arterial pH by activating brainstem chemoreceptors, which increase minute ventilation, leading to reduced partial pressure of carbon dioxide in the arterial blood ($Paco_2$), providing an additional means of compensating for evolving acidosis.

With progressive blood loss, cardiovascular reflexes can no longer sustain adequate filling of the vasculature, and frank hypotension supervenes. Arterial hypotension is generally and arbitrarily defined as an arterial BP less than 90 mm Hg. Usually coincident with the development of hypotension, the compensatory chemical and respiratory buffering mechanisms become overwhelmed, resulting in acidosis. The hypothalamic-pituitary-adrenomedullary axis is activated, releasing stress hormones and inducing glycogenolysis, lipolysis, and mild hypokalemia. Significant traumatic hemorrhage in otherwise normal ED patients, therefore, will generally cause an arterial lactate concentration greater than 4.0 mmol/L, $Paco_2$ less than 35 mm Hg, mild hyperglycemia (150 to 170 mg/dL), and mild hypokalemia (3.5 to 3.7 mEq/L). Although hemorrhagic hypotension reduces lung perfusion, arterial hypoxemia should not be attributed simply to blood loss, but instead should prompt investigation for aspiration, airway obstruction, alveolar consolidation, or lung injury.

The second phase of organ injury from hemorrhagic shock occurs during resuscitation. The acute phase of hemorrhage initiates the inflammatory cascade, and resuscitation unleashes these volatile inflammatory mediators on the body, inducing organ injury. During resuscitation, neutrophils become more aggressive, binding to the lung endothelium and causing capillary leakage that characterizes acute respiratory distress syndrome (ARDS). Inflammatory cytokines are liberated, causing additional cellular damage and compounded by persistent microischemia in numerous organs due to an imbalance between vasodilation by nitric oxide (NO) and vasoconstriction by endothelins. The liver demonstrates centrilobular injury, demonstrated clinically by elevated transaminase levels, whereas the kidney may manifest acute spasm of the preglomerular arterioles, with resultant acute tubular necrosis. Although necessary with significant hemorrhage, resuscitation may exert greater injury on end-organs than the actual hypotensive insult.

Septic Shock

Septic shock can result from infection with any microbe, although no specific organism is identified in at least half of cases. Lipopolysaccharide (LPS), a component of the outer cell membrane of gram-negative bacteria, contributes to sepsis pathophysiology and is often used to approximate the disease in animal models. However, gram-positive organisms represent the leading cause of sepsis in hospitalized patients, indicating that the pathophysiology of sepsis cannot be explained by the response to LPS alone.

Although historically presented as the archetype of distributive or vasogenic shock, the clinical progression of septic shock is complex and varies over the course of the disease (see Chapter 127). Septic shock causes three primary effects in variable degrees that must be addressed during resuscitation: hypovolemia, cardiovascular depression, and induction of systemic inflammation. First, septic shock produces both relative and absolute hypovolemia, reducing right ventricular filling. Absolute hypovolemia results from gastrointestinal volume loss, tachypnea, sweating, and decreased fluid intake during development of the illness. Further relative hypovolemia results from increasing venous capacitance in conjunction with increased capillary leak, with the resultant loss of intravascular volume into third spaces.

Second, septic shock causes direct myocardial depression. Measurements of cardiac contractility have shown that mechanical function becomes impaired early in the course of septic shock, even in the

hyperdynamic stages prior to the development of decreased ejection fraction, which can be detected using advanced echocardiographic markers such as global longitudinal strain. The cause of this myocardial dysfunction is complex and incompletely understood but is likely caused by a combination of circulating inflammatory mediators such as tumor necrosis factor alpha (TNF-α) and interleukin-1 beta (IL-1β), overproduction of NO by inducible nitric oxide synthase (iNOS), as well as impairment in mitochondrial oxidative phosphorylation.

Finally, widespread systemic inflammation plays a role in the development and persistence of multisystem organ failure in sepsis through microvascular and mitochondrial dysfunction. Similar to hemorrhagic shock, systemic inflammation causes capillary leak in the lung, resulting in ARDS. Similar processes induce kidney and liver dysfunction as well. Despite the importance of inflammation in the pathophysiology of sepsis, clinical trials to date have yet to consistently demonstrate the effectiveness of specific or general anti-inflammatory therapies in mitigating this response. Although steroids continue to suggest potential benefit, clinical trial results are mixed.[1] Rather, the treatment of septic shock relies primarily on the reversal of shock, source control, and supportive care of evolving organ failure.

Cardiogenic Shock

Cardiogenic shock results when more than 40% of the myocardium becomes dysfunctional from ischemia, inflammation, toxins, or immune injury. Otherwise, cardiogenic shock essentially produces the same circulatory and metabolic alterations as those observed with hemorrhagic shock. Undoubtedly, impaired baseline cardiac function can contribute to the development of shock secondary to infection, hemorrhage, or vasodilatory drug overdose. However, when shock results from a pure cardiac cause, severe left or right ventricular dysfunction will be evident on echocardiography early in the course. Patients with shortness of breath, abnormal cardiac enzymes, ischemia on the EKG, or lacking fever are more likely to have a cardiac etiology of their shock.[2]

Neurogenic Shock

Neurogenic shock results from interrupted sympathetic and parasympathetic input from the spinal cord to the heart and peripheral vasculature, typically resulting from acute traumatic injury. Traditionally, it has been described as peripheral vasodilation in conjunction with bradycardia. However, ED patients with shock from acute spinal injury actually manifest a range of HRs and peripheral vascular resistance, most likely due to variable location of injury and the balance between disrupted efferent sympathetic and parasympathetic tone. As a result, no single presentation adequately summarizes patients with neurogenic shock. It is likely that the downstream pathophysiologic consequences of persistently impaired perfusion mimic those of cardiogenic and hemorrhagic shock.

MANAGEMENT

Decision Making

Patients presenting to the ED in shock frequently have no obvious cause on initial presentation, requiring timely assessment and treatment, sometimes before identifying the etiology. Rapid recognition of shock requires the integration of information from the immediate history and physical examination and is strongly supported by the presence of a worsening base deficit or lactic acidosis. In general, patients with shock exhibit a stress response; they are ill-appearing, asthenic, pale, often sweating, usually tachypneic, and often have a weak and rapid pulse (Box 3.2).

In all patients with shock, HR, BP, and oxyhemoglobin saturation should be continuously monitored. HR can be normal or low in shock and BP initially can be normal because of compensatory adrenergic reflexes. Noninvasive measurement of BP may be inaccurate in severe hypotensive states. Insertion of an arterial pressure monitoring line improves the ability to monitor the dynamic response to therapy, which is particularly important if vasoactive medications are administered, and should be placed if noninvasive measurements are unreliable or inconsistent. BP and HR correlate poorly with the cardiac index (CI) in shock and often underestimate the severity of systemic hypoperfusion. Moreover, children with hypovolemic shock frequently demonstrate a normal BP until they rapidly deteriorate.

BOX 3.2 Empirical Criteria for Diagnosis of Shock

- Ill appearance or altered mental status
- Heart rate >100 beats/min
- Respiratory rate >20 breaths/min or $Paco_2$ <32 mm Hg
- Arterial base deficit <–4 mEq/L or lactate level >4 mM/L
- Urine output <0.5 mL/kg/h
- Arterial hypotension >30 min duration, continuous

Regardless of cause, majority should be met in patients with shock.

Beyond vital signs, an assessment of end-organ perfusion can provide additional evidence of shock and a gauge of response to treatment. Urine output provides an excellent indicator of vital organ perfusion and is available with insertion of a Foley catheter. Measurement of urine output, however, requires 30 to 60 minutes for accurate determination of whether output is normal (>1.0 mL/kg/h), reduced (0.5 to 1.0 mL/kg/h), or severely reduced (<0.5 mL/kg/h), and is of limited use in patients with preexisting renal disease. Confusion or altered mental status can be an indicator of decreased cerebral perfusion, but its usefulness is limited in the setting of preexisting dementia or the setting of prescription or recreational drug use. Impaired liver or coagulation system responses are often not clinically evident but can be identified via blood tests. Generally, these organs are slow to respond to treatment, limiting the usefulness of their evaluation in the ED, except for providing ancillary evidence of end-organ injury.

More useful is real-time, arterial or venous lactate concentration and the base deficit. Both provide an accurate assessment of global perfusion and are strongly predictive of patient outcomes. A lactate concentration greater than 4.0 mM or base deficit more negative than −4 mEq/L are associated with circulatory insufficiency severe enough to cause subsequent multiple organ failure. A downward trend of the serum lactate concentration or upward trend of the base deficit, with correspondingly improving vital signs and urine output, reliably gauge the adequacy of resuscitation and prognosis in shock from any cause. A rising lactate concentration, refractory hypotension, or worsening base deficit despite ongoing resuscitation suggests the need for more intensive measures.

Once the diagnosis of shock has been made, the next step is to consider the cause of the shock. Fig. 3.1 shows a potential sequence of decisions to help arrive at a diagnosis in a patient with undifferentiated shock.

The history, vital signs, and physical examination documented by prehospital providers can be useful in ED evaluation and management. Patients with prehospital hypotension, whether of medical or traumatic origin, have up to a fourfold higher in-hospital mortality rate than patients without hypotension, so these values should not be discounted. On physical examination, dry mucous membranes suggest dehydration, whereas jugular venous distention suggests congestive cardiac failure, severe valvular abnormality, or right ventricular strain from pulmonary embolism (PE). Muffled heart sounds with

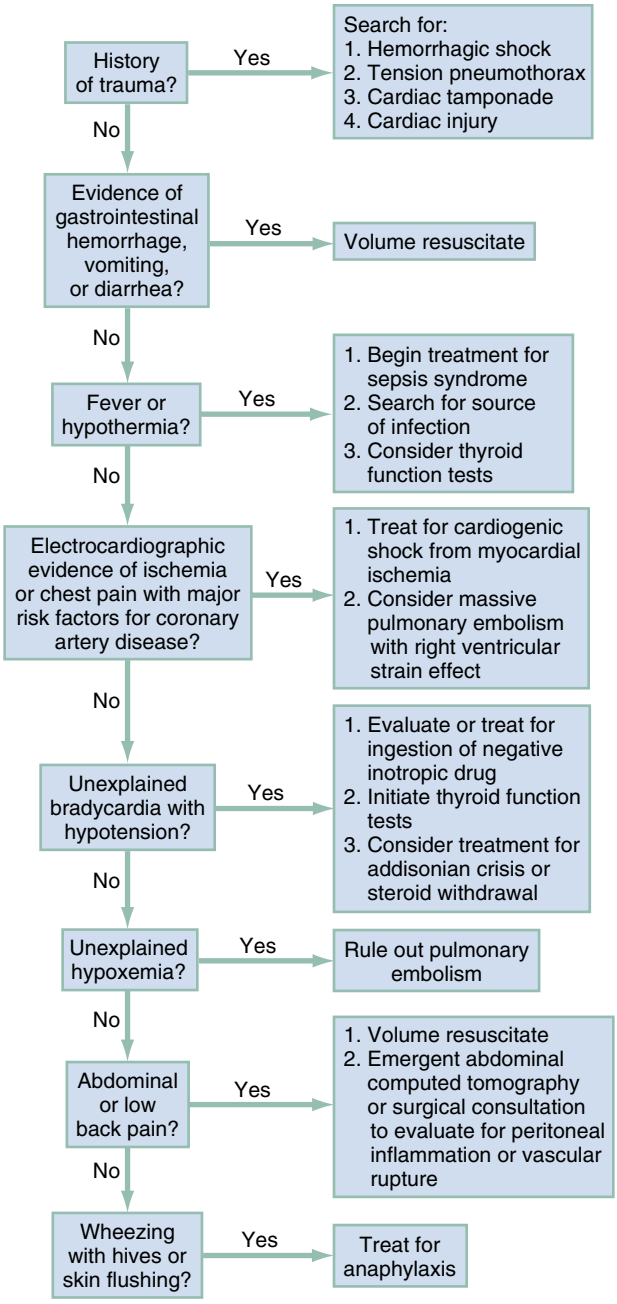

Fig. 3.1 Flow Diagram to Classify Undifferentiated Shock.

jugular venous distention suggest cardiac tamponade, whereas a loud, machine-like, systolic murmur indicates acute rupture of a papillary muscle or interventricular septum. Diffuse rhonchi suggest bronchospasm, cardiac failure, or pneumonia. Abdominal tenderness may indicate peritonitis, intestinal perforation, or occult trauma. The presence of melanic stool on rectal examination indicates gastrointestinal hemorrhage. The neurologic examination documents responsiveness, cognition, and the presence of any focal deficits and can be a means of clinically assessing end-organ perfusion. In children, documentation should include response to parents, appropriateness of crying, symmetry of grimace, symmetry of extremity movements, and motor tone.

Laboratory, radiographic, and other ancillary data can be useful to assess tissue and vital organ perfusion, injury from trauma, the source of infection with sepsis, or the cause of cardiac failure. Chest radiography, electrocardiography, finger stick glucose measurement, complete blood count (CBC), urinalysis, serum electrolyte levels, and kidney and liver function tests should be obtained for most patients with suspected shock. Arterial blood gas determination provides the base deficit and allows correlation of arterial gas tensions (Pao_2 and $Paco_2$) with those measured by pulse oximetry and capnography. Venous or arterial lactate level measurement is performed as early as possible in patients with suspected shock. If the peripheral venous lactate level is used, the effect of time, storage temperature, and tourniquet use have no significant effect if the measurement is done within 15 minutes after the sample was obtained.

Cardiac and abdominal bedside ultrasound scanning can screen for inadequate central venous volume, occult hemoperitoneum, abdominal aortic aneurysm, left ventricular failure, right ventricular dilation or septal bowing, cardiac tamponade, or the presence of a pneumothorax or hemothorax (see Chapter e3). A systematic ultrasound protocol can significantly improve the emergency clinician's ability to accurately diagnose the cause of undifferentiated shock in ED patients, while the finding of hyperdynamic left ventricular function in patients with undifferentiated shock strongly suggests sepsis.[3]

Consensus definitions of shock show the spectrum of hypoperfusion for the following three common causes of shock (Box 3.3):

1. *Hemorrhagic shock.* The American College of Surgeons has divided hemorrhagic shock into four stages, depending on the severity of blood loss and physiologic response to this loss. However, such arbitrary divisions are of little value and are not accurate reflections of degree of hemorrhage in clinical practice. A more useful approach defines hemorrhagic shock as being present when systemic hypoperfusion manifests as lactic acidosis or increasing base deficit with concomitant organ dysfunction.
2. *Septic shock.* International consensus definitions no longer incorporate the systemic inflammatory response syndrome (SIRS), but

BOX 3.3 Definitions and Criteria for Septic, Hemorrhagic, and Cardiogenic Shock

Septic Shock

Sepsis—Suspected or confirmed infection with a new or increased Sequential Organ Failure Assessment (SOFA) score of 2 from baseline (see Table 3.1)

Septic shock—Sepsis plus hypotension requiring vasopressors after fluid loading plus lactate >2 mmol/L (Patients requiring vasopressors with a normal lactate should still be treated as having shock)

Hemorrhagic Shock

Simple Hemorrhage

Suspected bleeding with pulse rate <100 beats/min, normal respiratory rate, normal blood pressure, and normal base deficit

Hemorrhage with Hypoperfusion

Suspected bleeding with base deficit <–4 mEq/L *or* persistent pulse rate >100 beats/min

Hemorrhagic Shock

Suspected bleeding, with at least four criteria listed in Box 3.2

Cardiogenic Shock

Cardiac Failure

Clinical evidence of impaired forward flow of the heart, including presence of dyspnea, tachycardia, pulmonary edema, peripheral edema, and/or cyanosis

Cardiogenic Shock

Cardiac failure plus four criteria listed in Box 3.2

TABLE 3.1 Calculation of Sequential Organ Failure Assessment Score

	0	1	2	3	4
Respiratory (PaO_2/FiO_2 ratio)	>400	301–400	201–300	101–200	≤100
Cardiovascular	Mean arterial pressure >70 mm Hg	Mean arterial pressure <70 mm Hg without vasopressor	Dopamine ≤5 mcg/kg/min or any dose of dobutamine	Dopamine >5 mcg/kg/min or norepinephrine ≤0.1 mcg/kg/min or epinephrine ≤0.1 mcg/kg/min	Norepinephrine >0.1 mcg/kg/min or epinephrine >0.1 mcg/kg/min or Any dose of vasopressin
Coagulation (platelet count; 10^9/L)	>150	100–149	50–99	20–49	<20
Renal (Creatinine; mg/dL)	<1.2	1.2–1.9	2.0–3.4	3.5–4.9	>5
Liver (Total Bilirubin; mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Neurologic (Glasgow Coma Scale)	15	13–14	10–12	6–9	<6

dL, Deciliter; *FiO_2*, fraction of inspired oxygen; *kg*, kilograms; *mcg*, micrograms; *mg*, milligrams; *min*, minute; *mm Hg*, millimeters of mercury; *PaO_2*, Arterial partial pressure of oxygen.

BOX 3.4 Variables Indicating Tissue Hypoperfusion

Hypotension
Tachycardia
Low cardiac output
Dusky or mottled skin
Delayed capillary refill
Altered mental state
Low urine output
Low central venous oxygen saturation
Elevated lactate level

rather have refocused the condition on the dysfunctional host response to an infection. As such, the most recent Sepsis-3 definitions identify sepsis as the suspicion of infection and a new or increase in the fairly complex Sequential Organ Failure Assessment (SOFA) score (Table 3.1) of 2 or more.[4]

Septic shock, meanwhile, has be redefined as sepsis plus shock requiring vasopressors and a lactate level greater than 2 mmol/L. Patients not meeting Sepsis-3 definitions still exhibit a nontrivial mortality rate, and should still undergo careful evaluation and prompt treatment.[5] Despite this new definition, in the United States the Centers for Medicare and Medicaid Services (CMS) still uses the 2001 definitions of severe sepsis, defined as 2 or more SIRS criteria plus evidence of end-organ dysfunction.[6] While SIRS often precedes shock, the nonspecific criteria for SIRS are found in a large variety of conditions, many of which are benign, so the clinical context is vital to understanding the significance of these physiologic variations. Regardless of the definition, initiation of treatment for empirically diagnosed sepsis should not await the onset of hypotension where possible. Incorporating an indicator of tissue hypoperfusion (Box 3.4) into the clinical assessment may improve identification of hypoperfusion, particularly in subtle cases.

3. *Cardiogenic shock.* Cardiogenic shock should be thought to be present whenever cardiac failure (ischemic, toxic, or obstructive) causes systemic hypoperfusion that manifests as lactic acidosis with organ dysfunction.

Box 3.5 presents the general treatment approach for these three common causes of shock.

BOX 3.5 Clinical Management Guidelines for Three Common Causes of Shock

Hemorrhagic Shock
- Ensure adequate ventilation and oxygenation.
- Provide immediate control of hemorrhage, when possible (e.g., traction for long bone fractures, direct pressure, REBOA), and obtain urgent consultation as indicated for uncontrollable hemorrhage.
- Initiate judicious infusion of isotonic crystalloid solution (10–20 mL/kg).
- With evidence of poor organ perfusion and 30-min anticipated delay to hemorrhage control, begin packed red blood cell (PRBC) infusion (5–10 mL/kg).
- With suspected massive hemorrhage, immediate PRBC transfusion may be preferable as the initial resuscitation fluid, with balanced transfusions of PRBCs, fresh frozen plasma, and platelets.
- Treat coincident dysrhythmias.

Cardiogenic Shock
- Ameliorate increased work of breathing; provide oxygen and positive end-expiratory pressure (PEEP) for pulmonary edema.
- Begin vasopressor or inotropic support; norepinephrine (0.5 mcg/min) and dobutamine (5 mcg/kg/min) are common empirical agents.
- Seek to reverse the insult (e.g., thrombolysis, percutaneous transluminal angioplasty).
- Consider intraaortic balloon pump counterpulsation for refractory shock.

Septic Shock
- Ensure adequate oxygenation; remove work of breathing.
- Administer 30 mL of crystalloid/kg and titrate infusion based on dynamic indices, volume responsiveness, and/or urine output.
- Begin antimicrobial therapy; attempt surgical drainage or debridement.
- Begin PRBC infusion for hemoglobin level <7 g/dL.
- If volume restoration fails to improve organ perfusion, begin vasopressor support with norepinephrine, infused at 0.5 mcg/min.

PRBCs, Packed red blood cells; *REBOA*, resuscitative endovascular balloon occlusion of the aorta.

Monitoring Perfusion Status and Obtaining Intravenous Access

Patients with cardiac failure or renal failure may benefit from closer measurement of dynamic variables of fluid responsiveness that can be measured from an arterial line (e.g., stroke volume variation or

stroke volume index) or a central venous line (central venous pressure [CVP]). A triple-lumen catheter allows for accurate measurement of the CVP, although the clinical utility of these measurements has been debated. However, a triple-lumen catheter can be useful in patients with poor peripheral access as it allows for safe infusion of vasopressors in hypotensive patients unresponsive to an initial fluid bolus, as well as simultaneous infusion of intravenous (IV) fluids and antibiotics when IV access is limited. In children, a 3- or 5-Fr bilumen catheter can be placed in the femoral vein with few complications.

If unable to attain adequate peripheral or central venous access rapidly in patients with shock, intraosseous (IO) access should be established, because it is easy and can provide a temporary method of administering fluid resuscitation and medications to adults and children. In situations where both central venous access and IO access are unavailable, but the patient remains in shock, vasoactive medications should be given through a large-gauge (18g or larger) peripheral catheter at the level of the antecubital fossa or more proximally.

If vasoactive medications are administered, additional peripheral IV catheters are required for infusion of crystalloid and other treatments. Many patients with renal disease or cancer often have indwelling catheters in place. In patients with empirical criteria for shock, this catheter should be used for IV access, unless satisfactory access has already been established at other anatomic sites. In EDs where the standard practice is not to use these ports at the request of other clinicians, a specific hospital policy and training session should be developed to make an exception in the case of shock. In general, the risk of the failure to administer fluids and vasoactive agents rapidly outweighs considerations about preservation of the line for future therapy.

Quantitative Resuscitation

Quantitative resuscitation, also called goal-directed therapy, goal-oriented resuscitation, or hemodynamic optimization, was first described in 1988 and refers to the practice of resuscitating patients to predefined physiologic endpoints (i.e., CVP, central venous oxygen saturations) indicating that systemic perfusion and vital organ function have been restored. In the ED, routine use of central venous monitoring for patients with septic shock does not improve outcomes compared to usual care. Therefore, a central line is typically placed when there is lack of adequate peripheral access or anticipated use of high-dose vasopressor agents.

Over the last 3 decades, many studies have evaluated the efficacy of a quantitative approach to shock. In such an approach, patients are resuscitated early, within the first 6 hours, to achieve normalization of markers of volume status, perfusion, and adequate oxygen delivery. The first description of an ED-based quantitative resuscitation strategy targeted specific volume, perfusion, and oxygen delivery endpoints and was termed *early goal-directed therapy* (EGDT). As mentioned previously, external validation in three large multicenter trials did not demonstrate a mortality advantage for patients receiving EGDT compared to modern usual care of shock. Patients in these studies received 2 to 4 L early volume resuscitation and relatively prompt antibiotic administration, suggesting that early recognition and initiation of fluid and antibiotic therapy, in conjunction with close monitoring and thoughtful care, may be more important than the use of invasive measurements to attain the specific resuscitation goals suggested by earlier studies.

Given these findings, the importance of specific quantitative targets for the resuscitation of ED septic shock is unproven. For complex patients for whom the physician is unclear as to the adequacy of oxygen delivery, it is recommended to use one of two readily available clinical methods, central venous oxygen saturation or lactate clearance. Central venous oxygen saturation drawn from the central circulation (via a triple lumen catheter) was a key component of EGDT and has been used as an indicator of the ratio of oxygen delivery to oxygen consumption. Central access is time-consuming and invasive, therefore, this approach is rarely taken in the ED anymore.

Alternatively, lactate clearance refers to serial measurements of the venous or arterial lactate level. Lactate clearance has been shown to be equivalent to central venous oxygen saturation as an endpoint of early septic shock resuscitation, though it has not been systematically studied in other forms of shock. Lactate clearance measurements are easily obtained from peripheral venous blood and therefore represent a simpler and preferred endpoint of resuscitation. If the lactate concentration has not decreased by 10% to 20% 2 hours after resuscitation has begun, additional steps are undertaken to improve systemic perfusion.

Pharmacology

Volume Replacement

Most patients with shock can be fully resuscitated with peripheral venous access established with at least two 18-gauge catheters. The goal in volume replacement is slightly elevated left ventricular end-diastolic volume, which is difficult to measure in the ED. Historically, CVP has been used to estimate right ventricular filling pressure and has been used in some quantitative resuscitation algorithms. CVP does not accurately reflect left ventricular end-diastolic volume, and poorly predicts the hemodynamic response to a fluid bolus. Thus, fluid resuscitation should not be based solely on CVP. A better approach involves the use of clinical response to fluid resuscitation, such as increases in urine output, BP, and decreasing lactate concentrations, either alone or in combination with CVP measurements. In patients for whom fluid resuscitation may be associated with higher risk of harm (e.g., severe systolic heart failure, dialysis-dependent renal failure), the use of dynamic variables of fluid responsiveness that can be measured from an arterial line (e.g., stroke volume variation, stroke volume index, passive straight leg raise) may be beneficial over empirical fluid boluses, but their use in the ED to guide therapy has not been sufficiently studied to recommend routinely.

Crystalloids. Standard treatment for hemorrhagic shock historically consisted of rapidly infusing several liters of isotonic crystalloid in adults or three successive 20-mL/kg boluses in children. Some studies have endorsed the concept of delayed resuscitation or hypotensive resuscitation for hemorrhagic shock (see Chapter 32), although recent consensus statements have come out against this practice and favor early transfusion and minimization of hypotension.[7]

Recent data suggest balanced isotonic crystalloids (predominantly lactated Ringers) decrease the risk of acute kidney injury in admitted ED patients, while treatment of patients in shock with balanced fluids in the intensive care unit decreases the combination of renal failure and death.[8] Therefore, balanced crystalloids are recommended once a patient is identified as having shock, if available, and in the absence of competing priorities (e.g., medication incompatibility with limited intravenous access). Initial volume replacement consists of the rapid infusion of 20 to 25 mL of isotonic crystalloid per kilogram, though these numbers represent conventional volumes utilized and clear evidence for the superiority of a specific volume of crystalloid bolus is lacking. More rapid initiation of fluid resuscitation may be associated with improved patient outcomes, reiterating the importance of early identification and treatment of shock.[9]

Colloids and hypertonic saline. Colloids offer the theoretical advantage of a high osmotic pressure, which should help maintain normal intravascular volume. Colloids, including albumin, have been used in patients with hemorrhage, but at a considerable increase in cost and without effect on morbidity or mortality. Initial resuscitation fluid treatment with hypertonic saline or hypertonic saline and dextran, compared with normal saline, does not decrease mortality in studies to date.[10]

In the setting of septic shock, initial fluid resuscitation should consist of serial boluses of IV isotonic crystalloid as long as the patient continues to demonstrate a positive hemodynamic response to fluid loading, and the majority of ED patients are initially volume responsive.[11] Persistent hypotension, despite 30 mL/kg of IV fluid, indicates the need to add vasopressors to the resuscitation (see below). If patients require large volumes of crystalloid (>4 L), we recommend adding 5- to 10-mL/kg boluses of a natural colloid (e.g., albumin), rather than additional isotonic crystalloid alone, until further volume fails to improve hemodynamics. We do not recommend the use of synthetic colloids, such as hydroxyethyl hetastarch, which are associated with a higher risk of renal failure. The infusion of hemoglobin-based blood substitutes as alternatives to packed red blood cells (PRBCs) for the resuscitation of hemorrhagic shock has been extensively studied and is associated with significant increased risk of death and myocardial infarction; we recommend against their use.

Blood products. In the setting of hemorrhage *or* a critically low hemoglobin level (<7 g/dL), we recommend transfusion of PRBCs (1 to 2 units in adults or 5 to 10 mL/kg in children) if criteria for shock persist despite crystalloid infusion. Fully crossmatched blood is safest and is always preferable unless the patient's need is considered sufficiently urgent to justify the use of type-specific or even uncrossmatched blood. Use of the latter is generally confined to patients with hemorrhagic shock with persistent, severe, arterial hypotension and massive or uncontrolled hemorrhage. O-negative blood is used in women of childbearing age, and O-positive blood is used in all others (see Chapter 108).

If patients require more than 2 units of PRBCs for hemorrhage, we recommend a balanced resuscitation using PRBCs, fresh-frozen plasma, and platelets in a 1:1:1 ratio, which is associated with better hemostasis and lower death due to exsanguination by 24 hours. We recommend transfusion of PRBCs when hemoglobin levels are less than 7 g/dL in patients with other forms of shock unless specific contraindications exist or patients refuse transfusion.

Vasopressors

The primary goal of vasopressor support is to increase cardiac output and oxygen delivery to vital organs when crystalloid resuscitation alone is inadequate. To reduce the potential for limb damage from extravasation from a peripheral IV injection, vasoactive medications are optimally administered through a central venous catheter, although this is not always feasible in the acute setting. In the setting of hemorrhage, vasopressors represent a purely ancillary means of supporting BP and their use is associated with an increased risk of death, so focus should remain on administration of blood products and control of ongoing bleeding as the primary means of reversing shock.[12]

Patients with septic shock who remain hypotensive after a 30-mL/kg fluid bolus generally require vasopressor support. Norepinephrine is the vasopressor of choice for correction of hypotension in septic shock. In patients who remain in shock after initial crystalloid boluses, norepinephrine should be initiated at a rate of 0.05 mcg/kg/min, or 3 to 5 mcg/min for most adult patients, and titrated at 3- to 5-minute intervals until the mean arterial pressure is greater than 65 mm Hg. There is no clear data to suggest higher BP goals improve outcomes, even in patients with preexisting hypertension,[13] and there are no data regarding an absolute maximum dose. Vasopressin may be added as a second vasopressor agent, be initiated at 0.03 to 0.04 units/min, but there are no data that vasopressin alters outcomes. Vasopressin or phenylephrine can be a useful adjunct or alternative agent if the patient develops a tachydysrhythmia (e.g., atrial fibrillation with rapid ventricular response), to improve both HR and cardiac output. Angiotensin II represents a newly FDA approved vasopressor, but there is insufficient evidence to recommend its routine use at this time.[14]

Following vasopressor initiation, particularly in patients who require high or rapid upward titration of the vasopressor dose, patients should be reassessed for their responsiveness to additional fluid boluses through the use of dynamic variables or empirical 500-mL boluses, with careful attention to the clinical response. Vasopressor support, along with crystalloid therapy, is continued until the patient can maintain the goal mean arterial pressure without vasopressor support, which can be tested at the bedside by weaning the vasopressor agent, such as decreasing norepinephrine at a rate of 2 to 3 mcg/min every 5 to 10 minutes.

Patients with neurogenic shock may need some combination of increased HR, increased contractility, and vasoconstriction. As such, norepinephrine represents a reasonable first choice, although unlike in sepsis, studies have not demonstrated superiority of one vasopressor over another. Phenylephrine may be used if the hypotension appears to be purely a result of peripheral vasodilation or the patient develops a tachydysrhythmia from norepinephrine.

Recent data suggest epinephrine, alone or with other agents, is associated with an increased risk of death in cardiogenic shock.[15] As such, norepinephrine or inotropes are preferred first-line pharmacologic agents for cardiogenic shock.[16]

Inotropes

Dobutamine may be used with norepinephrine to increase cardiac output and maintain adequate oxygen delivery in both cardiogenic and septic shock. In the setting of cardiogenic shock, indications for dobutamine may include some combination of hypotension, cool extremities, poor urine output, and elevated lactate level. In the setting of septic shock, if the lactate level does not decrease at least 10% despite fluid resuscitation and vasopressor administration (see earlier), particularly in the setting of echocardiographic evidence of decreased left ventricular function, dobutamine can be added at a dose of 2 mcg/kg/min and titrated every 5 to 10 minutes, to a maximum of 20 mcg/kg/min. Due to stimulation of vasodilating peripheral beta receptors, dobutamine has the potential to decrease the BP, so careful attention to a patient's individual response is necessary. If simultaneous BP and inotropic support is necessary for septic shock, epinephrine alone, 0.2 mcg/kg/min starting dose, provides similar outcomes and adverse event rates as a combination of norepinephrine plus dobutamine. When norepinephrine is the first pressor initiated and an inotrope is indicated, we recommend the addition of dobutamine, with the ability to titrate each agent individually. However, it is acceptable as an alternative to discontinue the norepinephrine and initiate epinephrine infusion to provide vasopressor and inotropic support via a single agent.

Antimicrobial Therapy

Treatment of the infection with antimicrobial therapy and, where necessary, surgical drainage (see later, "Source Control"), should be instituted as soon as practical in cases of septic shock. Current evidence does not support an absolute time requirement for administration but, when septic shock is the working diagnosis in the ED, we recommend initiation of appropriate antibiotics as soon as practical after the diagnosis is made (see Chapter 127). When there is no focus of infection identified in a patient with presumed septic shock, a semisynthetic penicillin with a β-lactamase inhibitor or fourth generation cephalosporin, in combination with vancomycin, is a rational empirical choice. One such regimen would include piperacillin-tazobactam, 4.5 g IV every 6 hours or cefepime 2 g IV every 8 hours, and vancomycin, 30 mg/kg (maximum dose, 2 g) given every 12 hours, adjusted as appropriate for trough levels and renal failure. Addition of another agent (such as levofloxacin, 750 mg IV every 12 hours) is recommended to provide double

coverage in patients with risk factors for or in areas of high prevalence of multi-drug resistant bacteria, particularly *Enterococcus* and *Pseudomonas* spp. (see Chapter 62). Use of another agent with an alternative mechanism with the intention of increasing bactericidal kill rates and clearances in patients without suspected multi-drug resistant bacteria remains controversial and is not universally recommended.

Patients with neutropenia and sepsis syndrome are at particular risk for progressive sepsis, organ failure, and death. Neutropenia can be suspected in patients who have recently undergone chemotherapy, and these patients often know that they are neutropenic. Antimicrobial administration is particularly urgent for these patients and should occur rapidly after blood cultures are obtained, optimally within the first hour, in parallel with crystalloid administration. Antibiotic considerations for the neutropenic patient are discussed in Chapter 112. Chemotherapy patients with sepsis represent a special challenge because the pathophysiology may be complicated by anemia, thrombocytopenia, dehydration from vomiting, and the effects of adjunctive steroid therapy. Chemotherapy patients often have indwelling catheters, which predispose them to more unusual causes of sepsis, including gram-positive bacteria and fungi.

Corticosteroids

High-dose, short-course corticosteroid therapy in unselected patients with septic shock likely decreases the duration of shock with potential risks of secondary infection and gastrointestinal bleeding. There is no evidence of reduced ICU or in-hospital mortality, but a possible small reduction in mortality at 28 days.[17] Due to the nondefinitive results of steroids trials to date, empiric corticosteroids are not routinely recommended in all ED patients with sepsis. Most current guidelines recommend that low-dose hydrocortisone be administered only to patients receiving chronic steroid replacement and in patients with refractory shock despite adequate fluid and vasopressor support. Corticotropin stimulation testing is no longer considered of value.

Special Cases

Systemic thrombolytic therapy is indicated in patients with shock from PE (see Chapter 74) without contraindications. Specific treatments for shock due to poisoning with vasoactive medications and other toxins are discussed in the relevant chapters in this text.

Devices and Procedures

Ventilation

Rapid sequence intubation is the preferred method of airway control in most patients with refractory shock (see Chapter 1). Tissue hypoperfusion leads to increasing fatigue of the muscles of respiration, and respiratory failure commonly supervenes in patients with persistent shock. Intubation prevents aspiration, increases oxygenation, treats acute respiratory failure, provides initial treatment for metabolic or hypercarbic acidemia, and protects the patient who will be sent to an uncontrolled environment for testing. Intubation reduces the work of breathing, which, in the patient with hypoperfusion, further exacerbates lactic acidemia. Strenuous use of accessory respiratory muscles can increase oxygen consumption by 50% to 100% and decrease cerebral blood flow by 50%. More importantly, if the patient has increased airway resistance (e.g., bronchospasm with anaphylaxis) or a decrease in lung compliance (e.g., pulmonary edema, ARDS), a more negative intrathoracic pressure must be generated to fill the lungs with each inspiration. The greater suction effect is also exerted on the left ventricle, impeding its ability to eject and increasing functional afterload. Positive-pressure ventilation removes this impedance and can improve ventricular function and cardiac output up to 30%. The use of etomidate for airway management in patients with septic shock is discussed in Chapter 1.

Source Control

Controlling hemorrhage remains the cornerstone of treating hemorrhagic shock, and evidence continues to support immediate surgery when direct vascular control cannot otherwise be obtained (see Chapters 32 and 38). In the setting of traumatic shock from an injury distal to the renal arteries without evidence of aortic injury, Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) is a more recent technology that can maintain cardiac and cerebral perfusion while definitive source control is obtained through the insertion of an intra-aortic balloon via an arterial puncture. However, additional training is required, and it is not universally available.[18] Gastrointestinal bleeding may require urgent endoscopy, often in the ED or ICU, and aortic rupture requires emergency consultation by a vascular surgeon. In septic shock related to an abscess, aggressive infection (e.g., necrotizing fasciitis or perinephric abscess; see Chapter 126), or wound (e.g., toxic shock syndrome; see Chapter 126), removal of the infectious stimulus through surgical intervention should proceed as soon as practical.

Mechanical Circulatory Support and Percutaneous Coronary Intervention

The use of mechanical circulatory support and percutaneous coronary intervention in selected patients with cardiogenic shock or acute cardiovascular emergencies is discussed in Chapters 64 and 67.

Pericardiocentesis and Thrombectomy

Shock caused by mechanical obstruction can be managed by direct intervention. Large, acute pericardial effusions should be managed with pericardiocentesis. Tension pneumothorax or hemothorax should be treated with tube thoracostomy. Surgical thrombectomy for massive PE is performed rarely. Direct thrombolysis via interventional radiology is gaining acceptance as a therapeutic option in patients with shock, particularly if systemic thrombolytics are contraindicated.

OUTCOMES

Outcomes for patients with shock vary with the underlying cause of the shock state and the premorbid or comorbid status of the patient. Outcomes have progressively improved, with emphasis on early diagnosis and treatment. In general, persistent hypotension (refractory shock) is associated with worse outcomes. Patients meeting consensus definitions for hemorrhagic shock have a mortality rate of about 20%, whereas this exceeds 40% in septic and cardiogenic shock.

CHAPTER 3: QUESTIONS AND ANSWERS

1. A 72-year-old male presents with crushing substernal chest pain with associated diaphoresis starting 2 hours prior to arrival. Blood pressure is 72/50. ECG shows anterior ST elevation myocardial infarction. Lungs demonstrate diffuse rales, and chest XR demonstrates bilateral infiltrates consistent with pulmonary edema. Bedside ultrasound demonstrates severely impaired left ventricular function. In addition to arranging for rapid reperfusion with either cardiac catheterization or intravenous thrombolytics, which is the most appropriate initial treatment for his cardiogenic shock?

a. Bolus of 30 mL/kg crystalloid fluid.
b. Initiate epinephrine at 0.1 mcg/kg/min.
c. Initiate norepinephrine at 0.1 mcg/kg/min.
d. Transfer patient for placement of an intraaortic balloon catheter.

Answer: c. Norepinephrine (or inotropes such as dobutamine) are first-line agents for cardiogenic shock. Crystalloid fluids should not be administrated to patients with cardiogenic shock and pulmonary edema. Epinephrine carries an increased risk of tachydysrhythmias and no better outcomes than norepinephrine or inotropes in cardiogenic shock. While this patient might benefit from an intraaortic balloon pump, treatment of his shock should not be delayed through transfer.

2. A 56-year-old female presents with fever, dyspnea, and productive cough. Heart rate is 122, respiratory rate is 24, and blood pressure is 82/46. Which of the following is the most appropriate choice for initial fluid resuscitation?

a. Lactated Ringers.
b. Blood products.
c. Hydroxyethyl starch (HES).
d. Normal Saline.

Answer: a. Balanced crystalloids are the preferred choice of fluid for patients with septic shock. Blood products may be indicated for patients with a hemoglobin greater than 7 mg/dL. Synthetic colloids such as HES cause renal failure and should be avoided. Hypertonic saline has not been proven to improve outcomes in sepsis. Normal saline can cause a hyperchloremic metabolic acidosis and acute kidney injury, particularly using large volumes.

3. An 18-year-old unrestrained driver is transported to the emergency department (ED) after being thrown from his vehicle during a motor vehicle collision. He was intubated in the field and received an intravascular bolus of 3 L of normal saline before arrival to the ED. His initial Glasgow Coma Score (GCS) is 7, and his blood pressure on arrival is 80/50 mm Hg. Which of the following would be the most appropriate to initiate immediately on arrival to the ED?

a. Dobutamine.
b. Dopamine.
c. Norepinephrine.
d. Packed red blood cell (PRBC) transfusion.

Answer: d. In patients with signs of hemorrhagic shock, immediate PRBC transfusion should be initiated. This assists with volume expansion and oxygen delivery to the brain. Vasopressors and positive inotropes will be of little benefit before volume replacement, and hetastarch has no proven benefit for initial resuscitation in head injury patients.

4

Brain Resuscitation

Craig A. Williamson and William J. Meurer

KEY CONCEPTS

- Neuronal injury is a dynamic process that continues for hours or days after an ischemic insult to the brain.
- Avoid hypotension and hypoperfusion by maintaining a mean arterial pressure greater than 65 mm Hg and a cerebral perfusion pressure of 60 mm Hg.
- Maintain normal oxygen levels or mild hyperoxemia, with a PaO_2 of 80 to 120 mm Hg and oxyhemoglobin saturations in the high 90s. Avoid hypoxemia and significant hyperoxemia.
- Intracranial pressure (ICP) elevation can further exacerbate ischemic brain injury. Initial management should include optimizing patient positioning while providing adequate analgesia and sedation. Management should then be escalated in a stepwise fashion to include hypertonic therapy, deeper sedation and ultimately barbiturates, hypothermia, and surgery as needed.
- Avoid hyperventilation (target $PaCO_2$ of 35 to 40 mm Hg) as it reduces cerebral blood flow. In the event of life-threatening cerebral herniation or significant ICP elevation, therapeutic hyperventilation is appropriate only as a short-term intervention bridging to more definitive therapy (i.e., craniotomy).
- Promptly treat seizures with intravenous (IV) lorazepam. Prophylactic administration of antiepileptic drugs is not recommended. Initiate continuous electroencephalogram (EEG) monitoring if ongoing seizures are a concern.
- Fever is an important mediator of secondary brain injury. Treat temperatures greater than 38°C with acetaminophen.
- Unresponsive survivors of out-of-hospital cardiac arrest should have rapid initiation of targeted temperature management (TTM) in the emergency department and be maintained at a constant target of 33°C–36°C in an ICU setting for 24 h after resuscitation.
- Because withdrawal of life-sustaining treatment due to perceived poor neurological prognosis is the most common cause of death in cardiac arrest survivors, it is important to provide accurate and evidence-based prognostic information to families. The neurological examination is generally an unreliable predictor of outcome until at least 72 h from normothermia.

FOUNDATIONS

Background and Importance

Despite our recognition of the brain's dominant role in determining quality of life, the ability to intervene and reverse neuronal injury remains limited. Consequently, modern brain resuscitation techniques are focused on restoring cerebral homeostasis and mitigating the effects of secondary brain injuries. Hypoxic-ischemic injury following cardiac arrest can be seen as a model of global ischemic disease, and recent advances in understanding its pathophysiologic mechanisms have led to improvements in neurologic outcomes. Although hypoxic-ischemic injury represents a so-called pure form of brain ischemia, its underlying pathology has significant overlap with other cerebral injuries, such as stroke and traumatic brain injury (TBI). Thus, many of the physiologic principles of brain resuscitation following cardiac arrest apply to these conditions. Therefore, this chapter reviews the pathophysiology of ischemic brain injury and discusses therapies for improving neurologic recovery following cardiac arrest and other critical neurologic illnesses in which cerebral ischemia may occur.

Anatomy, Physiology, and Pathophysiology

The human brain consists of 10 billion neurons, each with multiple connections to other cells, totaling an estimated 500 trillion synapses. Although the brain constitutes only 2% of body weight, it receives 15% of the body's cardiac output and accounts for 20% of its overall oxygen use. When the brain is deprived of adequate blood flow, the resulting ischemia is characterized by a bewildering array of interrelated physiologic and cellular responses that ultimately result in neuronal cell death (Fig. 4.1). Although this complex cascade of events can be triggered by periods of ischemia lasting only a few minutes, the resulting neuronal death is usually delayed by hours or days. Furthermore, the biology of cerebral cell death after global cerebral ischemia follows the pattern of delayed cerebral cell death after stroke, TBI, and other forms of hypoxic or toxic brain injury, with slight variations. Increased understanding of the brain's response to injury during the period between insult and neuronal cell death will eventually allow more specific brain resuscitation therapies.

Elevated Intracranial Pressure

Intracranial pressure (ICP) is an essential consideration in ischemic brain injury because cerebral ischemia can directly result in ICP elevation. Failure of oxidative phosphorylation depletes adenosine triphosphate (ATP) stores, resulting in an inability to actively maintain osmotic gradients. Increased intracellular osmolarity leads to water influx and the development of cytotoxic edema, which usually peaks 48 to 72 hours after injury. By decreasing cerebral perfusion pressure (CPP), elevated ICP is also an important contributor to secondary brain injury. This relationship is discussed in further detail as follows; additional information on ICP management is contained in subsequent sections.

To understand the pathophysiology of elevated ICP, note that the skull is a rigid container whose relatively non-compressible contents include the brain (~80%), blood (~10%), and cerebrospinal fluid (CSF; ~10%). According to the Monro-Kellie doctrine, any addition to the volume of one of these components—for example, increased brain volume due to cerebral edema—must be offset by reducing the volume of the other contents or the ICP will rise.

Typically, adaptation to increased intracranial volume is initially accomplished by shifting CSF from the intracranial to spinal subarachnoid compartment. Approximately two-thirds of cerebral blood volume is contained in the cerebral veins and dural sinuses, and this venous capacitance can be reduced to accommodate increased intracranial volume further. Unfortunately, these mechanisms can become quickly exhausted, resulting in decreased compliance and a rapid increase in ICP (Fig. 4.2). This may occur rapidly with acute cerebral injury or slowly with mass lesions such as tumors.

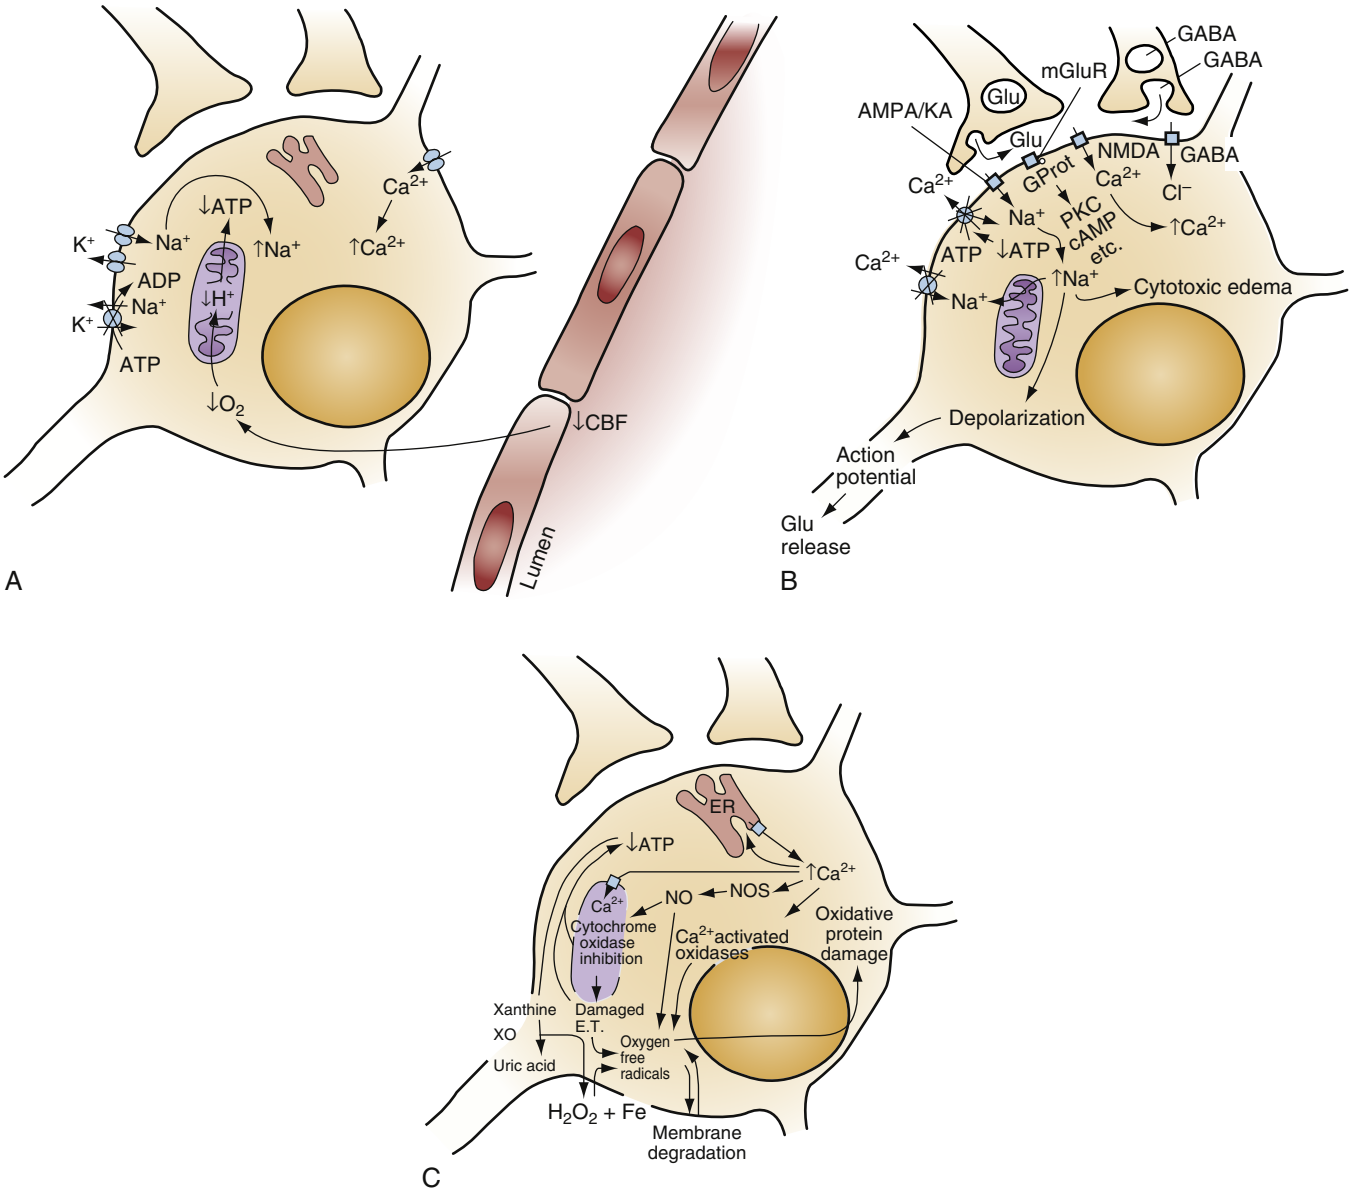

Fig. 4.1 **Synopsis of Events Contributing to Neuron Cell Death Cascade After Ischemia.** (A) Decreased cerebral flow *(CBF)* and arterial oxygen content during ischemia cause decreased adenosine triphosphate *(ATP)* production, failure of ATP-driven ion pump efflux of potassium ions (K^+), and influx of sodium ions (Na^+) and calcium ions (Ca^{2+}) through voltage-gated channels. *ADP,* Adenosine diphosphate. (B) Na^+ influx causes depolarization and glutamate *(Glu)* release, opening Glu receptor α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate *(AMPA)* and kainate *(KA)* channels and exacerbating intracellular Na^+ overload. Increased Na^+ concentration ($[Na^+]i$) leads to cytotoxic edema. Glu-mediated *N*-methyl-D-aspartate *(NMDA)* channels allow intracellular Ca^{2+} overload. Insufficient ATP causes failure of energy-dependent Ca^{2+} pumps, and high $[Na^+]i$ prevents removal of Ca^{2+} by Na^+/Ca^{2+} exchange pumps. γ-Aminobutyric acid *(GABA)* release can attenuate excitatory changes by opening a receptor-gated Cl^-. (C) Increased $[Ca^{2+}]i$ is amplified by calcium-induced release of Ca^{2+} from the endoplasmic reticulum *(ER)*. Mitochondria may be injured attempting to buffer increasing $[Ca^{2+}]i$, resulting in further metabolic failure and diminished ATP. Ca^{2+} activates nitric oxide synthase *(NOS)*, transforming it to nitric oxide *(NO)*, which is amplified by NO activation of NOS. NO contributes to the formation of damaging oxygen free radicals and inhibits mitochondrial cytochrome oxidase function. ATP degradation to xanthine and then uric acid by xanthine oxidase *(XO)* yields hydrogen peroxide (H_2O_2), which reacts with iron to form dangerous oxygen radicals. Oxygen free radicals react with lipids in the cell membrane, which leads to membrane degradation and more free radicals. Oxygen free radicals also can damage proteins.

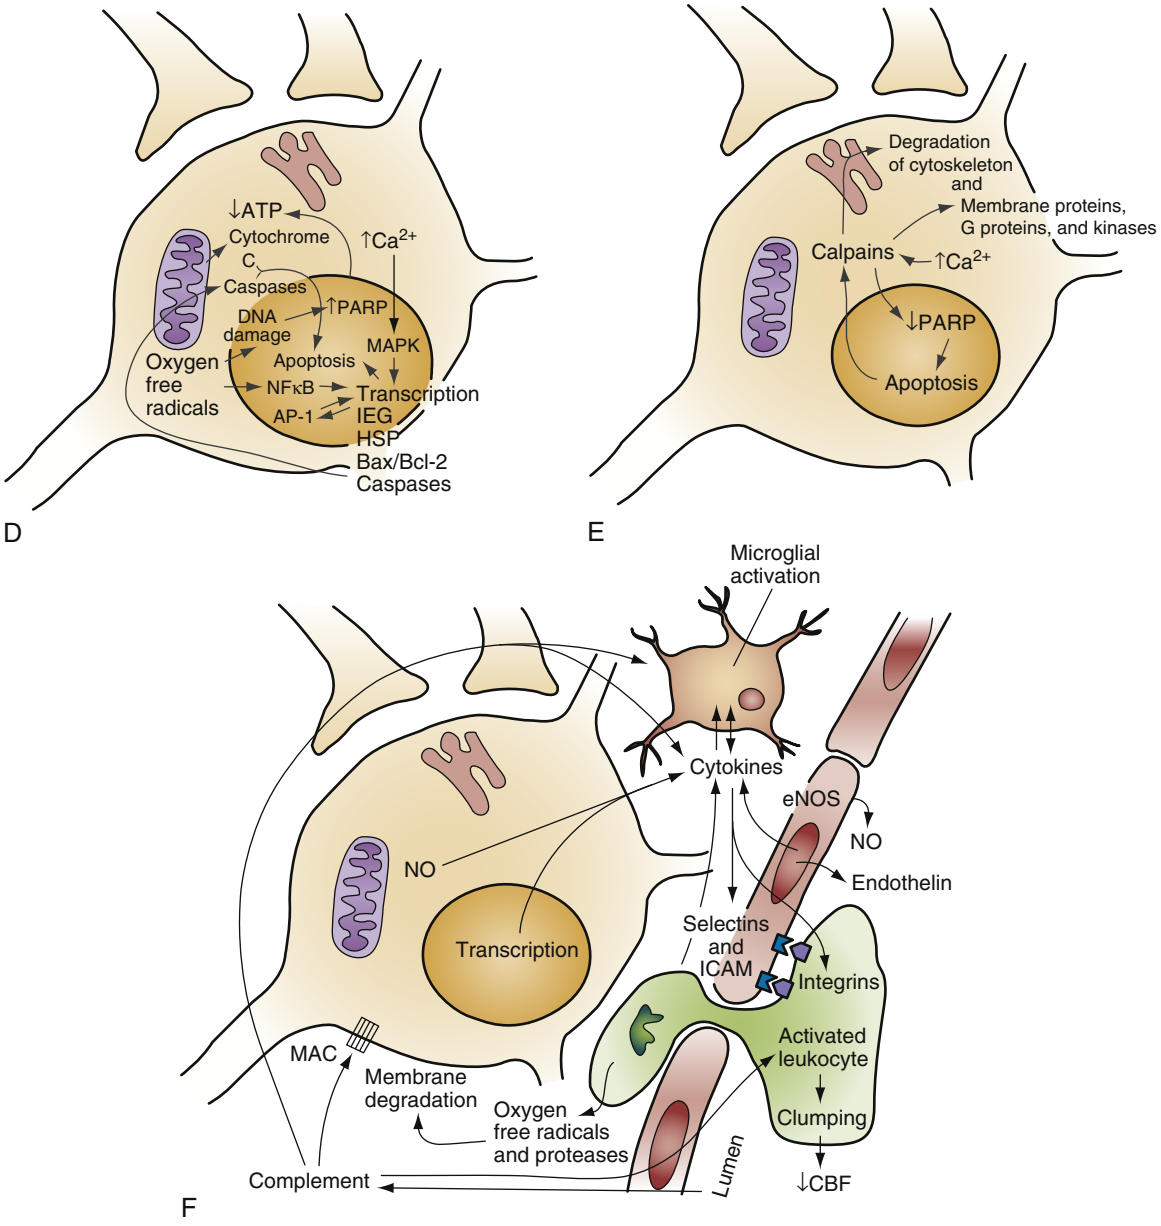

Fig. 4.1 cont'd (D) Ca^{2+} also activates kinase transcription factors, such as mitogen-activated protein kinase *(MAPK)*. Oxygen radicals trigger nuclear factor κB *(NFκB)*, another transcription factor. Many genes, including immediate early genes *(IEGs)*, heat shock protein *(HSP)* genes, genes for caspases, and the *Bax/Bcl-2* systems, are activated. IEG products include AP-1, another transcription factor. Mitochondrial release of cytochrome c, existing and newly formed caspases, and other factors trigger apoptosis. DNA is damaged by oxygen free radicals and by endonucleases formed in apoptosis. DNA damage activates poly(ADP-ribose) polymerase *(PARP)*, which further depletes ATP stores. (E) Ca^{2+} and apoptosis activate calpains, proteases that degrade a variety of structural elements (e.g., cytoskeletal and membrane proteins), signaling elements (e.g., G proteins, kinases), and PARP. (F) Transcription and NO contribute to the neuronal expression of cytokines, chemokines, and growth factors. These intercellular signals activate complement, epithelial cells, leukocytes, and microglia. Complement can amplify chemotactic signals, activate microglia directly, or cause cellular damage by creation of the membrane attack complex *(MAC)*. Leukocyte integrins, epithelial cell selectins, and intercellular adhesion molecules *(ICAMs)* allow demargination. Activated leukocytes cause neuronal injury by releasing potent oxidants and protease. Cerebrovascular resistance may be affected by the epithelial release of NO and endothelin and by leukocyte clumping. *ADP,* Adenosine diphosphate; *$[Ca^{2+}]i$,* Ca^{2+} concentration; *cAMP,* cyclic adenosine monophosphate; *eNOS,* endothelial nitric oxide synthase; *E.T.,* enzyme trafficking; *mGluR,* metabotropic glutamate receptor; *PKC,* protein kinase C.

In its final stages, uncontrolled intracranial hypertension results in downward herniation of the cerebellar tonsils through the foramen magnum, thereby compressing critical cardiorespiratory centers in the medulla. Prior to or concurrently with this, elevated ICP can exacerbate ischemic injury by reducing cerebral blood flow (CBF). CPP is equal to the mean arterial pressure (MAP) minus ICP. As ICP increases, CPP decreases, which is compensated for by cerebral arteriolar vasodilation. Unfortunately, this vasodilation may increase cerebral blood volume, which can additionally increase ICP and further reduce CPP. This vicious cycle is one of the primary inciting

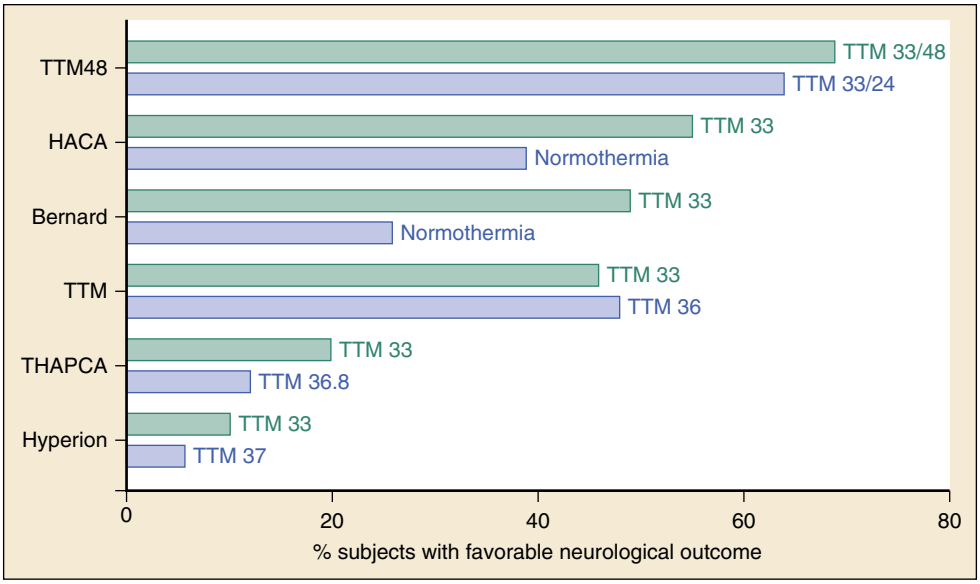

Fig. 4.2 Favorable Neurological Outcomes Across Cardiac Arrest Randomized Trials. Studies of neurologic outcome after out-of-hospital cardiac arrest (OHCA) generally demonstrate better outcomes with 33°C and longer duration of targeted temperature management (TTM). TTM48 demonstrated numerically better outcomes with 48 hours versus 24 hours of cooling but was not powered to detect the difference observed.[7] The 2002 Hypothermia After Cardiac Arrest (HACA) and Bernard trials compared cooling to no temperature management with large treatment effects. The 2013 TTM trial did not demonstrate the superiority of a target of 33°C versus 36°C, although with a median time to bystander CPR of 0 minutes likely enrolled a relatively mildly affected population. The Therapeutic Hypothermia After Pediatric Cardiac Arrest (THAPCA) trial in children with OHCA also demonstrated numerically better outcomes with 33°C. The 2019 HYPERION trial included only non-shockable rhythm patients (and some patients in HYPERION were inpatient arrests), but demonstrated significantly better outcomes with TTM to 33°C.[26]

factors for the prolonged periods of refractory ICP elevation that can occur after global ischemic injury.

MANAGEMENT

Decision Making

Standard medical management of ischemic brain damage involves restoring CBF and preventing secondary insult. Many standard treatments have not been studied in prospective, randomized, controlled trials, but have been supported by clinical experience and limited experimental data. Although proposed and experimental neuroprotectant therapies are generally aimed at specific molecular interventions in the pathophysiology of ischemic brain injuries, as yet none of these have proven effective in clinical trials. In the case of ischemic and other secondary brain injuries following cardiac arrest, the American Heart Association (AHA), the European Resuscitation Council (ERC), and European Society of Intensive Care Medicine (ESICM) published guidelines for post-cardiac arrest care based on the International Consensus on CPR and Emergency Cardiovascular Care Science with Treatment Recommendations (CoSTR) from the International Liaison Committee on Resuscitation (ILCOR).[1–3] Improvements in post–cardiac arrest care, through an inclusive multisystem approach, can increase the likelihood of meaningful recovery in these patients. However, tremendous disparities in outcomes following cardiac arrest exist, which appear to be driven by substantial variation in processes of care.[4]

In the United States, overall survival to hospital discharge following out-of-hospital cardiac arrest is 12% with three-fourth of those survivors having a favorable neurological outcome, while for in-hospital cardiac arrest, 25% survive to discharge.[5] However, some single-center registries suggest that nearly 50% of patients who are successfully resuscitated from cardiac arrest and receive TTM may achieve a favorable neurological outcome. The majority of patients with primary cardiac arrest enrolled in a recent TTM trial achieved a favorable neurological outcome.[6,7] Implementation of standardized protocols for post-resuscitation care including many or all of the following components have demonstrated increases in survival in patients following cardiac arrest, as well as other conditions where early resuscitation may avoid additional secondary ischemic brain injury.

While families will be most focused on whether their loved one will awaken intact, emergency clinicians must be firm that no historical, exam, imaging, or lab tests available in the emergency department can exclude the possibility of a full recovery. In fact, guidelines recommend waiting at least 72 hours to perform neurological prognostication. Despite this, many cardiac arrest patients have withdrawal of life-sustaining treatment before 72 hours. While families may not want to engage in prolonged intensive care if it is not within the patient's goals of care, the emergency department represents an opportunity to educate families. While there may be appropriate reasons to limit care, such as pre-existing terminal illness or the development of refractory multiple organ failure, families should not immediately limit care due to an assumption that a patient will not wake up. It is important for emergency physicians to temper expectations. Given the inability to predict neurologic prognosis in the first hours to days, it is important that families understand that it takes some time to determine if the brain will recover. Apart from restoring circulation, setting expectations for allowing adequate time and the uncertainty regarding prognosis is where emergency physicians can have the largest impact on increasing survival in this disease.

PHARMACOLOGY

Intracranial Pressure Management

As with other topics discussed in this chapter, successful management of elevated ICP requires a combination of pharmacological

and non-pharmacological interventions deployed in an organized, stepwise fashion. Initial management for all patients with brain injuries at risk of developing elevated ICP should focus on avoiding pain, agitation, and fever. We recommend titrated doses of a hemodynamically stable opioid medication, such as fentanyl 25 to 50 mcg every 5 minutes, as needed. Avoid coughing or ventilator dyssynchrony. This is best accomplished by achieving adequate sedation and analgesia to permit mechanical ventilation, as described in Chapters 2, 151, and 154. Propofol is our sedative agent of choice for this purpose because it decreases cerebral metabolic activity, oxygen demand, and blood flow, and rapidly clears for neurologic assessment. Propofol can cause or contribute to hypotension, which may be avoided by dosage adjustment, but can necessitate starting vasopressors.

Alternatively, dexmedetomidine can also control agitation and promote endotracheal tube tolerance while facilitating frequent neurological examinations. However, dexmedetomidine does not suppress respiratory drive, and therefore, patients may have ventilator dyssynchrony in controlled ventilation. Some patients will not tolerate this agent due to hypotension and bradycardia, and tolerance does develop with long-term use.[8] In refractory cases of intracranial hypertension, induced coma with a barbiturate will further decrease CBF and lower ICP. Pentobarbital is started with a 10 mg/kg loading dose over 30 minutes, followed by a continuous infusion of 1 to 4 mg/kg/h, titrated to achieve electroencephalographic burst suppression. Barbiturate administration is frequently accompanied by hypotension, which often requires vasopressors to maintain adequate CPP, and causes a variety of systemic side effects that should be carefully weighed when initiating treatment. Consideration of barbiturate infusion for severe TBI should simultaneously trigger consideration of a decompressive hemicraniectomy.

Acute spikes in ICP or cerebral herniation syndromes can sometimes be rapidly reversed via osmolar therapy with mannitol or hypertonic saline. Both work by drawing water across an intact blood-brain barrier, thereby lowering ICP. However, the extremely rapid onset of both agents is facilitated by changes in blood viscosity and reductions in cerebral blood volume. Mannitol, 0.25 to 1 g/kg is given every 6 hours, up to a serum osmolality of 320 mOsm/kg. Treating with 30 mL of 23.4% sodium chloride appears to be at least as effective as mannitol at rapidly lowering ICP and reversing herniation, and 30 to 60 mL can be given every 6 hours, up to a maximum serum sodium level of 160 mEq/L. A central line is preferred for safe administration. Hypertonic saline at 3% concentration can also be administered at an initial rate of 30 to 50 mL/hr as a continuous infusion. At present, there are insufficient data to recommend one agent over another, or to determine if continuous infusion or bolus dosing of hypertonic saline is preferred. Because it is a potent diuretic, mannitol is preferred in cases of fluid overload, whereas hypertonic saline can be used as a resuscitative fluid.[9]

Seizure Management

Although the prevention of seizures has not been demonstrated to improve neurologic recovery, seizures can result from global cerebral ischemia and may exacerbate underlying brain injury. Seizure activity can increase brain metabolism by 300% to 400%, worsening the mismatch between oxygen delivery and demand, with greater metabolic failure, neuronal loss and worsened neurologic outcome. When present, prolonged seizures or status epilepticus following cardiac arrest are strongly, although not invariably, associated with a poor neurologic outcome. Non-convulsive status epilepticus has been reported in 12% to 24% of survivors after cardiac arrest; consequently, continuous electroencephalographic monitoring is frequently used in comatose survivors, and we recommend its use for patients who are treated with neuromuscular blockade while receiving therapeutic hypothermia.[10] Electroencephalographic findings have been shown to predict neurologic outcome after cardiac arrest reliably and, in the future, electroencephalographic monitoring may be a core component in prognostication algorithms.[11]

We do not recommend the prophylactic use of anticonvulsant drugs in patients resuscitated from cardiac arrest, but seizures should be quickly and effectively treated. Lorazepam, up to 0.1 mg/kg, with a maximum dose of 4 mg, is the preferred first-line agent to abort seizures and should be followed by continued treatment with an antiepileptic drug. A recent randomized controlled trial suggested that IV loads of fosphenytoin at 20 mg phenytoin equivalents (PE)/kg (max 1500 mg PE), levetiracetam at 60 mg/kg (max 4500 mg), or valproic acid at 40 mg/kg (max 3000 mg) are equally efficacious second-line options.[12] In intracerebral hemorrhage (ICH), the prophylactic use of anticonvulsants has been associated with worse neurologic outcomes, and we concur with current guidelines that do not recommend their routine use.[13] In TBI, prophylaxis with phenytoin reduces early seizures during the first 7 days, but not beyond, and reduction of early seizures has not been shown to improve outcome.[9] Limited data suggest prophylaxis with phenytoin can worsen neurocognitive outcomes, so if prophylaxis is to be used, 7 days of levetiracetam 500 mg bid, adjusted for renal function, is our preferred regimen.[14]

Devices and Techniques

Cardiopulmonary Resuscitation

In the event of cardiac arrest, return of spontaneous circulation is the first priority in cerebral resuscitation. The degree of brain injury after cardiac arrest depends on the duration of complete cerebral ischemia (the downtime, or time before the initiation of cardiopulmonary resuscitation [CPR]) and duration of relative ischemia that occurs during CPR and that may occur from cardiogenic shock preceding or after the period of cardiac arrest. Events occurring after the restoration of flow (e.g., transient hypoxia, hypotension) can exacerbate brain injury in this dynamic and vital early resuscitation period. Extensive evidence on hospital discharge rates and neurologic recovery rates demonstrates that resuscitation success is inversely proportional to cardiac arrest duration. Although duration of arrest generally predicts outcome in the population of patients with sudden cardiac death, it cannot be reliably used to predict the outcome of individual patients. Modern brain resuscitation techniques focus on avoiding further secondary cerebral injury, which also affects outcome. Neurologic outcome of survivors is influenced by patient age, comorbidities, and other individual characteristics.

The efficacy of closed chest CPR in generating adequate cerebral perfusion is somewhat controversial. Cardiac output during optimal standard closed-chest CPR was previously estimated to be only 20% to 30% of normal. However, more recent studies have suggested that higher cardiac outputs are possible and, unquestionably, effective CPR is essential to neurologic recovery after cardiac arrest.

Reperfusion

With cerebrovascular insults due to embolic or thrombotic mechanisms, randomized clinical trials have shown a benefit of revascularization in ischemic stroke. This is discussed in detail in Chapter 87.

Optimizing perfusion and oxygenation. Maintaining cerebral oxygen delivery is a mainstay of therapy after ischemic brain injury. Oxygen delivery requires a sufficiently high CPP, sufficiently low cerebrovascular resistance (CVR), and adequate blood oxygen saturation.

Hypotension can dangerously lower CBF and is associated with worse outcome following cardiac arrest and TBI. Normally, a change in systemic blood pressure triggers corresponding changes in CVR, mediated by cerebral arterial vasodilation or vasoconstriction. This capacity, termed *cerebral autoregulation*, functions to maintain a constant CBF over a wide range of arterial blood pressures. Autoregulation is often lost in the injured brain and, as a result, perfusion of ischemic tissue

becomes passively dependent on CPP. Consequently, hypotension can compromise CBF and result in significant additional brain damage. Therefore, low arterial pressures should be rapidly normalized, with intravascular volume administration and vasopressors used as needed. In the absence of prospective clinical trial data, current recommendations are to maintain a MAP greater than 65 mm Hg and SBP greater than 90 mm Hg[1] for cardiac arrest patients. Although some studies suggest an association between higher blood pressures and improved outcomes, concerns related to disruption of the blood-brain barrier and worsening of vasogenic edema remain, and there is insufficient evidence to recommend inducing hypertension.[3,15]

Blood pressure goals fundamentally differ in ICH, in which elevated blood pressure at presentation is common due to a physiologic pressor response. Hypertension is a known risk factor for hematoma expansion, yet the targeted blood pressure goal in these patients remains controversial due to uncertainty regarding perfusion to the brain tissue surrounding the hematoma (ischemic penumbra). A large, multicenter, randomized controlled trial has demonstrated that rapid lowering of the systolic blood pressure (SBP) to less than 140 mm Hg is safe and may have a small but meaningful benefit on neurologic outcome. This result was not replicated in a subsequent multicenter trial, which also suggested a slightly higher rate of acute kidney injury (AKI) in patients who are rapidly lowered to less than 140 mm Hg.[16] We endorse immediate management with IV antihypertensives. Targeting an SBP less than 140 mm is a reasonable choice, though less than 160 may be preferred in patients with a history of chronic poorly controlled hypertension who are severely hypertensive on presentation. As in other conditions where there is a risk of secondary ischemic injury, hypotension should be diligently avoided by not allowing the MAP to drop below 65 mm Hg.

CVR is a critical determinant of CBF and may be affected by hyperventilation and microvascular patency. Although the cerebral circulation may lose its ability to adjust to blood pressure changes after ischemia, attenuated responsiveness to carbon dioxide and oxygen levels in arterial blood is generally present. Carbon dioxide is a potent vasoactive agent, and lowering the arterial carbon dioxide partial pressure ($Paco_2$) by hyperventilation results in a rapid reduction of CBF of 2% for every 1 mm Hg decrease in the $Paco_2$. Because reductions in CBF reduce total cerebral blood volume, hyperventilation quickly lowers ICP. Induced hyperventilation can transiently abort brainstem herniation in the presence of critically elevated ICP until an alternative therapy can be initiated. However, the vasoconstriction and increased CVR caused by hyperventilation can lead to dangerous reductions in CBF, with resulting cerebral ischemia. We recommend restricting the use of induced hyperventilation to the short-term treatment of immediately life-threatening cerebral herniation and severe intracranial hypertension that is not responsive to other measures, such as osmotic therapy. Chronic or prophylactic hyperventilation should not be used. Specific treatment for elevated ICP is described in the next section. In general, ventilation to maintain a $Paco_2$ of 35 to 40 mm Hg is safe and appropriate, and inadvertent hyperventilation should be avoided.

Normal arterial oxygen saturation following resuscitation from ischemic brain injury is a primary goal. The injured brain may not be able to compensate for hypoxemia by augmenting CBF, and cerebral oxygen delivery may diminish rapidly as the oxygen content of blood decreases. Hyperoxemia secondary to the use of high concentrations of oxygen, however, has also been shown to increase oxidative brain injury in animal models of cardiac arrest and is associated with increased mortality in stroke patients and in post–cardiac arrest patients. Normal oxygen or mild hyperoxemia (arterial partial pressure of oxygen, Pao_2, of 80 to 120 mm Hg with oxyhemoglobin saturation percentage maintained in the high 90s) should be maintained through use of the lowest fraction of inspired oxygen (Fio_2) possible.[10] Because hypoxemia, hypocapnia, and hypercapnia all must be avoided, controlled ventilation is appropriate in the period after resuscitation, with sedation and neuromuscular blockade if needed. Continuous oximetry and capnography, correlated with arterial blood gas determinations, provide the information necessary to optimize ventilation parameters.

Elevated Intracranial Pressure

The presence of intracranial hypertension is suggested by imaging and clinical features. Relevant computed tomography (CT) findings include compressed basal cisterns, diffuse sulcal effacement, and diffuse loss of differentiation between the gray and white matter, although ICP can be elevated without any of these findings. Suggestive clinical features include papilledema, bilateral sixth nerve palsies, and a new third nerve palsy in a comatose patient. Definitive diagnosis requires invasive ICP monitoring placement. The decision to place an ICP monitor should be guided by neurosurgery whenever consultation is available. Most data on the management of elevated ICP is derived from literature on TBI, a condition in which ICP elevation commonly occurs. Although support from randomized controlled trials is lacking, the Brain Trauma Foundation has published guidelines for ICP monitor placement, which we recommend in TBI patients whenever possible. The most recent guidelines reaffirm earlier recommendations that ICP monitors be placed in all TBI patients with an abnormal head CT scan and severe brain injury, defined as a Glasgow Coma Score of 3 to 8.[9]

Guidelines are not available for ICP monitoring in other conditions involving ischemic brain injury, such as stroke, which is generally not indicated. In particular, the clinical impact of intracranial hypertension due to anoxic brain injury following cardiac arrest is unclear and has not been studied in prospective trials. When cytotoxic edema severe enough to cause ICP elevation develops, it portends a very poor prognosis and is generally refractory to medical treatments.[17] Consequently, we do not recommend invasive ICP monitoring to manage global ischemic injury following cardiac arrest.

Medical treatment. Medical treatment for elevated ICP has similarly not been proven effective in randomized controlled trials, and treatment protocols are primarily based on clinical experience and expert opinion. To ensure adequate cerebral perfusion, the MAP should be maintained above 65 mm Hg in all patients at risk for ICP elevation, and a CPP of 60 mm Hg should be targeted when ICP monitoring is available. Although the exact threshold for ICP treatment is unclear and may vary between individual patients, an ICP over 22 mm Hg has been associated with worse neurologic outcomes and should trigger treatment.[9,18]

Management of elevated ICP should proceed in a stepwise fashion, starting with routine interventions that should be employed in all patients at risk of intracranial hypertension, proceeding to more aggressive interventions that also carry a greater risk of side effects. Based on published guidelines[18] and expert opinion, we recommend the following interventions:

1. Position the patient with the head up by elevating the upper half of the bed or gurney to 30 degrees.
2. Maintain a neutral head and neck position to avoid jugular venous compression.
3. Treat fever. Administer antipyretic agents and use mist and surface cooling as necessary, targeting a temperature at or below 37°C.
4. Minimize triggers of ICP increases. This is accomplished by monitoring and, if necessary, minimizing interventions that trigger spikes of ICP, such as frequent turning and suctioning. Laying the patient flat should be avoided if at all possible, and the risk and benefits of imaging studies and other interventions that require transporting the patient should be carefully weighed.[19] Medications to control analgesia and promote sedation can be useful, as described in the pharmacology section.
5. Initiate osmolar therapy, as described in the pharmacology section.

6. CSF drainage via ventriculostomy (if ventriculostomy present)—If possible, a ventriculostomy should be clamped to provide continuous ICP measurement. However, when ICP becomes elevated, opening a ventriculostomy to drain CSF is a safe and frequently effective way to decrease ICP.
7. Treat cases of refractory ICP elevation not amenable to the previous therapies through more aggressive interventions.
   a. A continuous pentobarbital infusion, titrated to achieve deep levels of encephalographic burst suppression, can dramatically decrease cerebral metabolic rate and further reduce elevated ICP.
   b. Mild induced hypothermia is an additional option in highly refractory cases. Endovascular or surface cooling devices should be used to target a temperature of 32°C to 36°C, titrated to achieve ICP control. Once cooled, rapid rewarming should be avoided because this may precipitate a significant ICP elevation. A randomized controlled trial of early induced hypothermia for patients with ICP greater than 20 did not show a significant improvement in neurological outcome, but induced hypothermia remains a consideration for severe cases that are refractory to other medical interventions.[20,21] (Note: targeted temperature management should be initiated on all appropriate cardiac arrest patients as below; these recommendations are for increased ICP from other etiologies.)

Surgical treatment. Surgical options for the management of refractory ICP include decompressive craniectomy and evacuation of intracranial hematoma, when present, and should be guided by neurosurgical consultation. In the event of severe cytotoxic edema following middle cerebral artery stroke, there is a benefit of early (<48 hours) decompressive hemicraniectomy in patients younger than 60 years. A bifrontal craniectomy is typically used to treat refractory ICP in TBI. Since early decompressive craniectomy in patients with ICPs above 20 has been shown to result in worse neurological outcomes, this intervention should be reserved for cases in which most medical interventions have failed. The RescueICP trial randomized severe TBI patients with refractory intracranial hypertension, defined as ICP greater than 25 mm Hg for at least 1 hour, to decompressive craniectomy or medical management, which typically involved initiation of barbiturate infusions. Because there was such a significant mortality reduction in the decompressive craniectomy arm relative to other changes in the extended Glasgow Outcome Scale (GOS-E), the primary hypothesis of an ordinal shift in outcome using the GOS-E could not be statistically tested. Six-month mortality was significantly decreased by 22% in the decompressive craniectomy group, but rates of moderate disability and good recovery were similar in the two groups.[22] Based on these results, decompressive craniectomy remains a consideration for refractory cases prior to initiation of barbiturates, particularly when there is a strong desire to increase survival odds. However, decision making should be individualized, and families should be aware that the procedure is unlikely to increase the likelihood of disability-free survival.

Maintenance of Body Temperature

Hyperthermia exacerbates brain injury and is associated with worse outcome in multiple neurological conditions.[23,24] Elevated body temperature increases cerebral metabolic demand by 8% to 13% per °C, escalates glutamate release, increases oxygen free radical production, and increases cytoskeletal and blood-brain barrier breakdown, with increased vasogenic edema. The core body temperature should be monitored in patients resuscitated from cerebral ischemia, and measures should be initiated to prevent temperature increases in the post-ischemic period. In general, all temperatures higher than 38°C should be treated aggressively with acetaminophen and surface cooling. Targeted temperature management has emerged as a therapy for comatose survivors of hypoxic-ischemic injury following cardiac arrest.

Targeted Temperature Management

Hypothermia was first noted to have a protective effect in global and focal brain ischemia more than 50 years ago. The neuroprotective mechanism is linked to a reduction of glutamate release, metabolic demand, free radical formation, and production of inflammatory cytokines. Cell signaling and genetic responses to cellular injury are also affected, and hypothermia may protect the brain from programmed neuronal cell death.

Mild hypothermia (32°C to 34°C) is easier to achieve and has fewer adverse effects than lower temperatures, and has consistently been found to be neuroprotective in experimental models of cerebral ischemia. In 2002, two prospective, randomized controlled trials of mild hypothermia showed marked improvements in neurologic outcome in comatose survivors of out-of-hospital cardiac arrest (see Fig. 4.2). In these trials, the number needed to treat to have one additional patient with a good neurologic outcome was only about 7. Evidence-based guidelines subsequently recommend cooling unconscious adult patients after cardiac arrest to 33°C for 12 to 24 hours, but widespread adoption of this practice has been slow and incomplete.[25]

More recent investigations in adults and children have compared mild therapeutic hypothermia of 33°C to targeted temperature management of 36°C in patients with out-of-hospital cardiac arrest with an initial shockable rhythm of suspected cardiac etiology. The safety and efficacy outcomes at 33°C versus 36°C were no different. Strong biologic evidence from earlier clinical trials and animal models shows that 33°C provides better neuroprotection. The TTM trial did not provide evidence that one target was easier or safer than the other. Most patients included in these trials had immediate bystander CPR and, by extension, were likely to have less severe neurologic insults than cardiac arrest patients resuscitated in routine practice outside Europe. More recently, a randomized controlled trial compared normothermia to mild hypothermia to 33°C for patients with out-of-hospital cardiac arrest and an initial non-shockable rhythm. Consistent with earlier studies, this demonstrated significantly better neurological outcomes in the hypothermia group.[26] While we anticipate that knowledge in this area will continue to evolve, we recommend rapid initiation of TTM targeting 33°C upon hospital arrival for all unresponsive patients following cardiac arrest.

The optimal method of cooling patients resuscitated from cardiac arrest has not been established, but to accelerate the time to achieving target temperature, guidelines recommend the use of intranasal, intravascular, or surface temperature-modulating devices or cold saline infusions as opposed to older devices like ice packs, cooling fans, and air cooling blankets.[27] Animal experimentation and consensus recommendations have suggested that cooling should be initiated as early and rapidly as possible, but studies of initiation of cooling in the prehospital setting have not demonstrated benefit, and this practice is not recommended.[1] In the early clinical trials, hypothermia at 33°C ± 1°C was achieved by 2 or 8 hours after the return of spontaneous circulation and was maintained for 12 or 24 hours. A recent study did not show the benefit of a longer, 48-hour duration of 33°C TTM compared to 24 hours.[7] An ongoing clinical trial funded by the U.S. National Institutes of Health is addressing the optimal duration of cooling with a target of 33°C (ClinicalTrials.gov Identifier: NCT04217551).

Patients are allowed to rewarm passively or with a combination of passive and slow, active rewarming. Rebound hyperthermia is common with passive rewarming and should be avoided.

Therapeutic hypothermia is the established standard of care for infants with moderate to severe hypoxic-ischemic injury.[28]

The use of surface cooling devices to achieve normothermia may be beneficial to reduce ICP spikes in individuals with brain injury and

BOX 4.1 Abbreviated Protocol for Induced Hypothermia After Cardiac Arrest

- For access to a wide variety of detailed post–cardiac arrest care and hypothermia protocols collected by the University of Pennsylvania, see https://www.med.upenn.edu/resuscitation/hypothermia/.
- Hypothermia is most effective as part of an institutional comprehensive post–cardiac arrest critical care program that begins in the emergency department (ED) and continues into the intensive care unit (ICU) and into recovery and rehabilitation.
- Early resuscitation, excellent cardiopulmonary resuscitation (CPR), rapid return of spontaneous circulation (ROSC), and quick transport to definitive care are fundamental. The value of prehospital cooling is unproven, but if cooling is initiated by emergency medical services (EMS), transport should be to an institution capable of maintaining hypothermia on arrival and avoiding any early (even transient) rewarming.

Skeleton[a]

- Evaluate adult survivors of cardiac arrest by following institutional criteria for appropriateness of induced hypothermia.
- Begin cooling by rapidly infusing 2 L of cold (4°C) intravenous saline immediately after arrival or ROSC.
- Expose patient; avoid external warming—no blankets and no heated ventilator circuit.
- Place temperature-sensing urinary catheter and esophageal temperature probe. (Redundant monitoring allows esophageal temperature probe connection to cooling device and bladder temperature probe to patient monitoring system.)
- Initiate definitive cooling by endovascular or surface-cooling temperature control device at maximal rate to target temperature of 33°C.
- Prevent shivering with sedation and nondepolarizing paralytic—bolus in the ED, bolus or drip in the ICU.
- Avoid hypotension and hypoxia.
- Most ED diagnostic evaluation, if needed, should follow initiation of cooling. (In patients with acute myocardial infarction [MI] who are going to primary coronary intervention, cooling should not delay door to balloon time. Cooling is initiated in the ED if there is time before the catheterization laboratory is ready; otherwise, cooling is initiated in the laboratory.)
- Admit to ICU.
- Continuous electroencephalographic monitoring for occult status epilepticus recommended. Treat seizures if present.
- Manage arterial blood gases in a consistent manner (may choose pH stat or alpha stat).
- At 24 h after initiation of cooling, initiate rewarming to a target temperature of 36.5°C at a rate of 0.15°/h.
- Discontinue paralytics at the onset of warming. Control shivering with sedation, narcotics, and surface counterwarming.
- Lighten sedation as tolerated as rewarming progresses.
- Discontinue endovascular temperature control device after 48 h (may use the device to maintain normothermia after rewarming is complete until it is removed).
- Remove or minimize sedation to allow neurologic evaluation before 72 h to allow the best possible clinical prognostication at that time point; neurology consultation recommended.

[a] Modified from University of Michigan protocol (available at http://dx.doi.org/10.7302/818).

central fever and, as mentioned above, therapeutic hypothermia can be considered in patients with severe intracranial hypertension that is refractory to most other medical interventions. Therapeutic hypothermia following ischemic stroke is not of proven benefit, and we do not recommend its use (Box 4.1).

OUTCOMES

Cerebral ischemia is a frequently fatal and highly morbid condition, but the prognosis for its victims is not universally poor. An increasing body of data provides more precise estimates of survivors' functional outcomes and quality of life, and the results are better than many emergency clinicians assume.

However, identifying reliable prognostic indicators of severe brain injury is hampered by the self-fulfilling prophecy. Counseling provided to families of patients with a presumed poor prognosis leads to withdrawal of life-sustaining treatments, thereby confirming the poor prognosis. There is significant individual and institutional variation in the aggressiveness of care provided to patients with brain injuries. A higher rate of implementation of DNR orders within 24 hours, which is thought to reflect less aggressive early management, has been shown to be strongly associated with mortality, independent of other known risk factors. Consequently, ICH guidelines have emphasized the importance of avoiding assigning new DNR status within the first day of hospital presentation.[13] Prognostication in TBI, which disproportionately affects young adults, can be particularly difficult, and there are many examples of good outcomes despite a prolonged hospital course and severe intracranial hypertension requiring aggressive management.[29]

On the other hand, prolonged survival with significant disability also may be a tragic outcome, and consideration of this may lead emergency clinicians and families to consider changing the goals of care to comfort. Most survivors of cardiac arrest are comatose at the time of admission and without early prognostic findings suggesting which patients will have a favorable outcome. This may account, in part, for the nihilism common among emergency clinicians treating patients with cardiac arrest. Unfortunately, studies suggest that annually thousands of patients who would have a good neurological outcome have care withdrawn early in their hospitalization.[30] Because withdrawal of life-sustaining treatment due to perceived poor neurological prognosis is the most common cause of death in cardiac arrest survivors, it is critically important to provide accurate and evidence-based prognostic information to families. Early examination findings, including an absence of pupillary and corneal reflexes, are poorly predictive of eventual neurological outcome. Consequently, it is well accepted that prognostication cannot accurately be performed until at least 72 hours after cardiac arrest. In practice, because patients receiving TTM typically receive high doses of analgesia and sedation for 24 to 48 hours, accurate examination and prognostication will typically require additional time for these medications to fully clear.[1–3,10]

Older studies and guidelines using data prior to the adoption of therapeutic mild hypothermia identified a number of clinical and laboratory features that were thought to be invariably associated with a poor neurological outcome. However, more recent data suggests that almost all of these individual features are associated with an unacceptably high rate of false positives. We agree with current guidelines from the AHA and ERC which emphasize the importance of taking a stepwise, multimodal approach to neuroprognostication, and allowing greater time for monitoring in uncertain cases (Fig. 4.3).[1,2]

Based on currently available data, a bilaterally absent pupillary light reflex at 72 hours remains highly predictive of a poor outcome with a low false positive rate and narrow confidence interval. Additionally, bilateral absence of a cortical response to somatosensory evoked potentials (SSEPs) after rewarming or 24 to 72 hours from cardiac arrest appears similarly predictive. In conjunction with other findings, additional features suggestive of poor prognosis include absent corneal reflexes, absent reactivity or burst-suppression pattern on EEG, myoclonic status epilepticus, and diffuse anoxic injury on CT or MRI. Higher levels of neuron specific enolase (NSE) are correlated with a worse outcome, but laboratory testing is not standardized, and we do not recommend

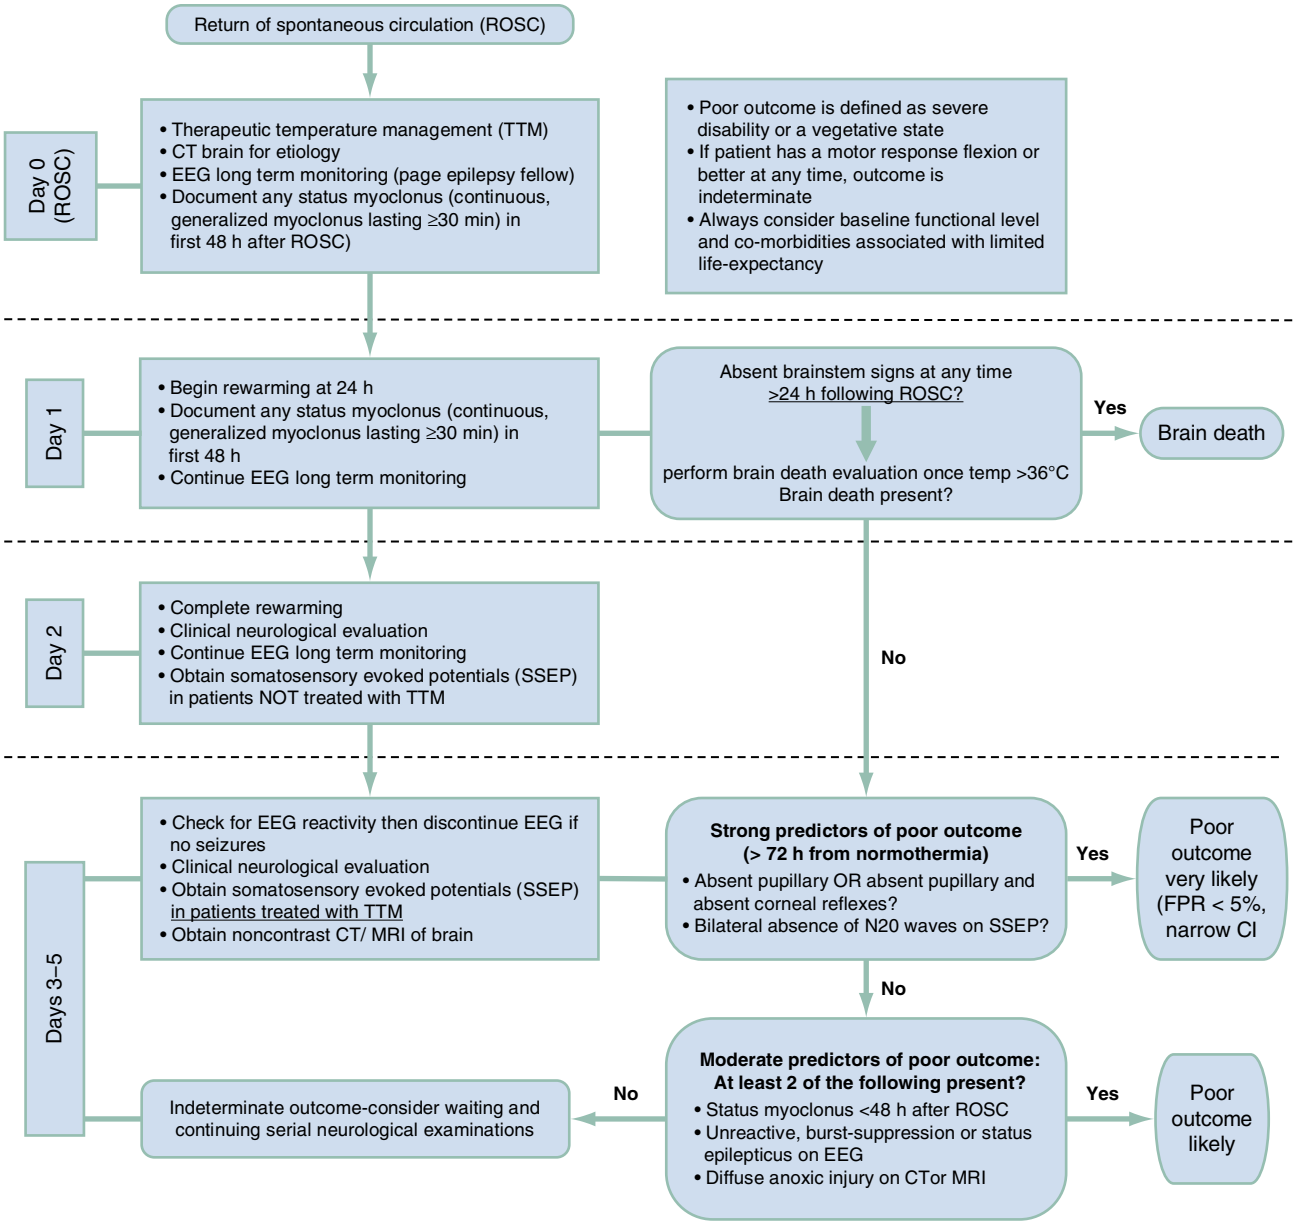

Fig. 4.3 Multi-Modality Neuroprognostication Pathway. (Adapted from Michigan Medicine neuroprognostication protocol and Nolan J, Soar J, Cariou A, et al. European Resuscitation Council and European Society of Intensive Care Medicine 2015 guidelines for post-resuscitation care. *Intensive Care Med.* 2015;41:2039-2056.)

adopting any single threshold to predict poor outcome. It should be noted that the accuracy of any of these findings must be tempered by the potential for confounding due to self-fulfilling prophecies.

Rapidly expanding knowledge of the pathophysiology of post-ischemic brain injury has stimulated the search for effective cerebral resuscitation therapies. Newly proven therapies such as resuscitative hypothermia will continue to be studied and will improve the outcomes of patients with ischemic brain injury in future years. Although experimental work has suggested many potentially promising brain resuscitation therapies, attention should also be paid to determining the benefits of existing standard therapies. Because of the complexity and interconnectedness of the pathophysiologic cascades that occur after cerebral ischemia, it is likely that a multifaceted therapeutic approach targeting mediators of secondary brain injury, rather than a single pharmacologic agent, is needed to reduce neurologic damage after cardiac arrest.

It is crucial that the emergency clinician recognize that the patient resuscitated from ischemic injury is, contrary to his or her outward appearance, in a dynamic stage of brain injury. At present, patients should be protected from further brain injury caused by hypotension, hypoperfusion, ICP elevation, hypoxia, hyperthermia, and seizures. Because early examination and clinical characteristics are unreliable in predicting ultimate neurological outcome and most patients with brain injury die due to withdrawal of life-sustaining treatment, emergency clinicians should avoid therapeutic nihilism and providing an early prognosis to families, instead emphasizing the need to wait several days to obtain reliable information. Unresponsive survivors of out-of-hospital cardiac arrest should undergo targeted temperature management. In the future, cerebral resuscitation may also involve other specific pharmacologic interventions to derail the process whereby brain cells slowly die after ischemic brain injury.

CHAPTER 4: QUESTIONS AND ANSWERS

1. To maximize cerebral blood flow, a patient with a normal intracranial pressure who is undergoing resuscitation should be ventilated to maintain a partial pressure of carbon dioxide ($Paco_2$) within what range?

a. 20 to 25 mm Hg.
b. 25 to 30 mm Hg.
c. 30 to 35 mm Hg.
d. 35 to 40 mm Hg.
e. 40 to 45 mm Hg.

Answer: d. Carbon dioxide is a potent vasoactive agent, and lowering of the $Paco_2$ by hyperventilation results in rapid reduction of cerebral blood flow (CBF). Since reductions in CBF reduce total cerebral blood volume, hyperventilation may transiently abort brainstem herniation in the presence of critically elevated intracranial pressure (ICP) until osmotherapy or ventriculostomy can be initiated. When ICP is not elevated, however, the vasoconstriction and increased cerebrovascular resistance (CVR) caused by hyperventilation can cause potentially dangerous reductions in CBF. In general, ventilation to maintain a $Paco_2$ between 35 and 40 mm Hg is safe and appropriate.

2. Which of the following is a class 1 recommendation from the 2015 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care?

a. Forty-eight hours from arrest is the earliest time the clinical examination may be used for neuroprognostication.
b. All comatose patients with return of spontaneous circulation (ROSC) after in- and out-of-hospital cardiac arrest, including both shockable and non-shockable rhythms, should receive targeted temperature management.
c. EEG monitoring is not necessary or indicated for comatose patients following cardiac arrest.
d. Infusion of cold saline should be used to induce cooling in the pre-hospital setting following cardiac arrest.

CHAPTER 4: QUESTIONS AND ANSWERS—CONT'D.

Answer: b. The 2015 guidelines update confirms that all comatose (lack of meaningful response to verbal commands) patients with ROSC following cardiac arrest should receive targeted temperature management (TTM), regardless of location of arrest or rhythm type. Because the neurological examination is unreliable in the first few days following arrest, 72 hours is the **earliest** possible time that one may consider using it to provide prognostic information to surrogate decision makers. Non-convulsive seizures are common following cardiac arrest therefore EEG monitoring, if available, should be performed frequently or continuously in comatose survivors of cardiac arrest. Finally, multiple randomized controlled trials showed that cold intravenous fluids in the pre-hospital setting increased the rate of pulmonary edema and rearrest. We do not recommend this practice.

3. Select the best answer. Which of the following statements is false?
   - **a.** Early magnetic resonance imaging (MRI) and serum biomarkers have a clearly established role in determining the prognosis of patients within 48 hours after cardiac arrest.
   - **b.** Recent data suggest that rate of survival to hospital discharge following cardiac arrest is 12%, with 75% of survivors achieving a favorable neurological outcome.
   - **c.** In cardiac arrest survivors presenting to the emergency department , the initial neurological examination is not a reliable predictor of long-term neurological prognosis.
   - **d.** The vast majority of 1-year survivors of cardiac arrest are able to live independently without disability.

Answer: Statement a is false. The role of early imaging, neurophysiologic testing, and serum biomarkers in predicting outcome has not yet been clearly established at any time point, especially not within 48 hours.

4. Which of the following statements about neuronal damage following ischemic injury is correct?
   - **a.** A patient with return of spontaneous circulation after 15 minutes of cardiac arrest has likely already suffered substantial neuronal cell death.
   - **b.** There is a single biological pathway by which ischemia triggers neuronal injury and eventually results in cell death.
   - **c.** Cell death is delayed following cardiac arrest, suggesting that therapeutic interventions may mitigate long-term neuronal injury.
   - **d.** It is not important to avoid secondary neuronal injury following cardiac arrest.

Answer: c. Although a cascade of cellular pathways will have been triggered, the resulting neuronal cell death is usually delayed by hours or days. This suggests that therapeutic interventions, such as targeted temperature management, can reduce cell death and improve outcomes. Careful avoidance of additional secondary insults is also important to maximize the potential for favorable neurological recovery.

5. Select the best answer. Which of the following is associated with worse neurologic outcomes in comatose survivors of cardiac arrest?
   - **a.** All of these.
   - **b.** Hyperthermia.
   - **c.** Hypotension.
   - **d.** Hypoxia.
   - **e.** Only hypotension and hyperthermia.

Answer: Statement a is the best answer. Hypotension, hypoxia, and hyperthermia (as well as hyperglycemia and seizures) are all associated with worse neurologic outcomes in comatose survivors of cardiac arrest.

Adult Resuscitation

Nathan L. Haas, Michael C. Kurz

KEY CONCEPTS

- Cardiopulmonary resuscitation (CPR) quality is critical to successful resuscitation from cardiac arrest. Important benchmarks of quality CPR include compression rate 100–120 compressions/min, compression depth 5–6 cm, compression fraction at least 80%, full chest recoil between compressions, and a ventilation rate of 10 breaths/min.
- Restoration of adequate cardiac function is the defining factor of return of spontaneous circulation (ROSC). Restoration of good neurologic function is the defining factor of a successful resuscitation.
- Resuscitation of a cardiac arrest victim does not end with ROSC. Rapid diagnosis and proper management of the pathologic condition(s) that precipitated and resulted from the arrest, as well as goal-directed post–cardiac arrest care, can improve outcomes.
- Immediate percutaneous coronary intervention is indicated in patients with ST segment elevation myocardial infarction following ROSC, independent of neurological status.
- Hypothermic targeted temperature management (32°C–36°C [89.6°F–96.8°F] for 24 h) has been shown to improve survival and functional outcome of comatose cardiac arrest survivors.

FOUNDATIONS

Background and Importance

Cardiopulmonary arrest is defined by the triad of unconsciousness, apnea, and pulselessness. It is estimated that more than 340,000 out-of-hospital cardiac arrests (OHCAs) occur annually in the United States, an estimated annual incidence of 140/100,000.[1] Of these, approximately 180,000 are treated by emergency medical services (EMS).[1] Most EMS-treated, OHCAs occur at home (70%) and are unwitnessed (50%).[2] The proportion of EMS-treated cardiac arrest patients with an initial shockable rhythm of ventricular fibrillation (VF) or pulseless ventricular tachycardia (pVT) has declined over time to approximately 18%.[2] Furthermore, the number of patients receiving bystander cardiopulmonary resuscitation (CPR) remains low, averaging 40%.[2] Automated external defibrillators (AEDs) are applied prior to EMS arrival in a minority of cases.[2]

Recent epidemiologic data from cardiac arrest registries indicate the survival rate to hospital discharge for EMS-treated, OHCA is about 10%.[2] Comparatively, survival to hospital discharge following in-hospital cardiac arrest (IHCA) is about 26%.[1] Of patients surviving to hospital discharge, independent of neurologic status on presentation, 79% have good neurologic function (cerebral performance category of 1 or 2).[2] For comatose post-cardiac arrest patients who underwent hypothermic targeted temperature management (HTTM), the reported survival rate with good neurologic function has ranged from 20% to 50%.[3] Regional and inter-institutional variability in survival exists after EMS-treated cardiac arrest. The entire system of care affects patient outcomes, and differences in outcomes across the country may reflect local practice variability and differences in delivery of the chain of survival.

Anatomy, Physiology, and Pathophysiology

Awareness of underlying causes of cardiac arrest helps direct therapy and diagnostic testing both during resuscitation and in the immediate post-cardiac arrest period (Table 5.1).

Cardiac arrest with presenting rhythm of VF or pVT often has a primary cardiac origin. Coronary artery disease is a common pathologic condition found in patients who experience OHCA, and multiple observational studies have demonstrated disease rates comparable to those of patients undergoing clinically indicated coronary angiography.[4,5] Other primary cardiac etiologies of cardiac arrest include syndromes associated with sudden cardiac death due to ventricular dysrhythmias, including hypertrophic cardiomyopathy, Brugada syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia, and arrhythmogenic right ventricular cardiomyopathy.[1]

Cardiac arrest can result from non-cardiac origins, and common etiologies include circulatory causes, metabolic disturbances, and drug toxicities. Circulatory etiologies of cardiac arrest include tension pneumothorax, pericardial tamponade, pulmonary embolus, and hypovolemia/hemorrhage. These conditions must be recognized early to manage the underlying problem and maximize the chance of a successful resuscitation. The most common electrolyte disturbance leading to cardiac arrest is hyperkalemia, which results in progressive widening of the QRS complex that can deteriorate to pVT, VF, asystole, or pulseless electrical activity (PEA). Cardiac arrest from drug toxicity has specific characteristics, depending on the offending agent and presenting toxidrome. Specific therapy directed at drug toxicity (e.g., naloxone for opiate overdose) is essential, but may not be immediately effective depending on the agent involved. Prolonged resuscitation efforts that provide adequate perfusion may be needed (e.g., veno-arterial extracorporeal membrane oxygenation [VA-ECMO] for refractory cardiac arrest due to local anesthetic systemic toxicity).

Environmental etiologies including electrocution, hypothermia, and drowning can also result in cardiac arrest. Electrocution causes cardiac arrest through primary dysrhythmias or apnea. Alternating current in the range of 100 mA to 1 A (household and light industry) generally causes VF, whereas currents greater than 10 A (heavy industry or electrical transmission infrastructure) can cause ventricular asystole. Lightning produces a massive direct current electrocution that can result in asystole and prolonged apnea (see Chapter 130). Hypothermia-induced cardiac arrest can manifest with any electrocardiographic rhythm, and successful resuscitation

TABLE 5.1 Common Causes of Non-traumatic Cardiac Arrest

General	Specific	Disease or Agent
Cardiac		Coronary artery disease
		Cardiomyopathies
		Structural abnormalities
		Valve dysfunction
Respiratory	Hypoventilation	CNS dysfunction
		Neuromuscular disease
		Toxic and metabolic encephalopathies
	Upper airway obstruction	CNS dysfunction
		Foreign body
		Infection
		Trauma
		Neoplasm
	Pulmonary dysfunction	Asthma, COPD
		Pulmonary edema
		Pulmonary embolus
		Pneumonia
Circulatory	Mechanical obstruction	Tension pneumothorax
		Pericardial tamponade
		Pulmonary embolus
	Hypovolemia	Hemorrhage
	Vascular tone	Sepsis
		Neurogenic
Metabolic	Electrolyte abnormalities	Hypokalemia or hyperkalemia
		Hypermagnesemia
		Hypomagnesemia
		Hypocalcemia
Toxic	Prescription medications	Anti-dysrhythmics
		Digoxin, beta blockers
		Calcium channel blockers
		Tricyclic antidepressants
	Drugs of abuse	Cocaine
		Heroin
	Toxins	Carbon monoxide
		Cyanide
Environmental		Lightning
		Electrocution
		Hypothermia or hyperthermia
		Drowning or near-drowning

CNS, Central nervous system; *COPD,* chronic obstructive pulmonary disease.

depends on rapid rewarming, which often requires invasive measures (e.g., intravascular rewarming, peritoneal or thoracic lavage, or VA-ECMO; see Chapter 128). Once circulation is restored, patients should be warmed to a target of 32°C to 36°C (89.6° to 96.8°F) for 24 hours.[6] Drowning is a form of asphyxia usually resulting in bradyasystolic arrest. Patients experiencing cardiac arrest secondary to hypothermia or drowning may benefit from prolonged resuscitation efforts.

MANAGEMENT

Decision Making

Prehospital

Most cardiac arrest cases managed in the emergency department (ED) initially occur outside the hospital. An increasing number of first responders, nontraditional providers (e.g., teachers, flight attendants), and public venues (e.g., airports, casinos, sports arenas, schools) are being equipped with AEDs. When coupled with regional and statewide campaigns to improve bystander CPR rates, including hands-only and dispatcher-assisted CPR, dramatic resuscitation rates have been achieved in communities where lay public providers feel empowered to respond within the first few minutes of arrest.[7] Programs that fail to improve rates of bystander CPR or AED use within this critical time window are less likely to achieve increased survival rates.

Advanced life support units staffed by paramedics often have standing orders to follow advanced cardiac resuscitation protocols. In cases of cardiac arrest refractory to properly performed advanced prehospital measures, the patient may be pronounced dead at the scene per protocols. However, if advanced hospital-based resuscitation strategies such as extracorporeal cardiopulmonary resuscitation (ECPR) or percutaneous coronary intervention (PCI) are available, then transport to a comprehensive resuscitation center may still be warranted.[8] In systems where patients are transported in cardiac arrest, mechanical CPR results in better quality chest compressions during transport and is likely to be safer for EMS providers. Mechanical CPR can minimize interruptions in chest compressions, eliminate the need to switch rescuers due to provider fatigue, and can deliver consistent depth and rate of compressions.[9]

History and Physical Examination

It is often difficult to determine the cause of cardiac arrest at presentation. Although a differential diagnosis can be formulated based on history, physical examination, and electrocardiographic rhythm on arrival, key information is often unreliable or not available. The differential diagnosis can potentially be narrowed by the patient's age, underlying diseases, and medications, when known.

Historical information from family, bystanders, and EMS personnel provides key information regarding cause and prognosis. Information surrounding the event includes whether the arrest was witnessed, time of arrest, what the patient was doing (e.g., eating, exercising, trauma), possibility of drug ingestion, whether bystander CPR was performed, time of initial CPR, initial electrocardiographic rhythm, and interventions by EMS providers. Important past medical history includes baseline health, previous heart, lung, or renal disease, malignancy, hemorrhage, infection, and risk factors for coronary artery disease and pulmonary embolism. The patient's current medications and allergies should be obtained if possible.

Physical examination of a cardiac arrest patient is necessarily focused on a few key goals: (1) ensuring the adequacy of airway patency and ventilation; (2) confirming the diagnosis of cardiac arrest; (3) finding evidence of the cause; and (4) monitoring for complications of therapeutic interventions. This examination occurs in descending order of importance, simultaneously with therapeutic interventions, and is repeated frequently to assess for response to therapy and occurrence of complications (Table 5.2). After the initial minutes of cardiac arrest, the physical examination may provide little evidence of the duration of arrest. Pupils dilate within 1 minute but may constrict if CPR is initiated immediately and performed effectively. Dependent lividity and rigor mortis develop after hours of cardiac arrest. Temperature is an unreliable predictor of duration of cardiac arrest because it does not

TABLE 5.2 Physical Examination Findings Indicating Potential Cause of Cardiac Arrest and Complications of Therapy

Physical Examination	Abnormalities	Potential Causes
General	Pallor	Hemorrhage
	Cold	Hypothermia
Airway	Secretions, vomitus, or blood	Aspiration
		Airway obstruction
	Resistance to positive-pressure ventilation	Tension pneumothorax
		Airway obstruction
		Bronchospasm
Neck	Jugular venous distention	Tension pneumothorax
		Cardiac tamponade
		Pulmonary embolus
	Tracheal deviation	Tension pneumothorax
Chest	Median sternotomy scar	Underlying cardiac disease
Lungs	Unilateral breath sounds	Tension pneumothorax
		Right mainstem intubation
		Aspiration
	Distant or no breath sounds or no chest expansion	Esophageal intubation
		Airway obstruction
		Severe bronchospasm
	Wheezing	Aspiration
		Bronchospasm
		Pulmonary edema
	Rales	Aspiration
		Pulmonary edema
		Pneumonia
Heart	Diminished heart tones	Hypovolemia
		Cardiac tamponade
		Tension pneumothorax
		Pulmonary embolus
Abdomen	Distended and dull	Ruptured abdominal aortic aneurysm or ruptured ectopic pregnancy
	Distended, tympanitic	Esophageal intubation
	Gastric insufflation	
Rectal	Blood, melena	Gastrointestinal hemorrhage
Extremities	Asymmetrical pulses	Aortic dissection
	Arteriovenous shunt or fistula	Hyperkalemia
Skin	Needle tracks or abscesses	Intravenous drug abuse
	Burns	Smoke inhalation
		Electrocution

decrease significantly during the first hours of arrest, and hypothermia may cause cardiac arrest or be caused by prolonged arrest.

Resuscitation

Management of cardiac arrest occurs in an orchestrated effort by a health care team led by a clinician who can monitor the efficacy and response to therapeutic interventions. Interventions should be performed rapidly and efficiently to maximize the chances of a good neurologic outcome. Restoration of adequate cardiac function is the defining factor of return of spontaneous circulation (ROSC), but restoration of good neurologic function is the defining metric of a successful resuscitation. The likelihood of achieving both of these goals decreases with every minute that the patient remains in cardiac arrest. Fig. 5.1 depicts an algorithm for the management of cardiac arrest.

The goal of CPR is to maintain vital organ perfusion until ROSC is achieved. The quality of CPR is perhaps the most underappreciated component of the resuscitation effort. Important quality performance measures include compression rate (100 to 120 compressions/min), compression depth (5 to 6 cm), chest compression fraction at least 80% (i.e., CPR performed 80 out of every 100 seconds of the pulseless interval), full chest recoil between compressions (no residual leaning between compressions), and ventilation rate (10 ventilations/min).[10]

While chest compression–only CPR (hands-only-CPR) is recommended for lay-providers in the out-of-hospital setting, trained providers who are willing and able to provide ventilations should do so.[10] A 30:2 compression-to-ventilation ratio is currently recommended for health care professionals in all adult resuscitation scenarios until an advanced airway has been established.[11] While either bag-mask ventilation or an advanced airway strategy may be considered in any setting for adult cardiac arrest, the strategy employed should minimize CPR interruptions. If an advanced airway strategy is pursued, a supraglottic airway may be used and can be placed without interruptions to CPR. Endotracheal intubation may also be pursued in settings with high intubation success rates.[12] Once an advanced airway is secured, CPR should be performed continuously, without pausing for ventilation, while providing one ventilation every 6 seconds (10 ventilations/min). Hyperventilation during CPR should be avoided, as it is associated with reduced cardiac output during CPR.[10]

Ventricular Fibrillation and Pulseless Ventricular Tachycardia

Cardiac arrest with presenting rhythm of VF or pVT often has a primary cardiac origin. VF and pVT are treated identically as they are generally caused by the same mechanisms and respond to the same interventions. Therapy for VF and pVT includes defibrillation, high-quality CPR, and administration of vasopressors and anti-dysrhythmic agents.

For a pulseless unresponsive patient in VF or pVT, chest compressions should be initiated immediately and continued until a defibrillator is available. Current consensus favors delivering a single countershock with minimal pause in chest compressions.[13] Defibrillation is followed immediately by the resumption of chest compressions for 2 minutes before a rhythm check and additional defibrillation, as appropriate.[10] If a patient is defibrillated into a different pulseless rhythm (PEA or asystole), subsequent treatment should be modified to address those specific rhythms.

Traditional monophasic defibrillators have almost completely been replaced by defibrillators using biphasic waveforms. With biphasic defibrillation, the energy required for successful defibrillation (the defibrillation threshold) is lower than with monophasic defibrillation. The biphasic waveform increases the likelihood of initial defibrillation success and decreases the likelihood of post–countershock myocardial dysfunction. However, data are currently inadequate to conclude that a biphasic or monophasic waveform is superior in achieving ROSC or survival to hospital discharge. Health professionals should use device-specific manufacturer-recommended countershock energies for biphasic defibrillators,[13] while the recommended energy for a single monophasic defibrillation is 360 J. Assurance of maximal compression fraction can be accomplished by

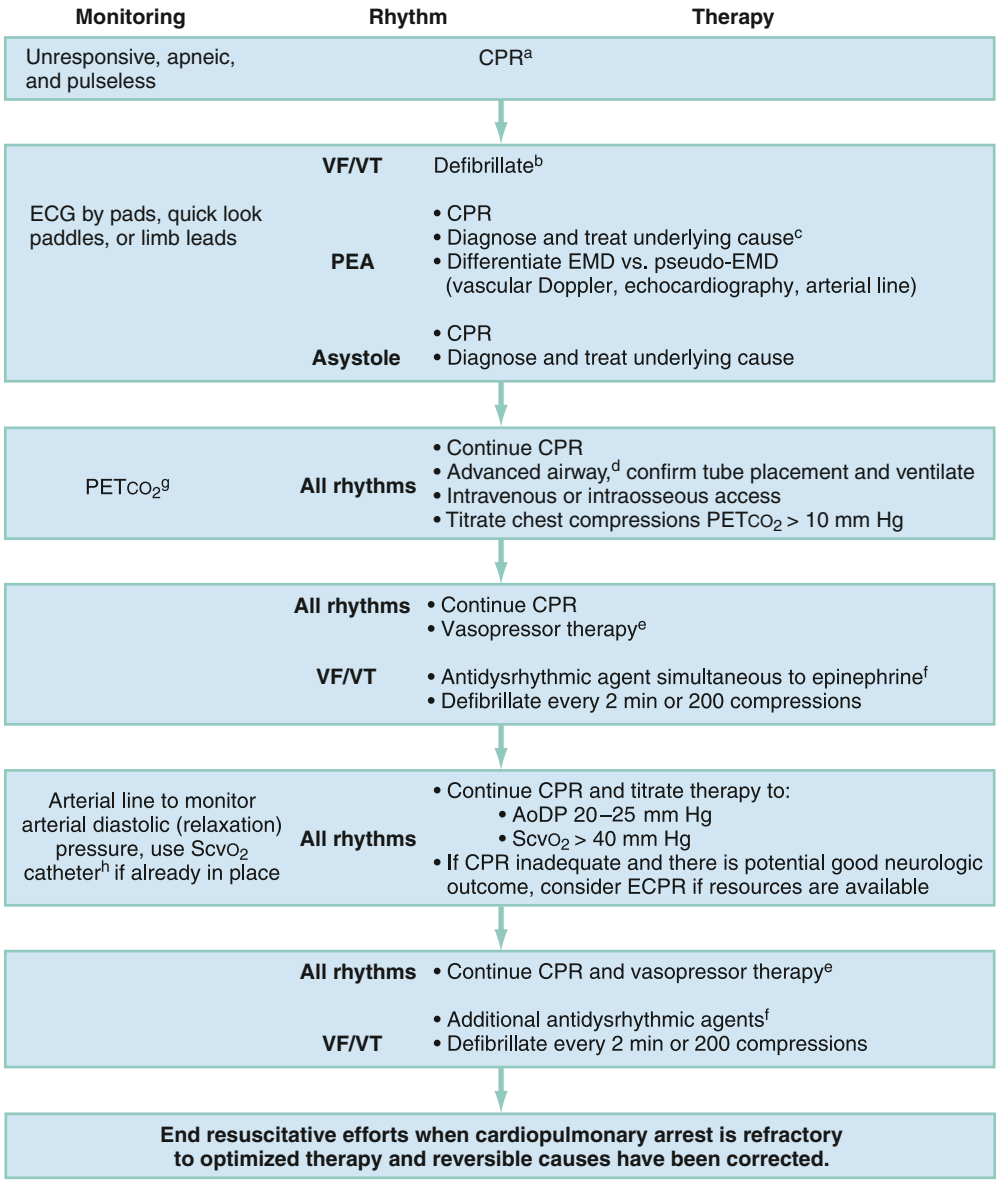

Fig. 5.1 Emergency Treatment Algorithm for Treatment of Cardiac Arrest. [a]If arrest is witnessed and known to be of short duration, immediate rhythm assessment and defibrillation of ventricular fibrillation/ventricular tachycardia *(VF/VT)* precede cardiopulmonary resuscitation *(CPR).* [b]Biphasic defibrillation should use manufacturer-recommended energy versus monophasic defibrillation (360 J). [c]See Table 5.3. [d]Endotracheal intubation or supraglottic airway, when feasible, with minimal interruption in chest compressions. [e]Epinephrine, initial dose of 1 mg IV or IO. Repeat every 3 to 5 minutes. [f]Amiodarone, 300 mg via IV push, followed by 150 mg. Lidocaine is an alternative antidysrhythmic if amiodarone is not available. Magnesium sulfate may be given in torsades de pointes or hypomagnesemia. [g]Changes in the partial pressure of end-tidal carbon dioxide ($PETco_2$) may not be predictive of myocardial blood flow in the setting of high-dose vasopressor therapy. [h]Invasive monitoring should be performed only if adequate personnel are available and if it would not delay therapeutic interventions. *AoDP,* Aortic diastolic pressure; *ECG,* electrocardiogram; *EMD,* electromechanical dissociation; *PEA,* pulseless electrical activity; *$Scvo_2$,* central venous oxygen saturation.

placing defibrillation pads early in the resuscitation sequence, thus not requiring a pause while defibrillation paddles and conducting gel are placed for each shock, and continuing chest compressions while the defibrillator charges.

Pulseless Electrical Activity

PEA is defined as coordinated electrical activity of the heart (other than VF or pVT) without a palpable pulse. PEA can further be characterized as electromechanical dissociation (EMD), in which no myocardial contractions occur, and pseudo-EMD, in which myocardial contractions occur but are inadequate and no pulse can be palpated. Distinguishing EMD from pseudo-EMD may be useful in determining cause and guiding treatment,[14] though in most cases of primary PEA arrest there is a natural progression from hypotension to pseudo-EMD to EMD. Initial assessment of PEA may include echocardiography to distinguish EMD from pseudo-EMD, as volume loading or continuous

TABLE 5.3 Diagnosis and Treatment of Common Causes of Pulseless Electrical Activity

Cause	Diagnosis	Palliative Therapy	Definitive Therapy
Hypovolemia	Response to volume infusion	Volume infusion	Hemostasis if hemorrhage
Hypoxia	Response to oxygenation	Oxygenation, assisted ventilation	Treat underlying cause
Cardiac tamponade	Echocardiogram; jugular venous distention	Pericardiocentesis	Thoracotomy or pericardiotomy
Tension pneumothorax	Asymmetric breath sounds, tracheal deviation	Needle thoracostomy	Tube thoracostomy
Hypothermia	Rectal temperature		Warm peritoneal or thoracic lavage, veno-arterial ECMO
Pulmonary embolus	Risk factors or evidence of deep venous thrombosis	Veno-arterial ECMO	Lytic therapy, pulmonary embolectomy
Drug overdose	History of drug ingestion	Drug-specific	Drug-specific
Hyperkalemia	History of renal failure or elevated serum potassium level	Calcium chloride, insulin and glucose, sodium bicarbonate	Hemodialysis
Acidosis	Arterial blood gas	Hyperventilation, sodium bicarbonate	Treat underlying cause

ECMO, Extracorporeal membrane oxygenation.

vasopressor infusions, which are not used in many cardiac arrest resuscitations, may be helpful in select cases of pseudo-EMD.

True EMD is the result of a primary disorder of electromechanical coupling in myocardial cells. It often is associated with abnormal automaticity and conduction, resulting in bradycardia and a wide QRS complex. Although the mechanism of uncoupling is unclear, it usually is associated with global myocardial energy depletion and acidosis resulting from ischemia or hypoxia. True EMD often occurs after defibrillation following prolonged VF and is associated with hyperkalemia, hypothermia, and drug overdose.

Pseudo-EMD is typically a transient state in the progression to EMD. Cardiac causes of pseudo-EMD include papillary muscle and myocardial wall rupture, in which the ventricle continues to contract but forward flow is greatly diminished, or primary supraventricular tachycardia. Additional extra-cardiac causes of pseudo-EMD include hypovolemia, tension pneumothorax, pericardial tamponade, and massive pulmonary embolism. Pseudo-EMD of extra-cardiac origin most often has narrow complex tachycardia initially, which can progress to bradycardia, with conduction abnormalities and QRS widening.

Treatment of patients with PEA, including both EMD and pseudo-EMD, requires general resuscitation measures, including CPR, assisted ventilation, IV access, administration of vasopressors, and rapid diagnosis and treatment of the underlying cause. A mnemonic "4 H's and 4 T's" is often referenced to aid in rapidly identifying reversible etiologies of PEA arrest: hypoxia, hypovolemia, hypo/hyperkalemia, hypothermia, thrombosis (pulmonary embolism), tamponade (cardiac), toxins, and tension pneumothorax. History and physical examination may provide valuable clues to the underlying cause (Table 5.3). In hypoxia and hypovolemia, the diagnosis is based on response to empiric therapy, whereas other causes such as pericardial tamponade, tension pneumothorax, and hypothermia can be definitively diagnosed during resuscitation.

Asystole

Asystole represents complete cessation of myocardial electrical activity. Although asystole may occur early in cardiac arrest as a consequence of progressive bradycardia, asystole generally represents the end-stage rhythm after prolonged cardiac arrest caused by VF, pVT, or PEA. The potential exists for an organized rhythm or VF to appear as asystole in a single lead if the rhythm vector is completely perpendicular to the lead vector, and thus asystole should be confirmed in at least two limb leads. Although asystole may be difficult to distinguish from extremely fine VF, routine countershock of asystole has not been shown to improve survival.

Treatment of asystole requires general resuscitation measures, including CPR, assisted ventilation, IV access, and repeated administration of vasopressors. Administration of atropine is not beneficial, and asystole in the out-of-hospital setting seldom responds to pacing. To be effective, pacing must be initiated within several minutes of arrest before progression to asystole.

PHARMACOLOGY

Obtain intravenous (IV) or intraosseous (IO) access for an ongoing resuscitation that fails to abort following CPR and defibrillation. Epinephrine 1 mg every 3 to 5 minutes is currently recommended, based on improved survival and ROSC demonstrated in randomized clinical trials.[12,15] Vasopressin offers no advantage as a substitute for epinephrine in cardiac arrest, but use may be considered, typically at a dose of 40 IV push. High-dose epinephrine is not recommended for routine use. Epinephrine should be administered as soon as feasible for patients with non-shockable rhythms, and after initial defibrillation attempts have failed in those with shockable rhythms.

Hemodynamic directed resuscitation involves titrating chest compressions and vasopressor therapy to hemodynamic variables rather than a one-size-fits-all approach. Titration of chest compressions and vasopressor therapy to maintain systolic blood pressure of 90 mm Hg and a coronary perfusion pressure (CPP) of 20 mm Hg during CPR demonstrated improved outcomes in animal models.[16] CPP during CPR is defined as the difference between aortic and right atrial pressures during relaxation (CPR diastole). Although measuring CPP is not practical in most ED resuscitations, these data support the recommendation of titrating vasopressors to an arterial relaxation pressure of at least 20 to 25 mm Hg.

For VF or pVT refractory to defibrillation, anti-dysrhythmics can be administered, and amiodarone (first dose: 300 mg IV/IO; second dose: 150 mg IV/IO) or lidocaine (first dose: 1 to 1.5 mg/kg IV/IO; second dose: 0.5 to 0.75 mg/kg IV/IO) are recommended as first-line agents.[17] In a recent prospective randomized clinical trial, only lidocaine resulted in an increased rate of ROSC, although neither therapy

resulted in statistically significant improvements in survival.[18] Other medications that may be of value in special cases include magnesium sulfate in torsades de pointes (2 to 4g IV), calcium in hyperkalemia (1 g calcium chloride IV or 3 g calcium gluconate IV), sodium bicarbonate in tricyclic antidepressant overdose (1 to 2 mEq/kg), and dextrose in hypoglycemia (25 to 50g IV). Routine administration of atropine outside the setting of bradycardia is not beneficial.

DEVICES AND TECHNIQUES

Monitoring

In addition to monitoring specific CPR performance parameters, physiologic monitoring, if available, can help optimize CPR quality for the individual patient (Table 5.4). If the inadequacy of CPR is recognized early in the resuscitation despite optimized therapy, the clinician may consider more invasive measures such as ECPR or coronary angiography and PCI with ongoing chest compressions if these modalities are readily available and there is significant potential for survival with good neurologic function. After prolonged arrest, however, clear indications that CPR is inadequate (based on appropriate monitoring techniques) can be a contributing factor in the decision to cease resuscitation efforts.

Traditional monitoring during CPR has relied on evaluation of the electrocardiogram (ECG) in one or more leads and palpation of carotid or femoral artery pulses. Electrocardiographic monitoring during cardiac arrest indicates the presence or absence of electrical but not mechanical activity. Myocardial blood flow does not depend on the palpated arterial pressure during chest compression (CPR systole), but rather on CPP. Although these two monitoring modalities may be the best attainable in certain circumstances, they do not provide reliable information regarding the effectiveness of CPR and interventions or prognosis.

No single monitoring technique provides all desired information during a resuscitation, and the modalities discussed below can be challenging to initiate during CPR. A brief overview is provided of CPP, end-tidal carbon dioxide ($ETco_2$), and central venous oxygen saturation ($Scvo_2$) monitoring, which, if available, can be used to detect inadequate CPR with high specificity (see Table 5.4). In addition, several of these techniques are useful in the immediate post–cardiac arrest period.

End-Tidal Carbon Dioxide

The partial pressure of CO_2 in exhaled air at the end of expiration ($PETco_2$) can be a reliable indicator of cardiac output during CPR. This is most reliably measured through waveform capnography after endotracheal intubation, though can also be used with a supraglottic airway device or bag mask.[19] $PETco_2$ depends on CO_2 production, alveolar ventilation, and pulmonary blood flow (i.e., cardiac output) and correlates well with CPP and cerebral perfusion pressure during CPR. Therefore, when minute ventilation is held constant and no exogenous CO_2 is introduced (e.g., with sodium bicarbonate [$NaHCO_3$] administration), only increased cardiac output during CPR will significantly increase $PETco_2$. ROSC causes immediate and significant increases in $PETco_2$.[13] Therefore, $PETco_2$ monitoring can detect ROSC at any time during the chest compression cycle, providing valuable guidance for pharmacologic therapies and minimizing the need for a pulse check when organized rhythms are detected (Fig. 5.2).

Resuscitation after cardiac arrest is likely to fail if $PETco_2$ values of 10 mm Hg or more are not achieved. Therefore, values less than 10 mm Hg should prompt the clinician to enhance the quality of CPR by improving compression rate, depth, or recoil.[13] $PETco_2$ monitoring also can aid in the diagnosis and treatment of PEA. Patients in a state of PEA with mechanical heart activity may have pulsatile flow that simply cannot be detected by palpation of a pulse. In such cases, $PETco_2$ levels may be elevated, even without compressions. Use of ultrasound in such cases can identify corresponding cardiac activity. In these cases, volume expansion or the use of vasopressors and inotropes is indicated. $PETco_2$ monitoring is also useful in rapidly detecting the success of tension pneumothorax decompression, pericardiocentesis for pericardial tamponade, and fluid resuscitation for hypovolemia. Finally, $PETco_2$ monitoring is valuable in patients after ROSC to monitor endotracheal tube placement (waveform capnography recommended), titrate minute ventilation to avoid hyperventilation, and detect sudden hemodynamic deterioration.

Central Venous Oxygen Saturation

Central venous oxygen saturation, $Scvo_2$, when available, provides an additional method to monitor the adequacy of resuscitative measures. The mixed venous blood oxygen saturation in the pulmonary artery (SvO_2) represents the oxygen remaining in the blood after systemic extraction. Studies have shown a close correlation between $Scvo_2$ and SvO_2 during CPR. Because oxygen consumption remains relatively constant during CPR, as does arterial oxygen saturation (Sao_2) and hemoglobin, changes in $Scvo_2$ reflect changes in oxygen delivery by means of changes in cardiac output.

Although continuous $Scvo_2$ monitors have largely fallen out of favor with the diminution of early goal directed therapy for sepsis (see Chapter 127), if available, multi-lumen oximetric $Scvo_2$ catheters can be placed in the same manner as regular central venous catheters and used to monitor $Scvo_2$ in real time. $Scvo_2$ values normally range from 60% to 80%. During cardiac arrest and CPR, these values range from 25% to 35%, indicating greatly enhanced oxygen extraction of tissues owing to the inadequacy of oxygen delivery during CPR. Failure to achieve an $Scvo_2$ of 40% or greater during CPR has had a negative predictive value for ROSC of almost 100%. $Scvo_2$ also helps to detect ROSC rapidly without interruption of chest compressions, because ROSC results in a rapid increase in $Scvo_2$ as oxygen delivery to tissues dramatically increases. $Scvo_2$ monitoring is also useful in the post–cardiac arrest period for hemodynamic optimization and for recognition of any sudden deterioration in the patient's clinical condition as discussed later in this chapter.

Echocardiography

The main use of echocardiography is diagnostic, especially in patients with PEA by distinguishing EMD from pseudo-EMD. It may also help diagnose mechanical causes of PEA such as pericardial tamponade and pulmonary embolism, and in guiding pericardiocentesis. Transesophageal echocardiography (TEE) during CPR is an area of active research and has been associated with shorter chest compression pauses than

TABLE 5.4 Indicators of Inadequate Blood Flow During Cardiopulmonary Resuscitation

Monitoring Technique	Indicator
Carotid or femoral pulse	Not palpable
Coronary perfusion pressure	<15 mm Hg
Arterial relaxation (diastolic) pressure	<20–25 mm Hg
$PETco_2$	<10 mm Hg
$Scvo_2$	<40%

$PETco_2$, Partial pressure of CO_2 in exhaled air at the end of expiration; *$Scvo_2$*, central venous oxygen saturation.

transthoracic echocardiography.[20] TEE may provide an additional visual method to monitor effectiveness of chest compressions in real time by directly visualizing changes in the left ventricle with changes in chest compression technique. In the post-arrest period, echocardiography can prove valuable in evaluating myocardial dysfunction and determining the need for mechanical assistance of the failing heart.

Extracorporeal Cardiopulmonary Resuscitation

Despite lack of supporting evidence from randomized trials, use of VA-ECMO as rescue therapy for refractory adult and pediatric IHCA, deemed ECPR, is a well-established practice in many specialized centers.[21] Observational and case-control studies have suggested benefit in highly selected patients with refractory OHCA, reporting rates of survival with good neurologic function ranging from 11% to 33%.[8,22] Timely arterial and venous access, placement of cannulas, and initiation of ECPR support is critical to success. When used, ECPR is most successful when flow is initiated within 60 minutes of cardiac arrest onset. Survivors typically require 2 to 5 days before they can be successfully weaned from ECMO support. Common complications include coagulopathy, hemorrhage, limb ischemia, vascular injury, renal replacement therapy, and stroke.[22] The implementation of an ECPR program for refractory OHCA is resource-intensive and requires training and coordination among the entire resuscitation system of care—including EMS providers, receiving EDs, designated specialties, and participating intensive care units (ICUs)—to be successful. More research is needed to determine the feasibility and value proposition of implementation outside of high-volume, specialized centers.

Laboratory Testing

Intermittent arterial and venous blood sampling for gas or chemistry analysis is of limited use during CPR. Typical blood gas findings during CPR demonstrate venous respiratory acidosis and arterial respiratory

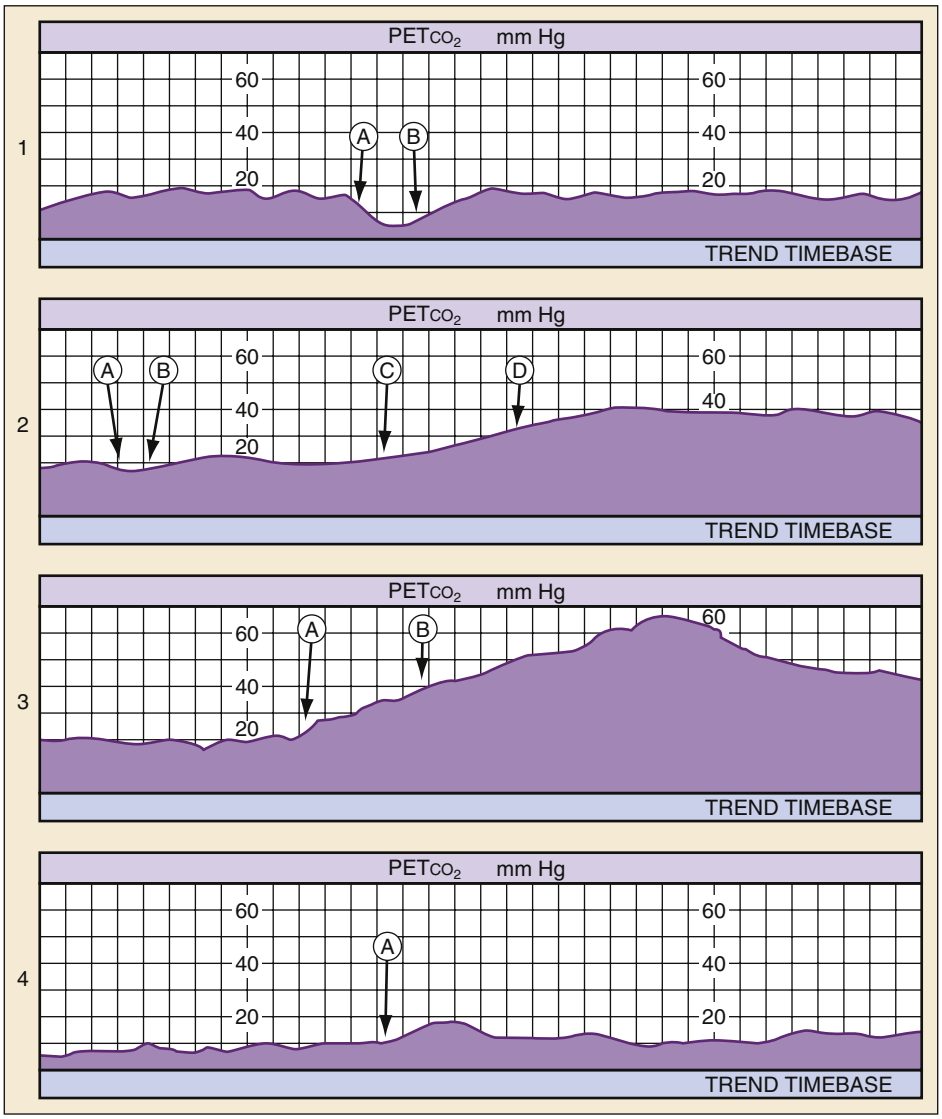

Fig. 5.2 Capnogram tracings of end-tidal carbon dioxide partial pressure *($PETco_2$)* during human cardiopulmonary resuscitation *(CPR)*. **1,** Effect of rescuer fatigue is shown at point A. Point B shows the effect of changing to a fresh rescuer. **2,** Patient with pseudoelectromechanical dissociation. At point A, the patient is pulseless but has a persistent $PETco_2$ value of 20 mm Hg without CPR; at point B, CPR is restarted; at point C, dopamine infusion is started; and at point D, CPR is stopped and a pulse is palpated. **3,** Sudden increase in $PETco_2$ (point A) heralds the return of spontaneous circulation; pulses are palpated at point B. **4,** Point A shows a transient increase in $PETco_2$, such as occurs during bolus administration of sodium bicarbonate.

alkalosis. Sao_2 is usually greater than 94% during CPR and is of little value in titrating resuscitation therapy, except in the case of massive pulmonary embolism or unrecognized esophageal intubation. Although $Scvo_2$ indicates adequacy of CPR, a single measurement may not be as useful as continuous, oximetric $Scvo_2$ monitoring.

Other laboratory studies during CPR are typically not available in time to guide therapy but may serve to confirm a diagnosis following successful resuscitation. Serum electrolyte levels may be ordered to rule out hyperkalemia, hypokalemia, hypomagnesemia, hypercalcemia, and hypocalcemia; however, empirical therapy should be initiated immediately if clinical suspicion exists. Low hemoglobin levels may indicate bleeding, but the initial hemoglobin value may be normal in acute exsanguinating hemorrhage, owing to a lack of rapid vascular and interstitial compartment equilibration.

Arterial Blood Pressure and Coronary Perfusion Pressure

Successful resuscitation of the arrested heart depends on generating adequate CPP during CPR. CPP during CPR is calculated by subtracting right atrial diastolic pressure from aortic diastolic pressure. Animal and human studies have indicated that a minimum CPP of 15 mm Hg is necessary to achieve ROSC if initial defibrillation attempts have failed.

However, CPP monitoring is rarely feasible in ED resuscitations of cardiac arrest patients, as it requires an indwelling arterial pressure catheter and central venous catheter, both transduced properly to provide simultaneous readings. Invasive arterial blood pressure monitoring alone can be helpful in guiding resuscitation and should be used when an indwelling arterial pressure catheter is already in place. When adequate personnel are available, it is often feasible to cannulate the femoral artery during CPR, especially with ultrasound guidance. Human studies have shown that radial or femoral arterial relaxation pressures reliably reflect aortic relaxation pressures during CPR. Monitoring arterial diastolic blood pressure as a surrogate for CPP has been proposed.[13] Titrating resuscitation efforts to arterial relaxation (diastolic) pressure is less reliable than CPP since improper CPR (e.g., leaning on chest during CPR diastole and hyperventilation) can cause undetected elevations in the right atrial pressure, reducing coronary perfusion.

Despite these limitations, it is reasonable to titrate resuscitation efforts to achieve an arterial relaxation (diastolic) pressure of 20 to 25 mm Hg or more when invasive arterial pressure monitoring is available.[10,13] Invasive arterial pressure monitoring during CPR may also help detect ROSC and assist in serial arterial blood gas monitoring. Although arterial and central venous catheters are usually placed in the post–cardiac arrest phase of care, 10% to 20% of patients initially achieving ROSC will re-arrest, making these modalities helpful during the patient's subsequent resuscitation.

OUTCOMES

Post–Cardiac Arrest Care

Resuscitation of a cardiac arrest victim does not end with ROSC. Management includes rapid diagnosis and treatment of the disorders that caused the arrest and complications of prolonged global ischemia. Simultaneous management of these two entities makes caring for a post–cardiac arrest patient particularly challenging. A comprehensive, goal-directed program of post–cardiac arrest care is necessary to optimize survival and neurologic recovery.[23]

Hypothermic Targeted Temperature Management

HTTM in comatose survivors of cardiac arrest has been shown to improve survival and functional outcome in two modestly sized, prospective randomized clinical trials. These studies enrolled only comatose survivors of OHCA that were witnessed arrests and had an initial rhythm of VF. The time to achieve target temperature (<34°C [93.2°F]) ranged from less than 2 hours to a median of 8 hours (interquartile range, 4 to 16 hours), suggesting a broad therapeutic window. HTTM was maintained for 12 to 24 hours, followed by gradual rewarming over 12 to 24 hours. A subsequent large, multicenter international randomized clinical trial of post–cardiac arrest HTTM which enrolled only patients with non-shockable rhythms found no improvement in survival with HTTM at 33°C (91.4°F) for 24 hours, but a near doubling of favorable neurologic function at 90 days (10.2% vs. 5.7%).[3] The largest multicenter international randomized clinical trial of post–cardiac arrest HTTM included all presenting rhythms except unwitnessed asystole and found that outcomes with a target temperature of 33°C (91.4°F) were not superior to those with a target temperature of 36°C (96.8°F). In this study, target temperature was maintained for 28 hours, followed by gradual rewarming at 0.5°C (32.9°F)/h and then maintenance of temperature below 37.5°C (99.5°F) for 72 hours post-ROSC.

Although these studies indicate that post–cardiac arrest HTTM is effective, additional preclinical and clinical data are needed to determine the optimal method of temperature control, time to achieve target temperature, target temperature, duration of therapy, and rate of rewarming. We recommend that emergency clinicians provide HTTM to comatose adult patients who achieve ROSC following cardiac arrest, independent of presenting cardiac rhythm (shockable vs. non-shockable) and location (OHCA vs. IHCA). Furthermore, clinicians should select and maintain HTTM at a constant temperature between 32° and 36°C (89.6° and 96.8°F) for 24 hours after achieving that target temperature.[23]

Although there are no absolute contraindications, relative contraindications may include another obvious reason for coma (e.g., drug overdose, status epilepticus), known end-stage terminal illness, and a preexisting do-not-resuscitate status. In each of the four randomized HTTM trials, the rates of complications, including bleeding, were not statistically different between groups. Specifically, thrombolytic therapy does not preclude the use of hypothermia.

When the decision is made to treat the comatose post–cardiac arrest patient with HTTM, efforts to achieve and maintain target temperature should begin in the ED, when feasible. However, prehospital cooling after ROSC using cold IV saline has not been shown to improve outcomes in three prospective randomized clinical trials.[24] In the ED, practical methods of rapidly inducing hypothermia include ice packs (applied to the neck, inguinal areas, and axilla), fan cooling of dampened exposed skin, cooling blankets, and disabling of ventilator warming circuits. Rapid IV infusion of limited volumes (1 to 2 L) of 4°C (39.2°F) saline facilitates induction of hypothermia, but additional measures are needed to maintain hypothermia.

No one cooling strategy or device has been demonstrated to result in superior clinical outcomes. A number of automated surface cooling devices are now available that use chest and thigh pads and continuous temperature feedback from bladder or esophageal temperature probes. Although more invasive, automated esophageal and endovascular cooling systems are also available that require placement of an orogastric silicone tube or central venous catheter respectively and offer tighter control of temperature at target (standard deviation usually <0.3°C [32.5°F]).

Shivering, which inhibits cooling, can be prevented with sedation and neuromuscular blockade. Continuous electroencephalographic monitoring during HTTM is strongly encouraged to detect seizures, a common occurrence in post–cardiac arrest patients (5% to 20%).[23] Seizures lasting more than 5 minutes should be treated in a manner similar to other emergency settings, initially with IV lorazepam (0.1 mg/kg/

dose to maximum of 4 mg) or diazepam (0.15 to 0.2 mg/kg/dose to a maximum of 10 mg) or intramuscular midazolam (0.2 mg/kg/dose to maximum of 10 mg), and repeated within 5 minutes.[25] Patients meeting the definition of status epilepticus should be treated with antiepileptics as described in Chapter 88. Target core body temperature is best monitored by an indwelling, temperature-sensitive bladder catheter or esophageal temperature probe. Although the optimal duration of post–cardiac arrest hypothermia is unknown and may be related to the total ischemic time,[26] target temperatures are typically actively maintained for at least 24 hours and routine use of longer intervals is associated with more frequent adverse events and not with improved neurological outcome at 6 months.[27] Following 24 hours at target temperature, patients are gradually rewarmed over 12 to 16 hours and provided active fever suppression at normothermia (37.0°C [98.6°F]) for 72 additional hours.[23]

Coronary Angiography and Primary Percutaneous Coronary Intervention

An immediate concern in a comatose cardiac arrest survivor is whether the patient has an acute coronary syndrome (ACS). Diagnosing ACS in an unconscious patient after cardiac arrest presents a unique challenge. A standard 12-lead ECG should be obtained as soon as feasible after ROSC, with additional right-sided and/or posterior leads as indicated. In one study, 50% of patients achieving ROSC after OHCA were found to have acute coronary occlusion on cardiac catheterization; more than 10% of them did not have ST segment elevation. Subsequent studies have reported that successful, immediate PCI is associated with improved hospital survival in post–cardiac arrest patients, with or without ST segment elevation.

Immediate PCI is indicated for post-ROSC patients with demonstrated ST segment elevation myocardial infarction (STEMI) and should progress via established systems of care.[7,23] Though OHCA patients are often initially comatose, their neurologic status should not be considered a contraindication to immediate angiography and PCI. Initiation of HTTM should not delay PCI; it can be accomplished simultaneously and in concert with interventional cardiology.[23] In the absence of signs of STEMI, a routine immediate angiography and PCI for OHCA was not found to improve survival at 90 days when compared to delayed angiography in one randomized clinical trial.[28] However, when clinical suspicion of ACS is high, rapid post-ROSC angiography and PCI, when indicated, have been associated with improved survival to hospital discharge when a competing non-cardiac cause for OHCA is not immediately evident.

When PCI is indicated but not available, transfer of post–cardiac arrest patients to a center capable of PCI or fibrinolytic therapy should be considered via usual ACS systems of care. Relative exclusion criteria for fibrinolytic therapy unique to the post–cardiac arrest patient include evidence of significant CPR trauma such as pneumothorax, flail chest, or pulmonary contusion with hemorrhage. The effects of HTTM on the efficacy and complications of fibrinolytic therapy in post-arrest patients have not been formally studied. However, an initial randomized TTM trial where fibrinolytics were given to approximately 50% of enrolled subjects demonstrated no increase in complications compared to controls.

Although the immediate post–cardiac arrest period is characterized by a hypocoagulable state, it is rapidly replaced by a hypercoagulable state for up to 72 hours as the post-ROSC surge of activated protein C abates. Dual anticoagulant and antiplatelet therapy (aspirin and a P2Y12 inhibitor) should be strongly considered for post-cardiac arrest patients with diagnosed or suspected ACS in the absence of contraindications. Recent clinical evidence has suggested that ticagrelor results in more effective platelet inhibition than clopidogrel in post–cardiac arrest patients treated with HTTM.

Antidysrhythmic Therapy

There is no proven benefit of prophylactic antiarrhythmic therapy or continuous infusion of an antiarrhythmic drug that has been associated with restoration of a stable rhythm during CPR. Concomitant therapies (e.g., nitrates, beta blockers) are best performed in conjunction with careful hemodynamic monitoring. If indicated, IV preparations of nitrates and short-acting beta blockers (e.g., esmolol) are preferred because of their brief duration of action and ease of titration. In patients with new left bundle branch block, right bundle branch block with left anterior or posterior hemiblock, second-degree type II block, or third-degree block, transthoracic pacing pads should be applied in case they are needed to treat bradycardic rhythms. Placement of a transvenous pacing catheter may be considered, but is less commonly done with the demonstrated efficacy of transthoracic cardiac pacing.

Oxygen Debt and Hemodynamic Management

Inadequate oxygen delivery (Do_2) causes cells to convert to anaerobic metabolism, resulting in increased lactate production (dysoxia). Continued resuscitation efforts are aimed at optimizing Do_2 to prevent subsequent multi-organ dysfunction and recurrent arrest. However, exposure to supranormal arterial oxygen partial pressure (>300 mm Hg) over the first six hours following cardiac arrest can exacerbate oxidative brain injury and cumulative exposure is associated with neurologic outcome in a dose-dependent manner.[29] Therefore, the fraction of inspired oxygen (FIO_2) should be titrated to the minimum concentration required to maintain an arterial oxyhemoglobin saturation of 94% as rapidly as clinically appropriate following cardiac arrest. This level of oxygenation avoids detrimental hyperoxia while ensuring appropriate oxygen delivery.

Serum lactate levels provide an indirect measure of whether Do_2 is adequate to prevent anaerobic metabolism. A single lactate level is almost universally elevated following resuscitation from cardiac arrest. Detection of ongoing lactate production requires monitoring of serial lactate levels. Insufficient Do_2 also causes increased oxygen extraction, resulting in decreased mixed venous oxygen saturation (S_{VO2}). Low S_{VO2} coupled with persistently elevated lactate levels indicates inadequate Do_2. Patients with prolonged duration of CPR and those who have received high-dose vasopressor therapy during CPR may develop impaired tissue oxygen extraction. In such patients, S_{VO2} is abnormally high (venous hyperoxia) in the presence of inadequate Do_2 and likely represents a state of severe systemic shunting resulting in an increase in nonnutritive blood flow. Lactate levels in these cases are persistently elevated. Treatment includes carefully reducing any continuous infusion of vasopressors and providing more aggressive volume loading.[30] The use of guided vasodilator therapy to recruit under perfused tissue beds, as well as consideration of mechanical adjuncts such as an intra-aortic balloon pump or VA-ECMO, may also be necessary in this situation.

The use of combined hemodynamic and metabolic endpoints to guide resuscitation in the ED has been shown to improve the outcome of patients with septic shock. Because the post–cardiac arrest condition represents a complex state of cardiovascular shock, the use of such goal-directed therapy is inherently valuable to reduce mismatches of oxygen delivery and consumption that cannot be determined by a simple physical examination and vital signs.

The use of goal-directed hemodynamic therapy is relatively straightforward and can be frequently accomplished via noninvasive means. Bedside ultrasound can be used to visualize the left ventricle in real time, allowing for direct assessment of cardiac contractility and myocardial wall function. Furthermore, in mechanically ventilated patients, volume responsiveness can also be reliably evaluated by

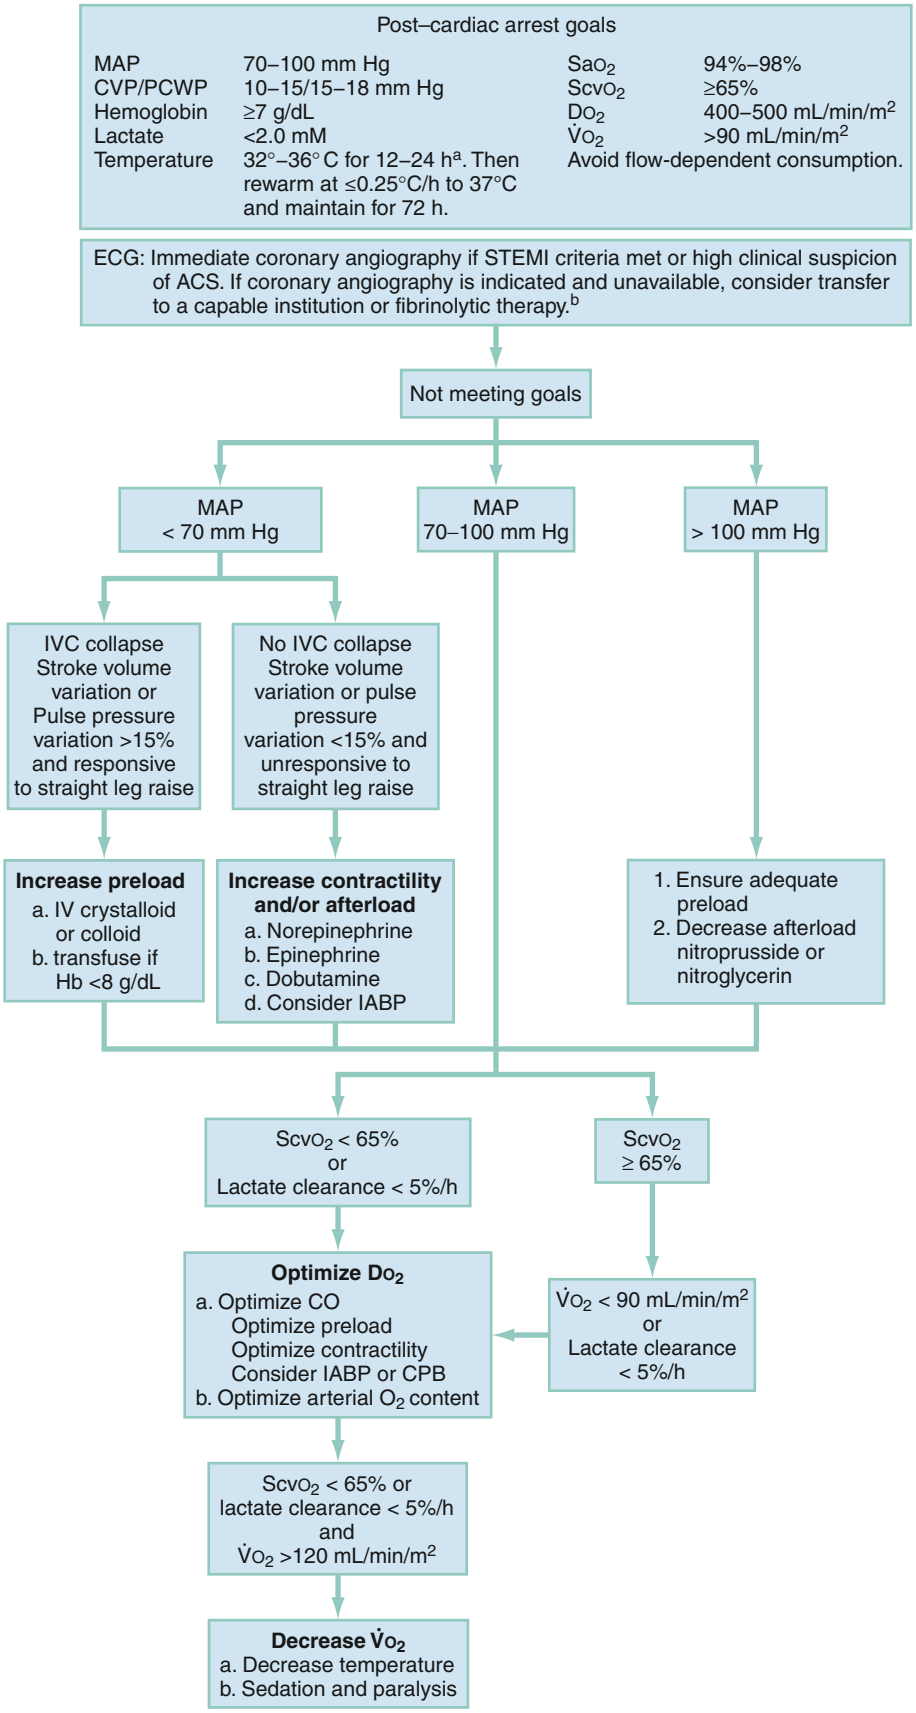

Fig. 5.3 Goal-Directed Post-Arrest Treatment Algorithm. [a]Hypothermic targeted temperature management (HTTM) is indicated in comatose survivors of cardiac arrest. Relative contraindications include uncontrolled bleeding, preexisting coagulopathy, another obvious reason for coma (e.g., drug overdose, status epilepticus), known end-stage terminal illness, and a preexisting do-not-resuscitate status. [b]Initiation of HTTM is not a contraindication to thrombolytic therapy. *CPB,* cardiopulmonary bypass; *CVP,* central venous pressure; *Do_2,* oxygen delivery; *ECG,* electrocardiogram; *Hb,* hemoglobin; *IABP,* intra-aortic balloon pump; *MAP,* mean arterial pressure; *MI,* myocardial infarction; *NTG,* nitroglycerin; *PCWP,* pulmonary capillary wedge pressure; *Sao_2,* arterial oxygen saturation; *$Scvo_2$,* central venous oxygen saturation; VO_2, oxygen consumption.

measuring the inferior vena cava collapse or passive leg raise. These dynamic noninvasive measures can guide volume expansion to maximize preload without inducing pulmonary edema.

When sonographic measures are unavailable, the placement of a supradiaphragmatic central venous catheter may be used to give further clinical context for intractable shock. If $Scvo_2$, a reliable surrogate for SvO_2, is abnormally low (<65%), but hemoglobin and Sao_2 values are normal, cardiac output is insufficient. Although central venous pressure (CVP) has limitations in certain disease states (e.g., pulmonary hypertension), a CVP can be followed in patients with cardiogenic shock. Although absolute values do not correlate well with volume responsiveness, a patient with a CVP less than 8 mm Hg is unlikely to have volume overload. If intravascular volume is adequate and the patient has a mean arterial pressure of at least 65 mm Hg, unmet resuscitation goals should prompt therapy with an inotropic agent such as dobutamine while reperfusion strategies or mechanical adjuncts are considered.[31]

The response to Do_2-optimizing interventions can be monitored by continuous or serial $Scvo_2$ measurements and serial lactate levels. An increase in $Scvo_2$, coupled with a decrease in lactate levels, indicates improved Do_2. An unchanging $Scvo_2$ level indicates the need to continue to increase delivery. Persistently elevated lactate levels and a low $Scvo_2$, despite maximum pharmacologic support and volume management, signal the need for additional interventions to optimize Do_2. Similarly, in patients with venous hyperoxia and elevated levels of lactate, the combination of these findings indicates severe microvascular dysfunction, which also leads to the accumulation of oxygen debt incompatible with survival. If oxygen debt continues to accumulate, the patient will be at increased risk of developing multisystem organ failure or death. Fig. 5.3 provides a goal-directed guide to care of the post-arrest patient.

Hospital protocols and resuscitation systems of care can be designed to ensure prompt transfer of post–cardiac arrest patients from the ED to the cardiac catheterization laboratory or an ICU, where intensive monitoring can guide subsequent therapy to achieve optimal patient outcomes. Unless prompt transfer to the ICU is anticipated and routinely achieved, comprehensive post–cardiac arrest care should be initiated in the ED.

CHAPTER 5: QUESTIONS AND ANSWERS

1. Which of the following statements regarding the epidemiology of out-of-hospital cardiac arrest is true?
   - **a.** Most patients have an automated external defibrillator applied prior to emergency medical services (EMS) arrival.
   - **b.** Most patients receive bystander CPR.
   - **c.** Most surviving to hospital discharge will not have major persistent neurologic deficits.
   - **d.** Only 2% of EMS-treated out-of-hospital cardiac arrests survive to hospital discharge.

Answer: c. It is estimated that 180,000 patients are treated for out-of-hospital cardiac arrest each year in the United States. The number of patients receiving bystander cardiopulmonary resuscitation (CPR) remains low, averaging 40%. The proportion of emergency medical services (EMS)–treated cardiac arrest patients with an initial shockable rhythm has declined over time to 18% in recent US studies. Automated external defibrillators are applied in a minority of cases prior to EMS arrival. Recent epidemiologic data from cardiac arrest registries indicate the survival rate to hospital discharge for EMS-treated, out-of-hospital cardiac arrest is about 10%. Of patients surviving to hospital discharge, independent of neurologic status on presentation, 79% have good neurologic function.

2. A 75-year-old man presents with return of spontaneous circulation (ROSC) after 2 minutes of ventricular fibrillation and successful defibrillation by EMS. The patient is unresponsive to verbal and painful stimuli. Vital signs on arrival are pulse, 120 beats/min; blood pressure, 130/70 mm Hg; respiratory rate, 10 breaths/min; temperature, 36°C (96.8°F); and oxygen saturation, 94%. The patient has intravenous access. The next most appropriate examination or procedure is:
   - **a.** Anteroposterior (AP) chest radiograph
   - **b.** Arterial blood gas (ABG)
   - **c.** Comprehensive neurologic examination
   - **d.** Electrocardiography

Answer: d. Acute coronary syndrome is a common cause of out-of-hospital cardiac arrest. Electrocardiography should be performed as soon as possible after ROSC to evaluate for ST segment elevation. Because it is impossible to determine survival or neurologic status in the immediate post-arrest period, ST segment elevation myocardial infarction (STEMI) should be treated aggressively with percutaneous coronary intervention (PCI) independently of coma or other laboratory values such as those provided on ABG analysis. Oxygen saturations above 94% are adequate for tissue perfusion, and hyperoxia may be harmful. AP chest radiographs may be important to evaluate ventilatory status if the patient is unstable.

3. Which chest compression/ventilation ratio is recommended during adult resuscitation efforts performed by health care professionals before placement of an advanced airway?
   - **a.** 10:1
   - **b.** 20:1
   - **c.** 20:2
   - **d.** 30:2

Answer: d. A 30:2 compression/ventilation ratio is currently recommended for health care professionals in all adult resuscitation scenarios. Although recent evidence has suggested that chest compression-only CPR is effective when performed by bystanders in the out-of-hospital setting, there is inadequate evidence to recommend this as an alternative strategy for health care professionals, except when inadequate personnel are present to provide compressions, ventilation, and other resuscitative activities.

4. Which of the following statements regarding hypothermic targeted temperature management (HTTM) in comatose survivors of cardiac arrest is true?
   - **a.** Gradual rewarming should occur over 4 hours.
   - **b.** Pregnancy is an absolute contraindication.
   - **c.** Prolonged pharmacologically induced paralysis without sedation is often required to control shivering.
   - **d.** Target core body temperature should be 32° to 36°C.

Answer: d. Induction of prolonged HTTM in comatose survivors of cardiac arrest has been shown to improve survival and functional outcome. A target temperature in the range of 32°C to 36°C (89.6°F to 96.8°F) should be selected and maintained. The time to achieve this temperature has not been clearly defined, and it has been suggested there is a broad therapeutic window. In the studies showing a benefit, maintenance of hypothermia occurred for 12 to 24 hours, followed by gradual rewarming over 12 to 24 hours. There are no absolute contraindications to induced hypothermia after arrest. Shivering, which inhibits cooling, can be prevented with sedation and pharmacologic paralysis. However, prolonged paralysis should be avoided because of the risk of unrecognized seizure activity in post–cardiac arrest patients.

5. For end-tidal pressure of carbon dioxide ($PETCO_2$) to be a reliable indicator of cardiac output during cardiac arrest, which of the following must be present?
   - **a.** Mechanical chest compressions must be performed.
   - **b.** The patient must be in asystole.
   - **c.** The patient must be normothermic
   - **d.** The patient must have relatively constant minute ventilation.

Answer: d. Although $PETCO_2$ will change in direct relationship to cardiac output, alterations in minute ventilation will concentrate or dilute the fixed amount of expired CO_2, influencing the $PETCO_2$ measured independently of cardiac output. Therefore, for $PETCO_2$ to be a reliable indicator of cardiac output, minute ventilation must be held relatively constant. The relationship of $PETCO_2$ and cardiac output during CPR is not dependent on rhythm, mechanisms of chest compressions, or temperature. High-dose vasopressor therapy can cause a decrease in cardiac output during CPR, despite increased myocardial blood flow, which results in a decreased $PETCO_2$.

6

Pain Management

James R. Miner and John H. Burton

KEY CONCEPTS

- Acute pain is an urgent condition for the patient. Pain should be rapidly assessed, treated, and frequently reassessed in tandem with diagnostic evaluations.
- Therapy for acute pain is different than for chronic pain. Chronic pain treatment should be undertaken in consultation with the clinician(s) responsible for the patient's long-term management. In general, opioid analgesic agents should not be administered in the ED or prescribed for outpatient therapy for chronic pain patients unless the plan is agreed to by the responsible outpatient clinician.
- Titrated IV opioid analgesics are the primary therapeutic approach for the treatment of moderate and severe acute pain. When intravenous access is not indicated or attainable, SC administration is preferable to the IM route.
- Opioid therapy should be reserved for pain that has not been or cannot adequately be treated with nonopioid therapies.
- Oral oxycodone, with an onset of action similar to that of IM or SC opioids, can be used for moderate pain when the IV route is not otherwise needed. Oxycodone and other oral opioids should be administered and prescribed as a single-drug preparation, not as part of a combination with acetaminophen.
- Ambulatory treatment with opioids should be confined to the period of acute pain. Most opioid prescriptions from the ED for acute injury should be for 3 to 5 days, after which the patient is transitioned to nonopioid analgesia or reevaluated by an outpatient clinician.
- Acetaminophen and NSAIDs should be added to pain therapy when not contraindicated. Their analgesic effects are additive to those of opioids and each other.
- There is no evidence to support the concept that diagnosis based on physical examination findings will be impaired by administering opioid pain medications to achieve reasonable patient comfort.
- There is no evidence that morphine causes more smooth muscle spasm than other opioids. Morphine is safe and appropriate for patients with acute biliary or renal colic.
- Patients who are known to be diverting or abusing opioids should not be prescribed opioids for use as outpatients. Patients with chronic pain syndromes, or those with chronic conditions that may cause acute pain (e.g., dental caries), should be offered alternative pain management options, and opioids should generally be avoided.
- Topical and local anesthetics can treat pain associated with most ED procedures and should be considered for use in isolated painful conditions.
- Low tissue pH (5 or 6) in infected tissue impairs the effectiveness of local anesthesia.

FOUNDATIONS

Background and Importance

Pain-related complaints represent the primary concern in up to 70% of patients presenting to the emergency department (ED).[1,2] Uncontrolled pain should be considered a medical emergency, and the estimated degree of pain experienced by a patient should play a role in determining a patient's overall acuity and urgency for therapy. Pain estimations, using both clinician- and patient-derived scales, should be obtained and recorded to determine the presence of pain and the response to pain therapy.

Although pain can be present in a wide variety of physical and psychosocial situations, it is typically present in the context of tissue injury. Pain can therefore be assumed to be present in patients with physically apparent disease or injury, even in those who cannot effectively communicate their condition. Important terms relating to analgesic practices are listed in Box 6.1.

A wide variety of treatments are available for both acute and chronic pain. The treatment of pain can be difficult and is often one of the most challenging and frustrating aspects of the practice of emergency medicine.[3]

Patients' perceptions of their ED care are highly influenced by pain treatment.[4-7] Satisfaction with emergency care often depends on the techniques and timeliness of analgesia, as well as the discharge plans for pain relief. In every interaction with a patient in pain, a balance must be achieved between relief of patient suffering and the diagnosis and treatment of the underlying medical condition.

A growing body of evidence has supported the importance of pain management as a central aspect of disease treatment. Unrelieved pain is associated with various potentially negative physiologic outcomes, including increases in sympathetic outflow, peripheral vascular resistance, myocardial oxygen consumption, and the production of carbon dioxide. Other adverse effects of unrelieved pain include hypercoagulability, decreases in gastric motility, and immune function impairment. Poorly treated acute pain can promote the development of chronic pain syndromes and vegetative symptoms, as well as increase the need for pain management during any recovery period. Similarly, pain during serial medical procedures may increase if successful analgesia was not provided during initial procedures. It is also likely that a patient's experience of pain increases his or her ability to perceive pain from similar stimuli in the future.

As an affirmation of the recognized importance of pain management in health care, the Center for Medicare and Medicaid Services and The Joint Commission for accreditation of health care organizations require hospitals to develop quality improvement efforts related to acute pain management, in addition to comprehensive programs for the measurement, documentation, and treatment of pain.[8]

Comprehensive approaches to pain management have become complicated by the widespread abuse of opioids.[9] In the latter part of

BOX 6.1 Definitions of Terms Related to Analgesia

Allodynia—pain from a stimulus that does not normally provoke pain
Amnestic—an agent that suppresses the formation of memories
Local anesthesia—creates an area of insensibility to pain by injection of a local anesthetic agent
Analgesia—relief from pain
Hypnotic—agent that promotes the onset of sleep
Narcotic—term with legal implications describing opioid agents together with various central nervous system depressant drugs of abuse
Nociceptor—receptor that is sensitive and responsible for transmitting pain stimuli
Noxious stimulus—stimulus that is damaging or potentially damaging and results in sensation of pain
Opiate—naturally occurring derivative of opium alkaloid that binds opiate receptors and produces effects similar to those of the endogenous endorphins
Opioid—naturally occurring or semisynthetic derivative of opium alkaloid (includes all opiates) that binds opiate receptors and produces effects similar to those of endogenous endorphins
Pain—unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage
Procedural sedation—pharmacologic induction of a state of sedation or dissociation with amnesia for pain control during a painful procedure
Sedative—agent that decreases a patient's level of awareness

the twentieth century, American clinicians and institutions emphasized using opioid therapy as a cornerstone of acute and chronic pain management. This emphasis rested on the widely held belief that opioid therapy prescribed to patients in pain posed a relatively small risk for chronic addiction, abuse, or harm. A dramatic rise in addiction rates, diversion, and death directly attributed to this practice has been documented in the early part of the twenty-first century.[10-12] This "opioid crisis" has largely been a phenomenon unique to the American health care system and culture. Additionally, chronic opioid therapy has not been demonstrated to confer patient-centric gains in life function, productivity or longevity.

As a result, pain management strategies have quickly shifted to support selective brief periods of opioid therapy in acute pain along with a concurrent reduction, or altogether removal, of opioids as a mainstay in patients with extended, chronic periods of pain.

Emergency medicine as a specialty accounts for 4% of opioid prescriptions in the US,[13] with 17% of patients receiving a median of 15 pills per prescription,[14] so while emergency departments represent a small part of this opioid crisis, there are significant opportunities for improvements in practice.[15]

Anatomy, Physiology, and Pathophysiology

Pain can be generally described by the terms *nociceptive* and *neuropathic*. Nociceptive pain results from the activation of sensory neurons that signal pain (nociceptors) in response to noxious stimuli. Neuropathic pain results from signal-processing changes in the central nervous system (CNS). Neuropathic pain is usually described as burning, tingling, or shooting sensations and includes neuropathies and deafferentiation. Both nociceptive and neuropathic pains involve peripheral and central sensitization with a complex array of mediators to sensitize peripheral nociceptors and perpetuate thalamic signals (Fig. 6.1). At each level in the physiologic process of pain production or transmission, there are interventions and therapeutic opportunities to consider to alter the process and improve the patient's pain experience.

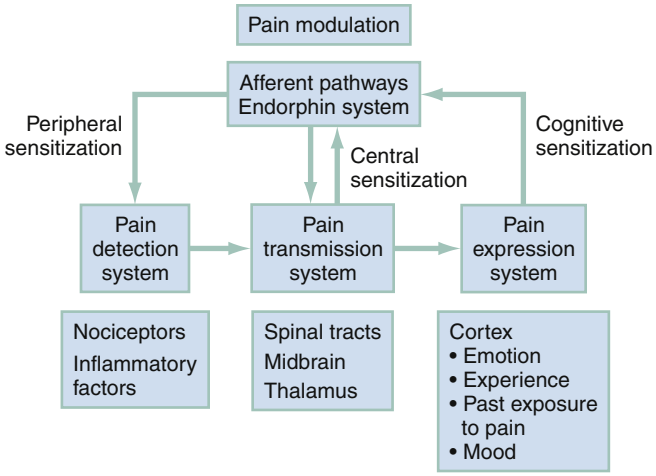

Fig. 6.1 The pain system algorithm.

Pain Conduction Pathways

Pain can be divided into four separate processes (see Fig. 6.1): pain detection, pain transmission, pain modulation, and pain expression (perception).

Pain Detection

The somatosensory system is responsible for detecting pain as well as tactile, proprioceptive, and thermal sensations. Receptors responsible for the detection of pain are termed *nociceptors*. Nociceptors include sensory nerves that are capable of detecting mechanical, thermal, or chemical stimulation. Several different subtypes of nociceptors are present in cutaneous tissues, including mechanoreceptors, polymodal nociceptors (PMNs), and a variety of thermoreceptors.

The threshold of activation of a nociceptor can be modulated—increased or decreased—by various chemical mediators, including prostaglandin, cyclic adenosine monophosphate, leukotrienes, bradykinins, serotonin, substance P, thromboxanes, platelet-activating factor, and endorphins. This change in nociceptor activation thresholds is termed *peripheral sensitization*. Trigger points, for example, are areas of frequent or constant low-level sensory stimulation (e.g., scar tissue or a degenerative joint) that have developed peripheral sensitized nociceptors that perceive pain from otherwise innocuous stimuli (allodynia).

Information Transmission

Peripheral nerve fibers. All sensory neurons are composed of a cell body located in the dorsal root ganglia. The dorsal root ganglia are connected by nerve axon fibers with sensory receptors located in a number of body sites, including dermatomes (cutaneous input), sclerotomes (input from bones), and myotomes (input from muscle). The discrete areas covered by each nerve provide a sensory map of the body surface.

Peripheral nerve fibers can be classified by the roles of each fiber group (Table 6.1). A-δ and C fibers are responsible for the transmission of pain. A-δ fibers transmit sharp, initial pain; C fibers, in contrast, transmit dull, aching, or burning pain. The pain transmitted by A-δ fibers persists only as long as the initial stimulus is in effect, whereas C fiber pain persists longer than the initial stimuli, rendering a prolonged pain sensory experience. The relative concentration of nerve fiber types, both C and A-δ, varies by body tissue.

TABLE 6.1 Peripheral Nerve Fibers

Fiber	Function	Myelin	Mean Diameter (mm)	Ascending Tract	Conduction Velocity (m/s)
A-α	Skeletal muscle motor	Deep	12–20	Ipsilateral dorsal column	70–120
A-β	Light touch and pressure	Superficial	5–15	Contralateral spinothalamic tract	30–70
A-γ	Motor	Superficial	6–8	Ipsilateral dorsal column	15–30
A-δ	Sharp pain (mechanoreceptors, thermoreceptors, PMNs)	Superficial	1–4	Contralateral spinothalamic tract	12–30
B	Sympathetic		1–3	Preganglionic	3–15
C	Long-lasting burning pain	Superficial	0.5–1.5	Contralateral spinothalamic tract	0.5–2

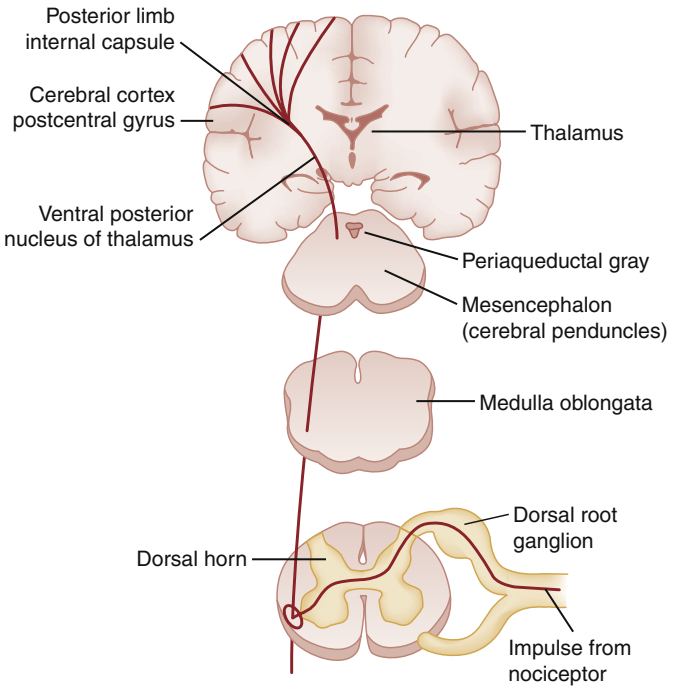

Fig. 6.2 Spinal tracts.

Pain Transmission

Dorsal horn. The dorsal horn is the gray matter of the posterior aspect of the spinal cord (Fig. 6.2). The dorsal horn acts as an integration system in which sensory input is filtered, attenuated, or amplified before being relayed to other spinal segments or the cortex.

The dorsal horn is a processing center for incoming information and is extensively involved in modulating nociceptive input. Afferents from visceral, muscle, bone, and cutaneous areas converge in the dorsal horn and likely account for the cutaneous referred pain associated with noxious visceral, muscular, or bony stimuli from the same spinal level.

Differentiation between innocuous stimuli and nociceptor input occurs in the dorsal horn by stimuli received in cells referred to as wide dynamic range neurons (WDRNs). WDRNs receive modulating input from a variety of chemical pathways, such as opioids, substance P, or inflammatory factors. These cells also receive modulating input from efferent and afferent neuronal pathways.

Visceral pain. The quantity and type of stimuli that produce pain vary among visceral structures. The myocardium, for example, is sensitive to ischemia but not mechanical stimulation. Tissues in the intestine may be severed, crushed, or burned without pain; however, traction or distention produces pain.

The quality of visceral pain is unique from somatic pain. Somatic pain is initially sharp, later becoming burning or throbbing in nature as the response is modulated. In contrast, visceral pain tends to start as poorly localized, burning or throbbing pain, with pronounced autonomic activation. These sensations may then develop into sharp, localized, referred pain as modulation progresses and the associated dermatome is activated. Visceral pain often produces referred pain. For example, periumbilical pain is often associated with appendicitis. This referred pain sensation occurs due to visceral afferents supplying the small bowel and traveling through the celiac ganglia and splanchnic nerves to enter the spinal cord at T10. This input sensitizes the dorsal horn at T10, leading to sensitization of all the dorsal horn nociceptive neurons and ultimately leading to the perception of pain in the T10 dermatome. As appendicitis progresses, the pain localizes to the right lower quadrant as inflammation extends to the parietal peritoneum with the same nerve supply as the overlying dermatome.

Ascending tracts associated with pain. Fibers carrying pain impulses exit the dorsal horn and ascend the spinal cord to the brain. The predominant pathways for pain conduction through the spinal cord are the spinothalamic, spinomesencephalic, and spinoreticular tracts, located in the anterolateral aspect of the spinal cord (Fig. 6.3; see Fig. 6.2).

Pain Modulation

Impulses from nociceptors are modulated by descending tracts in the spinal cord. The two primary descending pathways appear to be serotonergic and noradrenergic. These pathways originate in the midbrain (periaqueductal gray matter and locus ceruleus), and medulla (nucleus raphe magnus and nucleus reticularis gigantocellularis) and are transmitted to the spinal cord via the dorsolateral funiculus.

Electrical stimulation of descending pathways produces analgesia comparable to that produced with opioids. Stimulation of the thalamus can also produce analgesia. Inputs to this system come from the frontal cortex, limbic system, hypothalamus, reticular system, locus ceruleus, and spinal cord. Multiple neurotransmitters are involved in these pathways, including serotonin, norepinephrine, and substance P. It is believed that the activation of this system is responsible for effects such as placebo, acupuncture, and transcutaneous electrical nerve stimulation (TENS) units, as well as stress-associated pain tolerance.

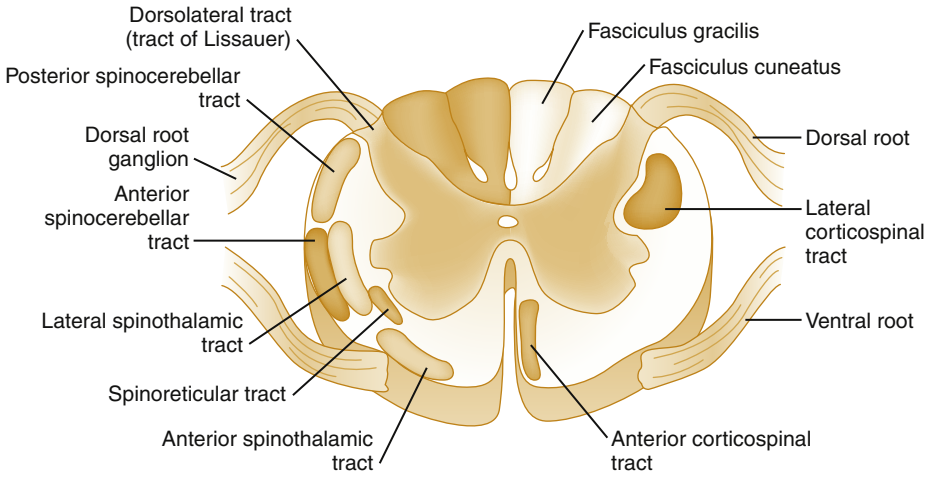

Fig. 6.3 Spinal cord.

Central Sensitization

Central sensitization involves the amplification of nociceptive signals. Central sensitization is mediated by several substances, including nitric oxide, glutamate, substance P, aspartate, prostaglandins, leukotrienes, norepinephrine, and serotonin. It plays a major role in the development of chronic pain and can be the result of damage at any point along the pain transmission system, or more commonly a feedback loop of propagation and sensitization. Central sensitization has been best described in the setting of traumatic and degenerative conditions of the spinal cord and brainstem and can be associated with thalamic strokes, multiple sclerosis, Parkinson's disease, Arnold-Chiari formation, and cervical stenosis.

Pain Expression

The transduction, transmission, and modulation of pain stimuli develop the perception of the subjective emotional experience of pain. Many factors other than the simple stimulation of nociceptors influence the final perception of pain. The discrete cognitive processes and pathways involved in the interpretation and experience of painful stimuli remain a mystery and are affected by cultural expectations, personality, experiences, and the underlying emotional state. Many of these factors, and therefore the subsequent perception of pain, can be greatly influenced by both pharmacologic and nonpharmacologic interventions.

Much of the analgesic effect for drugs such as nitrous oxide and low-dose opioids is due to the cognitive interpretation and emotional reaction to pain rather than an effect on transmission of the pain stimulus. Similarly, noninvasive techniques such as distraction and hypnosis can limit pain perceptions and increase pain tolerance. Changes in how a person experiences pain, based on previous experiences and learned behaviors, are referred to as cognitive (de)sensitization.

Reflex Responses to Pain

There are two types of reflex responses to nociceptor input, spinal segmental (or suprasegmental) and cortical. Spinal reflexes are generated by the transmission of nociceptive impulses from the dorsal horn to motor and autonomic neurons in the spinal cord, provoking a range of responses, including tachycardia, vasoconstriction, paralytic ileus, and muscle spasm (Box 6.2). Suprasegmental reflexes are transmitted through ascending tracts to the brainstem, hypothalamus, and cortex, where withdrawal reflexes and autonomic responses occur in connection with conscious responses. The autonomic reflex responses to pain are variable and cannot be used to quantify pain in an individual.

BOX 6.2 Reflex Responses to Pain

Increased Sympathetic Tone
Vasoconstriction producing increased peripheral resistance
Increased cardiac output from increased stroke volume and heart rate
Increased blood pressure
Increased metabolic rate and oxygen consumption
Decreased gastric tone and gastric emptying (may progress to ileus)
Decreased urinary tract tone (may lead to urinary retention)

Endocrine Responses
Decreased insulin production
Increased cortisol levels
Increased antidiuretic hormone levels
Increased growth hormone levels
Increased renin, angiotensin II, aldosterone levels
Increased glucagon levels
Increased catecholamine levels

Respiratory Responses
Hyperventilation

Cortical Responses
Anxiety and fear

Endorphin System

The endorphin system is a neuroendocrine system that serves to modulate responses to pain and stress. The endorphin system consists of widely scattered neurons that produce three types of opioids—beta-endorphin, met- and leu-enkephalins, and dynorphins. These opioids act as neurotransmitters and neuromodulators at three major classes of receptors—mu, delta, and kappa—and produce analgesia as well as counter the stress response (Table 6.2).

Under normal circumstances, the endorphin system decreases pain and stress after a person has adequately dealt with the inciting noxious stimuli. The endorphin system is typically a responsive system that can increase or decrease effect to produce the appropriate response to a painful event. Like other neuroendocrine systems, increasing stimulation of the endorphin system produces feedback inhibition of endorphin production. During prolonged periods of pain with high stimulation levels, the system can become less responsive and less effective at modulating the pain response.

TABLE 6.2 Opioid Receptors

Opioid Receptor Class	Effects	Associated Endogenous Endorphin
Mu 1	Euphoria, supraspinal analgesia, confusion, dizziness, nausea	Beta-endorphin
Mu 2	Respiratory depression, CV and GI effects, miosis, urinary retention	Beta-endorphin
Delta	Spinal analgesia, CV depression, decreased brain and myocardial oxygen demand	Enkephalin
Kappa	Spinal analgesia, dysphoria, psychomimetic effects, feedback inhibition of endorphin system	Dynorphin, beta-endorphin
Epsilon	Hormone	Beta-endorphin
Gamma	Dysphoria, psychomimetic effects	Beta-endorphin

CV, Cardiovascular; *GI*, gastrointestinal.

TABLE 6.3 Acute versus Chronic Pain

Parameter	Acute Pain	Chronic Pain
Inciting factor	Associated pathology present and recovery is expected	Associated pathology not identifiable or not expected to improve; recovery unpredictable or not expected
Relation to healing	Pain improves as the injury heals; limitation of activity due to pain assists healing	Neither pain nor injury expected to improve; pain may limit activities that could improve condition
Psychosocial effects	Limited to acute stress reaction	Negative effects a prominent feature of disease
Treatment	Analgesics, immobilization	Psychosocial aspects must be addressed; analgesics play a smaller role

Like their endogenous counterparts, opiates act at chemical receptors to produce analgesia and undesirable side effects. As opioid drugs are given over prolonged periods, they inhibit a person's endogenous endorphin system, blunting its ability to modulate pain and stress, and decreasing the endorphin system's adaptive effects. As these drugs are withdrawn, the normal effects of the endorphin system can resume over time.

Acute Versus Chronic Pain

Acute pain is usually associated with an identifiable pathologic condition and serves an adaptive function by warning the individual that an illness or injury exists. This sequence will motivate the person to cease activity that is causing the pain, look for a cause, seek help, and avoid the future stimulus.

Acute pain becomes chronic pain when the pain pattern persists, in changed or unchanged form, after the original physiologic insult has resolved. All chronic pain starts as acute pain, but only small subsets of patients with acute pain develop chronic pain (Table 6.3). The physiologic transition from acute to chronic pain is a complex process, with physiologic and psychosocial components. In many cases, the development of chronic pain is likely related to the treatment of acute pain.

Acute pain serves an important purpose in that it stimulates a person to protect the injured area and seek help. Also, the neurochemical factors that contribute to acute pain acknowledgment generally initiate and support recruitment of tissue repair mechanisms. As an injury heals, these adaptive responses may become maladaptive if the pain persists, with the pain leading to a decreased range of motion, decreased function of the area and, ultimately, increased susceptibility to injury and pain. Pain also causes a stress response that is initially adaptive in the face of injury. A prolonged stress response, however, causes an impaired immune system, hypercoagulabilty, sleep disturbances, anxiety, and depression.

MANAGEMENT

Decision Making

Pain Assessment

The early accurate recognition and assessment of a patent's pain are the most important aspects of effective acute pain management. When pain is inadequately treated, inaccurate assessment is often the root cause of the problem.

The degree to which a person experiences pain is a complex and subjective interaction between the physical stimulus and patient's cognitive and emotional state. However, it is clear that the degree of pain a patient perceives is not directly determined by the degree of physiologic injury. Patients in the ED with relatively identical injuries may experience and display completely different amounts of pain. Therefore, pain treatments, analgesic requirements, and how a patient describes pain cannot be uniformly described based on the nature of a patient's injury.

The assessment of pain depends on both the patient's ability to communicate the nature of the painful experience and the clinician's ability to accurately obtain this information. Unfortunately, there is no objective test or physiologic index to measure pain reliably. Objective observations, such as hypertension, diaphoresis, or tachycardia, do not correlate well with the degree of pain. Because pain cannot be objectively measured, a clinician's assessment depends on communication with the patient—verbal and nonverbal. Barriers to communication between patients and clinicians, including linguistic, socioeconomic, and cultural differences, limit the ability to assess pain effectively.

Oligoanalgesia

Because effective treatment is based on the assessment of pain, patients who have difficulty communicating are at risk of undertreatment of their pain (oligoanalgesia). These groups include infants and children, patients whose cultural and linguistic background differs significantly from the treating clinician, or are developmentally delayed, cognitively impaired, under severe emotional stress, or mentally ill. Racial and ethnic disparities have been identified in the treatment of acute pain in the ED.[16,17]

There are a variety of reasons why some patients receive inadequate analgesia. These include ineffective pain assessment, misconceptions about the safety and efficacy of various treatments, and concerns about the effect of analgesic interventions on a patient's evaluation. There may be a significant delay to providing adequate pain control, especially during high-volume periods.[18] Additionally, when opioids are used, they are often given in subtherapeutic doses.

Pain Measurement

The use of numeric rating scales, such as a verbal 0 to 10 score (none to worst imaginable), are ubiquitous (Fig. 6.4). Visual analogue scales, usually consisting of a 10-cm straight line with anchors at either extreme, are frequently used in research to provide continuous data for analysis. These scales offer little practical advantage over verbal reports

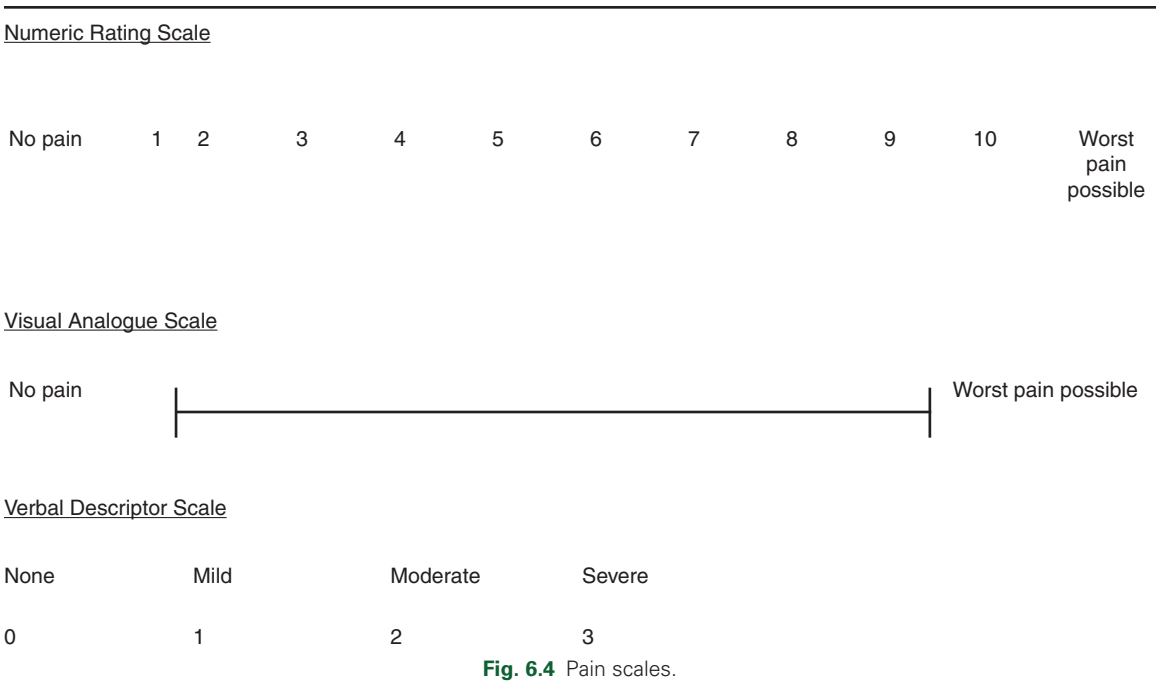

Fig. 6.4 Pain scales.

in the clinical setting. Routine verbal or visual pain scale assessment encourages emergency clinicians to communicate with patients to assess their pain and to evaluate responses to analgesic intervention attempts.

Children require alternative communication techniques to acknowledge and relate pain. The FACES pain scales are designed for children younger than 7 years. This scale has a series of cartoon faces expressing a range of emotions, from happiness to severe distress. The child is asked to point to the face that corresponds to how he or she feels. The FACES pain scale, and others like them, require less of an abstract reference than numeric and verbal scales and are useful in pain assessment for toddlers and cognitively impaired adults.

In preverbal children, observer-derived scales need to be used. These include the Modified Pre-Verbal, Early Verbal Pediatric Pain Scale (M-PEPPS), Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), and CRIES scale for neonates. These scales use a scoring system for observed criteria that is reproducible among trained observers, making them useful for research, but they have little clinical utility compared to the emergency clinician's or parents' overall impression of a child's pain.

Pain scores are accepted as the most accurate and reliable measure of assessing a patient's pain and response to pain treatment. Pain treatment should be targeted to a goal of reducing the pain score (e.g., by 50%, below 4/10, or referred to as mild/moderate or severe) rather than a specific (maximum) analgesic dose.

BOX 6.3 Common Outpatient Analgesic Agents by Pain Type

Acute Pain
1. Acetaminophen
2. Nonsteroidal antiinflammatory drugs (NSAIDs)
3. Opioids used in combination with NSAIDs and acetaminophen
4. Oxycodone
5. Hydrocodone

Chronic Pain
1. NSAIDs
2. Tramadol
3. Opioids used in combination with NSAIDs and acetaminophen[a,b]
4. Oxycodone, long-acting preparation, or for breakthrough pain
5. Tricyclic antidepressants

Neuropathic Pain
1. Gabapentin
2. Tricyclic antidepressants
3. Carbamazepine

[a] A variety of opioid and acetaminophen combination agents are available.
[b] Chronic opioid management should be managed by the primary outpatient physician.

Treatment Groups

The approach to patients in pain begins with a characterization of pain into four unique treatment groups: (1) acute pain; (2) recurrent pain; (3) chronic pain of malignancy and neuropathic pain; and (4) chronic pain. Other than acute pain, therapy should focus on a long-term, multidisciplinary approach (Box 6.3). Acute and chronic pain patients have different physiologic causes and thus require different treatment approaches based on their specific site and mechanism of affect (Fig. 6.5).

Acute pain. Symptomatic treatment of pain should be initiated promptly, titrated to an acceptable level of relief, and continued while the investigation for a cause is proceeding. Fig. 6.6 presents a common approach to acute pain in the ED setting, beginning at triage to assess pain type and severity and then progressing to clinical assessment, with therapeutic suggestions.

When the cause of acute pain is uncertain, immediate relief of pain occurs in parallel with initial efforts to establish the diagnosis. It is inappropriate to delay analgesic use until a diagnosis has been made. There is no evidence that the administration of adequate doses of opioid analgesia to establish patient comfort impairs the emergency clinician's ability to diagnose the cause of an acutely painful condition. On

the contrary, analgesia administration may enhance the accuracy of the physical examination and patient assessment.

Chronic pain. The assessment of pain in the absence of acute or obvious physical injury requires a great deal of communication skill on the part of the clinician and patient. Many patients with chronic pain develop experiences, some adaptive and others maladaptive, in describing their pain and interacting with clinicians to receive pain treatment. Many behaviors such as exaggerating symptoms or attempting to manipulate clinicians are developed around the patient's expectations for obtaining pain therapy or pain relief. These behaviors, combined with the negative psychosocial effects and sense of futility associated with chronic pain, can complicate the evaluation process and care of chronic pain patients.

The assessment of chronic pain represents some of the most challenging situations to obtain an accurate clinical history. Patients who are having difficulty describing their pain should be encouraged with detailed questions about the pain, combined with multiple examples, comparisons, and summarizing statements, to facilitate accurate communication. Assuring the patient that the questions are intended to aid understanding and enable the effective treatment of symptoms can facilitate developing a common goal and help establish the trust necessary to develop an effective treatment strategy.

Patients with chronic pain can exacerbate their chronic pain in the setting of ongoing therapy or with untreated chronic pain due to a gap or lack of ongoing care. These scenarios require different treatment approaches. For chronic pain patients with an exacerbation in their pain exceeding the pain control of their usual treatment strategy, treatment can be approached in a fashion similar to that for acute pain. The goal for these patients should be to control the exacerbation and return the patient to their baseline function and treatment strategy.

Many patients with chronic pain are in comprehensive treatment programs, most of which involve a so-called contract concerning the provision of their pain management. For such patients, a review of the pain management plan in the medical records, or contact with the health care clinician who manages the patient's treatment plan, is a critical element in determining the best short-term strategy in the ED.

Patients with chronic pain who have a gap in their baseline treatment or who have never established appropriate treatment for chronic pain require an approach that addresses the need to establish a consistent treatment plan. Patients with no ongoing treatment plan should have a basic chronic pain treatment plan implemented during their ED visit. This should consist of acetaminophen, if not contraindicated, and a nonsteroidal antiinflammatory drug (NSAID), if tolerated.

Adjuvants appropriate for neuropathic or central pain may be added, if appropriate.

Opioids for chronic pain, whether for a patient already on a treatment plan or without a treatment plan, are rarely indicated in the ED, with the exception of patients who experience pain related to advanced malignancy (see below.) Opioids should neither be administered nor prescribed unless their need is verified with the clinician responsible for the patient's chronic pain management plan. In general, opioids for chronic pain management are the domain of clinicians in ambulatory pain centers or primary care physicians who will follow the patient's therapy, response, and compliance. There is often difficulty communicating this with patients who may have received opioids at many EDs, including the one currently being visited. The establishment of a departmental policy empowers emergency clinicians to administer or prescribe opioids for chronic pain syndromes without judging the patient.

Chronic pain care in the ED should emphasize the use of multimodal treatments and reduce the use of opioid medications.[19] Nonpharmacologic treatments in multimodal chronic pain care include physical rehabilitative therapies, interventional pain procedures, psychological therapy, and integrative approaches. An important aspect of caring for chronic pain is recommending a nonpharmacological treatment, or at least determining if a patient is willing to consider such therapies. The factors associated with a patient's willingness to accept such therapies have not been well defined, and therefore nonpharmacological approaches should be discussed with chronic pain patients presenting to the ED.[20]

Recurrent pain. Recurrent pain is a subset of chronic pain; the term describes patients who have symptoms with repeated episodes of similar pain. Recurrent pain can include back pain, myofascial pain syndrome, migraine syndrome, sickle cell disease, and inflammatory bowel disease. The treatment of recurrent pain in the ED incorporates elements of the treatment of acute pain and chronic pain, and prevention of recurrent pain events must be considered part of the treatment strategy. These therapies may integrate nonpharmacologic approaches, such as physical therapy for back pain, in addition to the use of preventive medications.

Chronic pain of malignancy. Chronic malignant pain is similar to acute pain related to ongoing nociceptive stimulation and similar to chronic pain in its duration and psychobehavioral effects. The medications used, however, are similar to those used for acute pain. The psychosocial effects of the pain of malignancy must be addressed as part of an effective treatment strategy.

Patients with a significant change in the pattern of their chronic pain caused by cancer or a terminal illness, as with other chronic pain patients, should be evaluated for a new process to account for the pain. Opioids, especially in long-acting or transdermal preparations, should be used liberally to bring pain relief for patients with terminal illnesses.

Neuropathic pain. *Complex regional pain syndrome* (CRPS) is a term that includes most sympathetically maintained neuropathic pain. CRPS type 1 (often referred to as reflex sympathetic dystrophy) develops after a painful injury and typically follows the distribution of a peripheral nerve. It is associated with hyperalgesia, allodynia, changes in skin blood flow, and sympathetic dysfunction. This syndrome develops during the healing and recovery phases of acute painful injuries and is generally described as a burning, tingling sensation in the area of the previous injury. This pain is likely related to ongoing stimulation leading to the development of self-sustaining modulation of the pain transmission system.

CRPS type 2, commonly referred to as causalgia, is associated with burning pain and allodynia in the distribution of an injured nerve, with no association with sympathetic symptoms. Opioids are ineffective in preventing CRPS after an injury has occurred. Clonidine, N-methyl-d-aspartate receptor antagonists, and γ-aminobutyric acid receptor agonists are more effective in treating CRPS than opioids. Gabapentin is generally considered a first-line agent, with pregabalin used for patients who cannot tolerate its sedating effects.

Antidepressants have effects on neuropathic pain that appear to be distinct from mood effects. Other antidepressants, such as selective serotonin reuptake inhibitors, may be safer and more effective for patients with chronic pain thought to be unrelated to central or neuropathic origins.

Several anticonvulsants, including gabapentin, phenytoin, carbamazepine, and valproic acid, are described for neuropathic pain with lancinating or burning properties. Carbamazepine is used most frequently for trigeminal neuralgia, postherpetic neuralgia, and diabetic neuropathy. Gabapentin is described for both types of CRPS, postherpetic neuralgia, and diabetic neuropathy.

Pharmacologic Therapy

Opioids

In 1680, Sydenham wrote that "Among the remedies it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium." Centuries later, this statement is still accurate, and titrated opioids remain the therapeutic foundation for severe acute pain.

The beneficial effects of opioids have been well documented for centuries, as have their toxicity and potential for abuse. Unfortunately, opioids are often poorly used in clinical practice. Concerns regarding opioid toxicity or dependence and a poor understanding of the pharmacokinetics of the drugs have led to inadequate dosing and excessively infrequent dosing intervals. In terms of toxicity and the likelihood of causing future dependence, the safety of short-term opioids for acute pain is established. Opioids are the first-line agents in the management of acute severe pain (Table 6.4). This safety is not well established in relation to the treatment of mild or moderate pain, however. The effectiveness of opioids relative to nonopioid analgesics, and a similar comparison of potential adverse effects, including the potential for abuse, argues against their use in mild pain and for sharp limits on their use for moderate pain. To prevent the overuse and misuse of opioids, the quantity and strength of the opioids prescribed should closely match the anticipated duration of the severe pain, and the patient should be transitioned off the opioid analgesia at the earliest appropriate opportunity. For most short-term acute pain episodes, such as a fracture, 3 to 5 days of opioid analgesia is sufficient, pending outpatient follow-up evaluation.

Mechanism of action and toxic effects. Opioids bind to specific endorphin system receptors located throughout the nervous system. These receptors suppress pain detection peripherally, modify pain transmission in the spinal cord and thalamus, and alter pain perception at the level of the cortex. A variety of endorphin receptors are defined (see Table 6.2). The unique actions of opioids are determined by the specific binding properties of the agent to the various receptors.

Both the short- and long-term side effects of opioids can limit the success of therapy. The occurrence of side effects varies among individual patients and opioid agents. Tolerance of many acute side effects develops shortly after the initiation of therapy.

The most common side effect of opioids is constipation. Constipation is attributed to opiate receptors located in the antrum of the stomach and proximal small bowel. Constipation can be anticipated with long-term opioid use (more than a few days). An active laxative, such as senna, lactulose, or bisacodyl, should be prescribed, as needed.

Nausea and vomiting also frequently occur with the administration of opioids, especially in opioid-naïve patients. Both opioids and acute

TABLE 6.4 Opioid Analgesics

Analgesic Agent	INITIAL DOSE		Duration of Action	EQUIPOTENT DOSE		Comments
	Parenteral	Oral		IV	PO	
Morphine	0.1 mg/kg	0.5 mg/kg	3–4 h	10 mg	50 mg	Standard opioid for comparison
Hydromorphone	0.015 mg/kg	0.075 mg/kg	2–4 h	1.5 mg	7.5 mg	Inactive metabolites advantageous to patients with renal or hepatic disease
Methadone	0.1 mg/kg	0.2 mg/kg	4–8 h	10 mg	20 mg	Used for opioid addiction therapy and chronic pain; half-life longer than duration of action
Fentanyl	1.5 μg/kg	3 μg/kg	0.5–1.5 h	100 μg	NA	Oral dose actually transmucosal absorption rather than ingestion; metabolites inactive; transcutaneous patches used for chronic pain
Oxycodone	0.1 mg/kg	0.15 mg/kg	3–4 h	10 mg	15 mg	Excellent bioavailability, so it is an effective oral agent for acute pain
Codeine	1.3 mg/kg	2.5 mg/kg	2–4 h	130 mg	200 mg	Side effect to analgesia ratio is undesirable; pronounced peripheral effects—constipation, nausea and vomiting, cough suppression
Hydrocodone	NA	5–15 mg	3–4 h	NA	30 mg	Commonly used in preparations with acetaminophen; more potent than codeine
Meperidine	0.75 mg/kg	3 mg/kg	2–3 h	75 mg	300 mg	Toxic metabolite normeperidine accumulates at normal doses; generally should not be used for acute analgesia
Oxymorphone	0.01 mg/kg	0.1 mg/kg (PR)	3–4 h	1 mg	10 mg	Rectal dosing more predictable than other agents
Alfentanil	10–20 μg/kg	NA	8–12 min	1 mg	NA	Short duration due to redistribution; duration of action increases with size of dose
Sufentanil	0.1 μg/kg	30 μg (sublingual)	1–1.5 h	10 μg	NA	Minimal cardiovascular side effects
Remifentanil	0.5–1 μg/kg	NA	4–6 min	50 μg	NA	Used as a continuous infusion
Nalbuphine	0.4 mg/kg	0.1 mg/kg	3–4 h	40 mg	NA	Mixed agonist-antagonist; decreased respiratory depression relative to other opioids; limited analgesic effect; used during perinatal period

IV, Intravenous; *NA*, not applicable; *PO*, by mouth; *PR*, per rectum.

pain can cause nausea and vomiting, and it is often difficult to distinguish the two. Routine coadministration of an antiemetic, once an almost universal practice, is not necessary. However, nausea and vomiting in the context of persistent acute pain after opioid administration may require antiemetics and additional opioids. Typical antiemetics include promethazine, prochlorperazine, and odensatron.

Immunoglobulin-mediated allergies are rare for morphine and other opioids. Many patients experience mild pruritus of the trunk and face after parenteral administration. This common side effect is related to histamine release from opioid receptors on mast cells and does not constitute an allergy. To a varying degree, opioids destabilize mast cells in a dose-dependent fashion, causing histamine release and resultant urticaria, pruritus, and orthostatic hypotension. This reaction may appear as localized urticaria tracking up a vein after intravenous (IV) administration of an opioid, especially morphine. Rarely, bronchospasm may be seen in patients with reactive airway disease or atopy. This effect usually subsides rapidly, with no treatment required, although the symptoms can be controlled with the administration of an antihistamine.

Sedation and respiratory depression can occur with opioid administration for acute pain. Opioids decrease medullary sensitivity to carbon dioxide, resulting in respiratory depression. Combining opioids with other sedating agents, such as benzodiazepines, increases the likelihood of respiratory depression. Patients with underlying hepatic or renal dysfunction are also at increased risk because of their inability to clear opiates normally, resulting in the accumulation of active metabolites and a higher risk for sedation or respiratory depression. Patients with decreased cerebral perfusion are also at high risk of developing respiratory depression when treated with opioids, and care should be taken when treating patients in shock or with unstable illnesses.

Pain is a very effective stimulant of respiratory drive, rendering respiratory depression rare in the context of acute severe pain. Fear of respiratory depression should not deter the emergency clinician from treating pain adequately, although monitoring patients receiving significant doses of opioids is advised. It should be noted that patients who had previously tolerated a dose of an opioid may develop respiratory depression if the source of acute pain is removed, such as by local anesthesia or the reduction and stabilization of a fracture. Transient respiratory depression from opioids usually responds to simple verbal or tactile stimulation and, uncommonly, requires more aggressive interventions such as airway repositioning, stimulation, or opioid reversal.

Tolerance, physical dependence, and addiction are common effects of the prolonged use of opioids. Physical dependence is defined as the occurrence of an opioid withdrawal syndrome following abrupt cessation, rapid dose reduction, or administration of an antagonist. Tolerance is an expected phenomenon that occurs after prolonged exposure to opioids and is characterized by the diminution of an opioid's effect over time. The development of tolerance is a normal expected result of the prolonged use of opioids and does not represent addiction.

Addiction is a potential risk associated with prolonged opioid use and often limits use. The term *addiction* refers to a neurobiologic

BOX 6.4 Addiction Behaviors

Behaviors Typically Specific to Addiction

- Injecting oral formulations
- Concurrent abuse of alcohol or illicit drugs
- Selling or diversion of prescription drugs
- Prescription forgery
- Obtaining drugs from nonmedicinal sources
- Repeated dose escalation
- Repeated visits to other EDs without informing prescriber
- Drug-related deterioration in function at work or socially
- Repeated resistance to changes in therapy, despite evidence of adverse drug effects

Behaviors Less Specific to Addiction

- Aggressive complaining about the need for more drug
- Drug hoarding during periods of reduced symptoms
- Requesting specific drugs
- Openly acquiring drugs from other medicinal sources
- Occasional dose escalation or noncompliance
- Unapproved use of a drug to treat another symptom
- Resistance to change in therapy associated with tolerable side effects, with expression of anxiety related to the return of severe symptoms

ED, Emergency department.

disease, with many factors influencing its development and manifestations (Box 6.4). Addiction, including opiate use disorder, is characterized by compulsive drug use, continued use despite harm, and drug craving. While the risk of addiction from short-term opioid administration in the ED is small, ED opioid prescriptions may contribute to the development of addiction in some patients, and a patient's long-term risk should be considered in their treatment decisions.[21]

Drug-seeking behavior. Some patients feign or exaggerate pain to receive opioids to abuse medications or sell them to others, an occurrence defined as diversion. Opioid abuse and diversion is recognized as a growing problem, and the rapid growth in the number of opioid prescriptions has played a large role in rising rates of abuse and diversion.[14,15] In recognition of diversion and abuse, many states have developed prescription monitoring programs that allow for information exchange among clinicians to detect frequent opioid prescriptions. Prescription-monitoring programs effectively reduce the number of opioid prescriptions given to patients at risk for abuse or diversion as long as clinicians consider these data as a routine and integrated practice for patient care.[22-25] Some states require consultation with the registry before prescribing opioids.

A physician's impression of behaviors believed to be associated with patient drug-seeking is associated with reducing the treatment of the patient's pain. Unfortunately, prescriber perceptions are often complicated by differences between the health care clinician and the patient in socioeconomic class, ethnic and racial background, and age, making them frequent sources of bias in the treatment of pain.[16,17] Care must be taken to recognize these factors and consider their impact on treatment decisions. A thorough evaluation of drug-seeking behavior for a patient includes a review of medical records, prescription registries, and contact with other clinicians (e.g., hospitals, primary care physicians), as available and appropriate. Patients with chronic conditions that can cause acute pain, such as dental caries, some gastrointestinal (GI) syndromes, or long-standing back pain, should be offered alternative pain management approaches such as nerve block, nonopioid analgesia, or symptomatic treatment with antispasmodic agents until they can resume care with their usual health care clinicians.

Administration of pain control. The goal of opioid administration is to attain effective analgesia with minimal adverse effects. The effects of opioids vary widely among individuals. There is no ceiling effect to their potency. There is no standard, fixed, or weight-related dose that will consistently produce a given clinical effect. The correct dose that a patient requires at a particular time can only be determined by repeated assessment of the degree of pain relief and adverse effects. Therefore, the use of opioids requires titration based on frequent and accurate assessments (Fig. 6.7).

The most effective and safe way to achieve pain relief is to use a deliberate IV titration. The intramuscular (IM) route of administration of opioids has several disadvantages and is not advised to treat acute pain (Box 6.5). The principal limitation of the IM route is its inability to titrate specific doses to desired treatment effects. The time to achieve significant pain relief from an IM injection varies substantially for each patient and offers no therapeutic advantage over an oral medication dosing strategy.

Most patients with mild to moderate pain requiring opioid therapy are best treated with an oral (PO) opioid. If pain is severe or the patient is expected to require multiple doses for management, an IV route is desirable. If an IV line cannot be established, and the patient cannot tolerate PO medications, the subcutaneous (SC) route is preferable to the IM route. SC injection is less painful than IM injection, with a similar onset of pain relief.

Opioids can be delivered through an oral transmucosal or intranasal mucosal route.[26-28] Buprenorphine can be given via a sublingual route; whereas fentanyl is available in an impregnated sweetened matrix called Fentanyl Oralet (PO transmucosal fentanyl citrate). Transmucosal fentanyl, butorphanol, and sufentanil also produce rapid clinical effects via nasal mucosal absorption.[26]

The optimal use of IV opioids requires administering an initial loading dose followed by an assessment of the analgesic effect. Frequent (every 5–15 minutes) repeated doses should be administered until analgesia is achieved, followed by doses at regular intervals to prevent the return of significant discomfort (see Fig. 6.7).

Specific agents

Morphine. IV morphine is frequently used for the treatment of acute severe pain in ED patients. Morphine is the opioid analgesic agent with which all other opioids are compared. When administered IV, morphine reaches a peak of action in 15 to 20 minutes, with a half-life of 1.5 to 2 hours in healthy young adults and slightly longer in older adults. Its duration of action is 3 to 4 hours. An appropriate loading dose of morphine for acute severe pain is 0.1 to 0.15 mg/kg IV of ideal body weight, augmented by repeated doses of approximately half the initial dose every 5 to 15 minutes, depending on the severity of the pain and patient response.

Morphine is effective by oral administration; however, only 20% of the ingested morphine dose will reach tissues after first-pass metabolism, requiring a dose adjustment approximately five times that of an equipotent IV dose. The formerly held belief that morphine causes more smooth muscle spasm than other opioids, rendering it inappropriate for the treatment of patients with biliary or renal colic, has been thoroughly discredited.

Morphine is primarily metabolized by conjugation into three- and six-conjugate forms in the liver. The six-conjugate form morphine metabolite is a strong mu and delta receptor agonist. This form plays an important role in the efficacy and duration of clinical effects. The three-conjugate form (normorphine) has no opioid analgesic activity but has been associated with CNS side effects (e.g., tremors, myoclonus, delirium, seizures) when it accumulates. This risk is greatest in older patients and those with renal insufficiency.

Meperidine. Meperidine (Demerol), although once widely used, has several disadvantages compared with morphine and

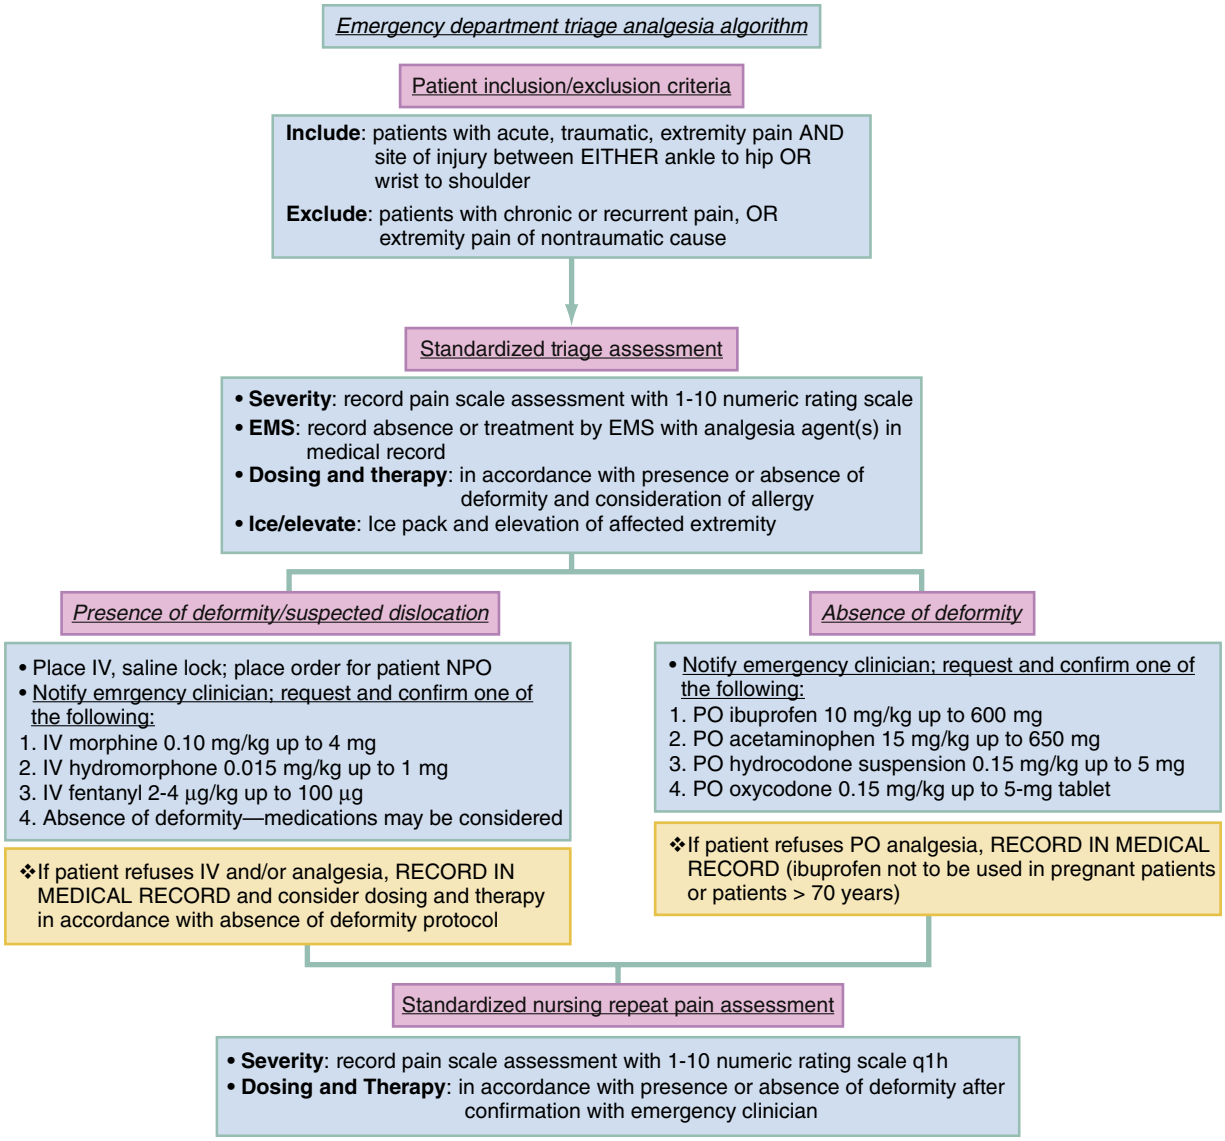

Fig. 6.7 Emergency department triage analgesia algorithm. *EMS,* Emergency medical services.

BOX 6.5 Disadvantages of Intramuscular Opioid Administration

Pain on injection
Delayed onset of action
Inability to predict therapeutic effect
Inability to titrate dosage
Diurnal variation in level achieved
Disease state may affect level achieved
Level dependent on intramuscular injection site

other parenteral opioids. The greatest disadvantage is that it is metabolized by the cytochrome P450 system to the active metabolite, normeperidine. Normeperidine can cause CNS toxicity at therapeutic meperidine doses. Normeperidine has a half-life of 12 to 16 hours and blocks muscarinic receptors, resulting in significant anticholinergic effects, including agitation and delirium. These effects may lead to seizures, hallucinations, and psychosis as the metabolite accumulates. Meperidine is not indicated for use in the ED.

Hydromorphone. Hydromorphone is a semisynthetic derivative of morphine that is a potent analgesic agent, frequently used to manage acute pain in the ED. Hydromorphone is the P450 metabolite of hydrocodone and is approximately seven times more potent than morphine, with a similar duration of action (7 mg of morphine is roughly equivalent to 1 mg of hydromorphone.)

Pruritus, nausea, and vomiting may occur less frequently with hydromorphone administration than with morphine at equianalgesic doses. Hydromorphone is primarily conjugated in the liver to hydromorphone-3-glucuronide (H3G), an inactive metabolite, and is excreted through the renal system. Thus, hydromorphone is better tolerated than morphine, particularly in older patients and those with hepatic impairment. Patients with renal insufficiency may be at some risk of neurotoxicity after prolonged exposure due to H3G accumulation. Patients allergic to morphine do not consistently have cross-reactivity with hydromorphone. Hydromorphone can be given via the IV, SC, PR (per rectum), or PO route.

Fentanyl. Fentanyl is a synthetic opioid that is highly lipophilic; it produces analgesia within 1 to 2 minutes following IV infusion. Fentanyl redistributes rapidly, and its duration of therapeutic action is approximately 30 to 60 minutes.

The P450 system metabolizes fentanyl into inactive metabolites. Drug accumulation and toxicity may occur after tissue saturation following a prolonged infusion, but this is unlikely to occur during acute therapy. The short duration of action for fentanyl makes it highly titratable and useful in patients who require serial examinations, such as trauma patients with possible occult head injury.

Fentanyl causes less histamine release than morphine at equianalgesic doses and is associated with fewer peripheral effects. Fentanyl is an excellent choice for treating pain in patients with bronchospastic lung disease or a history of opioid-associated pruritus. Fentanyl is more frequently associated with respiratory depression than morphine. Patients receiving repeated doses of fentanyl should be monitored with direct observation supplemented by pulse oximetry.

The ED use of fentanyl is associated with a very low incidence (1.1%) of serious complications. High or repeated fentanyl doses may produce muscle rigidity. This side effect, so-called rigid chest syndrome, usually occurs with anesthetic doses greater than 7–15 μg/kg, but also has been reported during use for procedural sedation; it may be so severe that it interferes with respiration. Rigid chest attributed to fentanyl is exceedingly rare at doses typically used for acute analgesia. Chest rigidity may respond to naloxone, but neuromuscular blockade may be necessary if naloxone reversal is not successful.

Fentanyl can be administered IV, transmucosally, or transdermally. Nebulized or intranasal fentanyl has been described to treat acute pain in patients without IV access at doses of 1–3 mcg/kg.[26]

Sufentanil. Sufentanil is a highly lipophilic synthetic opioid. It has been noted to have fewer cardiac effects than other opioids, and no breakdown products, making it an ideal medication for patients undergoing cardiac surgery or with renal or hepatic disease. Due to its high Cmax and initial dosing IV, it is associated with apnea after IV administration and is usually used in intubated patients in the operating room. Recently, its use sublingually has been described for postoperative pain and the treatment of moderate and acute pain in the ED.[26,27,29]

Buprenorphine. Buprenorphine is a synthetic opioid with a high affinity for the opiate receptor. Buprenorphine has no current indication for the treatment of pain. Rather, buprenorphine, either as a sole agent (Subutex) or when combined with naloxone (Suboxone), is used to reduce opioid drug cravings in patients with opiate use disorder. It has been described for the initiation of treatment for opioid use disorder in the ED.[30]

Buprenorphine is highly effective at reducing opioid cravings and therefore has become a mainstay of medication-assisted drug therapy recovery and rehabilitation programs. The combination of buprenorphine and naloxone is the most commonly used agent with the addition of naloxone acting as an intravenous or inhalation abuse deterrent. Naloxone absorbed in the gastrointestinal tract, by sublingual or oral forms, is largely inert; whereas, absorption via inhalation or intravenous routes results in significant uptake to the opiate receptors with resultant blockade of these receptors and the precipitation of acute withdrawal symptoms.

Oxycodone. Oxycodone is a strong opioid agonist that is highly bioavailable in an oral form. Oxycodone is widely sold in combination with acetaminophen as well as by itself and is also available in long-acting PO formulations. Oxycodone for acute pain should be prescribed in the noncombination form to allow a balance between oxycodone and a nonopioid medication to be individualized for the patient needs. Baseline administration of a nonopioid medication, supplemented by titrated doses of oxycodone, will achieve the optimal effect, with the fewest side effects. Oxycodone bioavailability is much higher than other oral opioids. It is quickly and efficiently absorbed, which may be a causative factor in its high abuse potential.

Oxycodone is not available in a parenteral form in the United States, although studies have demonstrated its IV form to be equianalgesic to morphine. Similar to other opioids, the analgesic effects of oxycodone are dose-dependent. A 15-mg oxycodone dose has similar efficacy to 10 mg of IV morphine. The onset of action of PO oxycodone is approximately 20 to 30 minutes.

Oxycodone undergoes hepatic metabolism into oxymorphone, a strong opioid agonist that principally accounts for its analgesic effects. Approximately 10% of patients do not metabolize oxycodone well and cannot generate the functional metabolite, oxymorphone. This defect in metabolism renders these patients unable to achieve clinically meaningful pain relief with typical dosing strategies and may require very large doses to achieve analgesia. This effect can also be caused by agents that compete with oxycodone for CYP2D6 metabolism, such as neuroleptics, tricyclic antidepressants, and selective serotonin reuptake inhibitors. Cases of serotonin syndrome have been reported when serotonin reuptake inhibitors and oxycodone are given together, likely due to this metabolic interaction.

Hydrocodone. Hydrocodone is metabolized in the liver to hydromorphone and is typically given orally. Hydrocodone provides greater pain relief when combined with acetaminophen or NSAIDs than either component alone. Hydrocodone combinations are less effective than oxycodone-acetaminophen combinations. Hydrocodone clinical analgesia effects typically last 4 hours, with typical dosing of 5 to 20 mg. As with oxycodone, hydrocodone should be prescribed in pure form, not in a combination agent, to allow individual titration of opioid and nonopioid analgesics.

Codeine. Codeine is a weak opioid receptor agonist, usually prescribed in combination with acetaminophen, but has little, if any, role in the modern ambulatory treatment of pain. Codeine is thought to exert its effects through metabolism into morphine and other active hepatic metabolites. Although, like oxycodone, approximately 10% of the population metabolizes it poorly. Although historically prescribed for mild to moderate pain, codeine is a poor choice for analgesia due to its tendency to cause side effects, particularly nausea, cramping, and constipation, at doses that provide minimal analgesia.

Methadone. Methadone has several unique features that distinguish it from other opioids. It has no known neurotoxic or active metabolites and has high bioavailability. In addition to being a strong opioid agonist, methadone also has N-methyl-d-aspartate antagonist and serotonin reuptake inhibitor qualities. Methadone has a slow elimination half-life of 27 hours due to its lipophilicity and tissue distribution. This slow clearance of methadone is the basis for its use in maintenance therapy, given that it can delay the onset of opioid withdrawal symptoms for up to 24 hours. The duration of its analgesic effects is closer to 6 to 8 hours. The discrepancy between the duration of analgesia and the duration of prevention of withdrawal symptoms is due to the biphasic elimination of the drug and its redistribution.

Naloxone. Naloxone is an opioid antagonist that reverses the effects of opioids and is used in the setting of adverse, opioid-induced events, such as opioid overdose. It can precipitate physiologic withdrawal in opioid-dependent patients. The duration of action of naloxone is approximately 45 minutes, which is shorter than that of most opioids, and care must be taken to monitor for the recurrence of opioid adverse events following this period. Naloxone can be given IV, IM, SC, or via an endotracheal tube, but is typically given in titrated doses of 0.2 mg IV until reversal of any adverse opioid effect is observed. In the setting of adverse events from opioid treatment, usually respiratory depression, careful titration allows for the smallest dose possible to be administered to not reverse the analgesic effect of the opioid completely. Naloxone, 0.4-mg autoinjectors, are available for outpatient use to prevent overdose complications. Patients seen in the ED for opioid overdose

are at high risk for subsequent death from overdose.[31] Distributing naloxone autoinjectors to opioid-dependent patients represents an opportunity to intervene and prevent future overdose complications.

Tramadol. Tramadol is a synthetic oral analgesic that is a weak mu agonist, with some serotonin and norepinephrine reuptake qualities. Its analgesic properties are thought to be primarily due to mu receptor agonist activity. Tramadol-induced analgesia is partially reversed by naloxone, suggesting that other properties play a role in its therapeutic effects. As a selective mu agonist without kappa agonist effects, tramadol should not cause physiologic dependence, although tramadol use is associated with abuse. Tramadol should not be considered a nonaddictive alternative to opioids.

Tramadol is metabolized in the liver by the cytochrome P450 system. One of its metabolites, M1, has a greater mu receptor affinity than tramadol and has an elimination half-life of 9 hours. Tramadol appears to affect GABA, norepinephrine, and serotonin receptors and the reuptake of the neurotransmitters. These properties may serve to activate descending pain modulation pathways.

Tramadol may be effective at low doses. At increasing doses, it is associated with nausea and vomiting, limiting its use to low doses and effectively creating a therapeutic ceiling to its clinical use. Tramadol, 37.5 mg, combined with acetaminophen, 325 mg, appears to have similar efficacy to hydrocodone, 5 mg, combined with acetaminophen, 325 mg. As with hydrocodone and oxycodone, tramadol should be prescribed in pure form, allowing accurate dosage adjustment from other agents.

The most common tramadol side effects are nausea, vomiting, dizziness, orthostatic hypotension, and sedation. These side effects are seen in as many as 17% of patients using the drug for chronic pain, with slightly lower rates in patients receiving controlled-release versions. Tramadol lowers the seizure threshold and therefore provokes isolated seizures in selected patients. Tramadol use along with other serotonergic medications (e.g., selective serotonin receptor inhibitors, monoamine oxidase inhibitors, serotonin norepinephrine reuptake inhibitors) is associated with serotonin syndrome.

Tapentadol. Tapentadol is a mu opioid agonist and norepinephrine reuptake inhibitor. It is thought to control acute pain via both these pathways. Tapentadol has similar efficacy to oxycodone to treat acute pain, with less frequent nausea and vomiting. Its dual mechanism of action makes it a potentially effective drug for use in chronic pain.[32]

Opioid use for acute abdominal pain. Historically, pain treatment was withheld from patients with abdominal pain to avoid confounding a diagnosis. These recommendations date from the turn of the 20th century, predating modern diagnostic techniques, and have no place in modern emergency care. Multiple studies have confirmed the safety of providing effective opioid analgesia to patients with undiagnosed abdominal pain.

Nonopioid Analgesic Agents

Acetaminophen. Acetaminophen is the first-line agent for treating acute and chronic pain and is the safest pharmacologic option for pain in children and adults. It has a high toxic-to-therapeutic ratio and lacks significant drug interactions compared with other pain medications.

Although acetaminophen has been in use since the 1880s, its pharmacologic mechanism of action is unknown. Acetaminophen has known analgesic and antipyretic activity, with no known peripheral antiinflammatory effects. Its activity may be due to the inhibition of prostaglandin endoperoxide H_2 synthase and a cyclooxygenase isoenzyme centrally. It may also affect the activation of beta-endorphin centrally. The analgesic actions of acetaminophen are comparable in magnitude to those of NSAIDs. The analgesic effects of the combination of acetaminophen with an NSAID are additive.

Acetaminophen is metabolized in the liver primarily through conjugation to a sulfate or glucuronide. A minor pathway for the oxidative metabolism of acetaminophen produces the toxic metabolite N-acetyl-p-benzoquinone imine (NAPQI). NAPQI requires glutathione for detoxification and elimination. Hepatic toxicity can occur when glutathione pathways are overwhelmed by an increase in NAPQI or a decrease in glutathione levels. Hepatic toxicity is rare with ingestions less than 10 g in a 24-hour period, unless underlying liver disease exists or there is concomitant ethanol abuse. In the latter cases, therapeutic doses can cause clinical hepatotoxicity.

Acetaminophen is generally well tolerated when used at therapeutic doses. Mild rashes are rarely reported, as is bone marrow suppression, manifested by neutropenia, thrombocytopenia, and agranulocytosis. Its use is associated with several important drug interactions. Many anticonvulsants, including phenytoin, barbiturates, and carbamazepine, induce hepatic microsomal enzymes. Increased conversion of acetaminophen to its toxic metabolite may occur in patients who are taking anticonvulsants, but this is rarely of clinical significance in the context of the usual doses for pain management.

Although uncommon, drug interactions resulting in an increased international normalized ratio (INR) have been reported for patients taking acetaminophen and warfarin, particularly among patients taking high doses of acetaminophen (>9100 mg/week). Chronic use of acetaminophen should be avoided in patients with hepatic or renal disease. Renal failure can worsen with acetaminophen use, but the mechanism is unknown. Patients with a history of salicylate hypersensitivity characterized by urticaria have an 11% cross-reactivity to acetaminophen, and the agent should be used with caution in this group.

For mild analgesia and fever reduction, acetaminophen is the first-line agent and is the first choice for use in combination with other agents, usually opioids, to treat patients with more severe pain. The recommended dose of acetaminophen for an adult is 650 to 1000 mg every 4 to 6 hours, not to exceed 4000 mg/day. No increase in analgesic effect has been reported for doses greater than 650 mg (Fig. 6.8).

Nonsteroidal Antiinflammatory Drugs

NSAIDs inhibit cyclooxygenase (COX) and, as a result, the synthesis of prostaglandin, a key mediator of inflammation. The analgesic effect of NSAIDs is peripherally mediated by decreasing prostaglandin levels and effectively raising the threshold of activation of nociceptors. NSAIDs have synergistic effects with opioids and can reduce the amount of opioids needed to achieve pain relief.

Two COX isoenzymes mediate prostaglandin synthesis. COX-1 is present in all cells and plays an important role in homeostatic functions. COX-2 is induced by injury or inflammation and generates prostaglandins as part of the inflammatory process. Nonselective NSAIDs inhibit both COX-1 and COX-2, resulting in multiple beneficial effects (e.g., reduction of inflammation, pain, fever) and some important undesirable effects.

As a group, and because of their common use, NSAIDs are responsible for more serious drug-related side effects than any other analgesic drug class. The major side effects of NSAID analgesic agents are GI bleeding, renal failure, anaphylaxis, and platelet dysfunction. Most of these side effects occur in patients who are taking NSAIDs for chronic conditions. More than 100,000 hospital admissions and approximately 16,500 deaths occur each year from GI bleeding related to NSAID use for osteoarthritis and rheumatoid arthritis. One survey has estimated that for every 100,000 people taking NSAIDs, there are 300 GI-related deaths, 5 hepatic-related deaths, 4 renal-related deaths, and some congestive heart failure–related deaths.

Bone and cartilage healing and repair during NSAID use is a concern in patients with acute fractures. There is limited evidence to

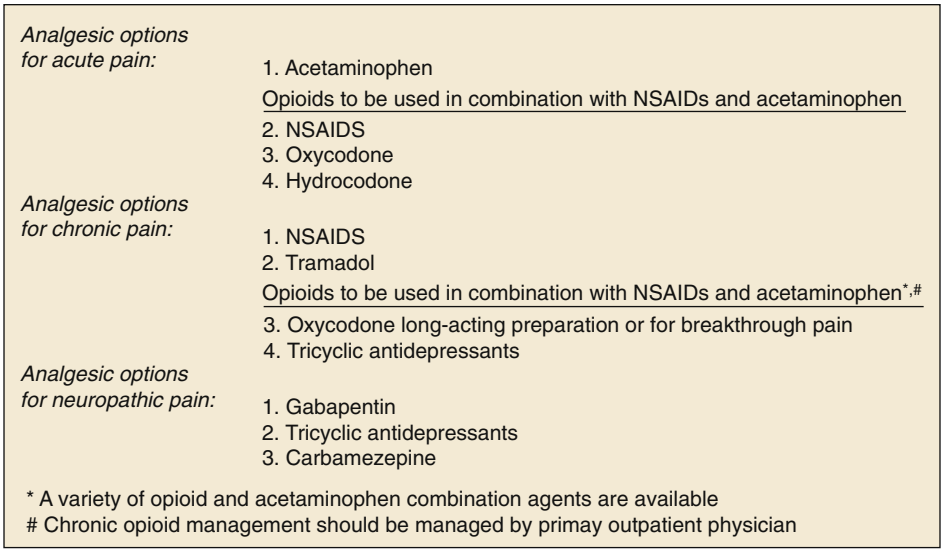

Fig. 6.8 Common outpatient pain treatments by pain type.

suggest that prostaglandins promote bone formation and that NSAIDs might inhibit the process. This issue has not been thoroughly pursued or established through properly conducted studies. There is no human subject evidence that short-term use of NSAIDs for analgesia after fracture is deleterious to healing.

COX also promotes the production of prostacyclin, a vasodilator that increases GI mucosal perfusion. In the stomach, COX-1 increases bicarbonate and mucus production, important for protecting the mucosal lining. Inhibition of COX-1 compromises these protective functions, predisposing patients to ulcerations and bleeding, exacerbated by concomitant NSAID-induced platelet dysfunction.

COX-1 and COX-2 affect the cardiovascular system by producing endothelial prostacyclin (vasodilatory) and thromboxane (platelet aggregation). Inhibition of COX-1 causes antiplatelet activity that may be cardioprotective by inhibiting thromboxane production more than prostacyclin. Inhibition of COX-2 inhibits prostacyclin production more than thromboxane and may produce prothrombotic effects, increasing the risk of cardiovascular events. In the case of nonselective COX inhibitors, these two effects appear to balance each other out, resulting in few changes in cardiovascular risk in studies of these drugs. In the case of selective COX-2 inhibitors, this may increase cardiovascular risk and has limited the use of these agents.

Prostaglandin produced by COX-1 causes renal vasodilation that maintains renal blood flow and the glomerular filtration rate (GFR). Inhibition of COX-1, especially in volume-depleted patients, can result in a decreased GFR and acute kidney injury. Sodium and water retention, hypertension, hyperkalemia, and acute renal failure may also ensue, particularly in patients with congestive heart failure.

The most common adverse effect of NSAIDs is GI mucosal injury. In patients taking NSAIDs continuously for 1 year, it has been found that 10% to 60% will develop abdominal pain, dyspepsia, or nausea and 2% to 4% will develop symptomatic ulcers. Risk factors include age, concomitant use of warfarin or corticosteroids, congestive heart failure, diabetes, and coronary artery disease. Cytoprotective agents such as misoprostol and proton pump inhibitors reduce this risk. The relative risk for GI side effects varies with various NSAIDs and treatment strategies (Table 6.5).

Drug interactions with nonsteroidal antiinflammatory drugs

Aspirin. NSAIDs may impair the cardioprotective effect of aspirin, although the available evidence is unclear, and the use of daily aspirin for cardiac prophylaxis should not deter the prescribing of an NSAID for acute pain or inflammation.

Oral anticoagulants. The antiplatelet effects of NSAIDs add to the anticoagulant properties of warfarin, compounding the risk of significant bleeding complications, especially from GI ulcers. Furthermore, NSAIDs displace protein-bound warfarin and cause subsequent increases in prothrombin times at a constant warfarin dose. NSAID use is generally avoided in patients who are taking warfarin.

Angiotensin-converting enzyme inhibitors. Concurrent use of NSAIDs with angiotensin-converting enzyme (ACE) inhibitors may impair renal function and impair the antihypertensive effects of ACE inhibitors.

Diuretics. Patients taking diuretics have a greater risk of developing renal failure due to NSAID-mediated decreased renal blood flow. Also, the natriuretic response to diuretics depends in part on prostaglandin-mediated vasodilation.

TABLE 6.5 Risk of Serious Gastrointestinal Effects of Nonselective Nonsteroidal Antiinflammatory Drugs (NSAIDs)

NSAID	Relative Risk of Serious GI Toxicity
COX-2 inhibitor	0.6
Ibuprofen	1.0
Diclofenac	1.8
Sulindac	2.1
Naproxen	2.2
Indomethacin	2.4
Tolmetin	3.0
Piroxicam	3.8
Ketoprofen	4.2
Ketorolac	24.7
Risk Reduction When Added to Ibuprofen	
Proton pump inhibitor	0.09
Misoprostol	0.57

GI, Gastrointestinal.

BOX 6.6 Patients at Risk for Adverse Events during Nonsteroidal Antiinflammatory Drug (NSAID) Therapy

1. Patients with dehydration, hypovolemia or who have impaired renal function are at increased risk for decreasing renal function or renal failure.
2. Patients with liver disease or congestive heart failure—in particular, those already taking ACE inhibitors, ARBs, or diuretics—in whom liver or heart conditions may worsen.
3. Older patients are at enhanced risk for GI and renal events.
4. Patients with asthma and known aspirin hypersensitivity are at increased risk of bronchospasm.
5. Women in the third trimester of pregnancy—NSAIDs may prolong gestation or prematurely close the ductus arteriosus.
6. Patients who use tobacco or ethanol with a history of gastritis or peptic ulcer disease are at increased risk for peptic ulcer or GI bleed.

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin II receptor blocker; *GI,* gastrointestinal.

Glucocorticoids. Patients on corticosteroids have an increased risk of peptic ulcer disease. NSAIDs should generally be avoided in patients concurrently taking glucocorticoids unless closely supervised by a physician.

Lithium. NSAIDs enhance lithium reabsorption and may directly reduce lithium excretion, leading to increased lithium levels. CNS symptoms (e.g., drowsiness, confusion, vertigo, convulsions, tremors), cardiac dysrhythmias, and QRS widening are warnings of lithium toxicity. The lithium dosage should be reduced when an NSAID is prescribed

Nonselective cyclooxygenase inhibitor selection. NSAIDs combine analgesia and antiinflammatory effects with low abuse potential and many different side effects compared to opioid agents. Oral NSAIDs can be as effective as oral opioids for mild to moderate pain. Parenteral NSAIDs offer little advantage over their PO forms. Different patients respond differently to the beneficial effects and side effects of different NSAIDs. Therefore, some individual experimentation may be necessary to determine the best NSAID choice for a particular patient. No particular NSAID has been proven to be superior for any indication. Drug selection should depend on availability, side effect profile, convenience, and cost. Patients at risk for adverse events using NSAIDs are listed in Box 6.6.

Ketorolac tromethamine. Ketorolac was the first nonopioid analgesic agent available for parenteral use in the United States. For acute pain management, ketorolac is rarely indicated in the patient able to receive oral medications, given that 60 mg of ketorolac administered IM is not clinically superior to 800 mg of oral ibuprofen. Additionally, NSAID agents can be administered at a fraction of the cost of parenteral routes. A primary indication for ketorolac use is in the early treatment of renal colic because of the difficulty in renal colic patients tolerating oral medications.

Ibuprofen. Ibuprofen is the most widely used agent in the NSAID class. It is available over the counter in various preparations, including tablet, liquid suspension, and suppository forms. Ibuprofen is rapidly absorbed from the upper GI tract and has minimal interaction with other medications. The adult analgesic dose is 400 mg. No NSAID is more effective as an analgesic than ibuprofen, 400 mg, including ibuprofen doses of 600 and 800 mg.

Skeletal muscle relaxants. Skeletal muscle relaxants have been advocated as an adjunct to analgesics in managing musculoskeletal pain with a spasm component, principally back pain. Despite the common use of skeletal muscle relaxants, little data exist supporting their role in the treatment of pain. Studies have demonstrated that muscle relaxants, such as cyclobenzaprine, are indistinguishable from ibuprofen in analgesic effect but have an increased side effect profile.

Skeletal muscle relaxants should not be used to treat acute musculoskeletal pain as a substitute for proper doses of effective analgesics unless there is a high degree of anxiety accompanying the pain. Benzodiazepines are not recommended for the routine treatment of musculoskeletal pain.

Nitrous oxide–oxygen mixtures. The analgesic and anesthetic properties of nitrous oxide were discovered more than 200 years ago, and it is one of the original forms of patient-controlled analgesia. Nitrous oxide–oxygen mixtures can be used in the ED or the out-of-hospital care setting to reduce anxiety in patients and manage mild to moderate pain states. Combined with oxygen, a mixture of nitrous oxide and oxygen in a 50:50 ratio is safe when self-administered by the patient.[33,34]

Dentists have long used nitrous oxide and oxygen administered by nasal mask to treat pain and anxiety. Experience in emergency medicine with nitrous oxide–oxygen mixtures is greatest in the ratio of a 50:50 mixture with a self-administered, hand-held mask.

The mechanism of analgesia and anxiolysis with nitrous oxide have not been fully delineated. The nature of its analgesic effect appears to be similar to that of low-dose opioids, although some of the anxiolytic effects of nitrous oxide appear to have more in common with benzodiazepines than opioids. It has been postulated that nitrous exerts an effect on GABA receptors.

Nitrous preparations are often administered in a two-tank system, with a fixed-ratio nitrous oxide–oxygen mixture delivered to the patient through a demand valve activated with inhalation through a facemask or mouthpiece. A negative pressure of 3 to 5 cm H_2O must be produced within the mask or mouthpiece to activate the gas flow, limiting the use of these devices in very small children. Having the patient hold the mask to the face allows him or her to titrate the dose to an effective level. In 10% to 15% of patients, nitrous oxide is ineffective. It is much more potent as an anxiolytic than as an analgesic agent and can be supplemented with other analgesics.

Nitrous oxide is a folate antagonist and is strictly contraindicated in pregnant patients. Advanced scavenger systems are necessary to allow the safe use of nitrous oxide in the ED to avoid accumulation and toxicity in health care workers, especially if pregnant. Nitrous oxide–oxygen mixtures are contraindicated in patients with a decreased level of consciousness who cannot follow instructions. Patients with severe chronic obstructive pulmonary disease who retain CO_2 should be given nitrous oxide–oxygen mixtures carefully, given that the mixture contains 50% oxygen, which may predispose to hypercapnia. Because nitrous oxide diffuses into body cavities, it can worsen a pneumothorax or bowel obstruction.

Minor side effects of nitrous analgesic gas mixtures have been reported in 5% to 50% of patients. The most common adverse effect is lightheadedness, with paresthesias and nausea reported less frequently. No documented adverse hemodynamic effects have occurred with the self-administered forms of this agent. Side effects attributed to nitrous oxide usually resolve within minutes of discontinuation.

Ketamine. Ketamine is a drug that has typically been used primarily as a dissociative anesthetic for procedural sedation; it is one of the most effective and widely used drugs for procedural anesthesia worldwide. Ketamine has also been evaluated for low-dose use as an analgesic. Low-dose ketamine is similar to morphine in its analgesic effect when used alone and as an additive to opioids when used in conjunction with them at doses of 0.1 to 0.3 mg/kg IV (one-tenth to one-third of a typical dose used for dissociative sedation).

TABLE 6.6 Characteristics of Common Local Anesthetic Agents

Agent	Potency (Lipid Solubility)	Duration of Action (min)	Onset	Comments
Procaine	1	60–90	Slow	Solutions of 0.5%–2% used in infiltration and blocks
Tetracaine	8	180–600	Slow	Topical for ophthalmic use
Lidocaine	3	90–200	Rapid	Most commonly used agent; 1.5 times as toxic as procaine
Mepivacaine	2.4	120–240	Very rapid	Less potent and less toxic than lidocaine
Bupivacaine	8	180–600	Intermediate	Long-acting agent used in infiltration and blocks
Etidocaine	6	180–600	Rapid	Twice as toxic as lidocaine; used mostly in epidurals

Adapted from Paris PM, Weiss LD: Narcotic analgesics: the pure agonists. In Paris PM, Stewart RD, editors: Pain management in emergency medicine, Norwalk, CT, 1988, Appleton & Lange.

The principal side effects of ketamine are dysphoria, vomiting, and hypersalivation. Ketamine appears to be effective via the *N*-methyl-D-aspartate receptor, a different pathway from opioids, acetaminophen, or NSAIDS, giving it potential to affect analgesia when adverse effects limit other agents. The use of low-dose ketamine as an analgesic in the ED setting has increased and represents a consideration for patients with acute pain in whom traditional opioids or NSAIDS are deemed inappropriate or ineffective.[35-41]

Local/Regional Anesthesia

Mechanism of action. Peripheral nerves are responsible for transmitting pain information from pain receptors to the spinal cord. Each fiber consists of an axon surrounded by a covering called the Schwann cell. A myelinated axon is one covered by the projection of a Schwann cell that wraps itself many times around the axon; hence, the term myelin sheath.

Local anesthetics are much more effective at penetrating unmyelinated or lightly myelinated fibers than heavily myelinated ones. This difference explains the finding that local anesthetic agents provide sensory block without motor neuron effects (see Table 6.1).

Local anesthetic agents reversibly block lipid membrane sodium channels and prevent the influx of sodium ions into the axon, blocking depolarization and the nerve action potential. After injection of a local anesthetic, tissue buffers increase the pH of the solution surrounding the agent, driving much of the water-soluble acidic form to its lipid-soluble nonionic form. The lipid-soluble phase of the drug is able to penetrate the axon lipid membrane, where it then ionizes and enters the sodium channel, blocking the ability of sodium to enter the cell.

The use of emergency physician-administered regional anesthesia has increased in recent years and has been described for a wide variety of painful injuries, including rib fractures, hip fractures,[42,43] and dislocations[44,45] in adults and children.[46]

Intravenous lidocaine has also been described for the treatment of central pain syndromes and neuropathic pain, and has been noted to have opioid-sparing effects in the operating room. It has been best described in the ED to treat pain from renal colic[47] and radicular back pain.[48]

Classes of local anesthetic agents. Local anesthetic agents are chemical compounds that consist of an aromatic and amine group separated by an ester (e.g., procaine, chloroprocaine, tetracaine) or an amide (e.g., lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine) intermediate chain. Esters are unstable in solution and are metabolized in the body by the plasma enzyme cholinesterase. The amides, after absorption into the body, are destroyed by enzymes in the liver. The main considerations in the clinical use of these agents are potency, duration of anesthesia, and speed of onset (Table 6.6). The lipid solubility of an agent determines its potency. Less potent local anesthetics must be given in more concentrated forms and larger doses to achieve an equivalent effect.

The duration of anesthetic agent action is determined by its protein-binding affinity to sodium channel proteins. The speed of onset of any local anesthetic agent is directly related to its diffusion through tissues to the nerve, as determined by its pKa (dissociation constant)—the pH at which 50% is ionized. After injection, the anesthetic agent is in two forms, ionized and nonionized. Only the nonionized form of the drug diffuses into nerves. Therefore, solutions with a low pK_a have a more rapid onset of anesthesia.

Low tissue pH (5 or 6) in surrounding infected tissue delays the onset of local anesthesia in cases such as abscess incision and drainage by keeping more of the agent in an ionized state. The onset of action can be hastened by the alkalinization of the solution carrying the drug, decreasing its irritant effect (pain) on injection. This can be done clinically by adding sodium bicarbonate solution to the anesthetic at a ratio determined by the pK_a of the agent. Anesthetic agents, except cocaine, are vasodilators, which tend to shorten the duration of anesthesia. Injection of the solutions into vascular tissues shortens the duration of anesthesia and increases systemic absorption and the chance of systemic toxicity when larger doses are used. Therefore, epinephrine is often added to local anesthetic solutions.

Allergic reactions. True allergies to local anesthetics are rare. When an allergy to local anesthetics is reported, the offending substance is often one of the preservatives used. Because the amide agents and amino ester agents do not cross-react and use different preservatives, a patient may be given medication from another class if the allergy history is consistent with a specific anesthetic group. In those patients who report they are allergic to all "-caine" anesthetic agents, and the allergy is believed to be legitimate, diphenhydramine can be used as an alternative agent. Diphenhydramine may be used with 1 mL of a 50-mg/mL ampule diluted with saline to 5 or 10 mL (1%–0.5% solution) for local infiltration or nerve block. Diphenhydramine may cause direct tissue toxicity and should be avoided in areas with poor collateral circulation.

Local and systemic toxicity

Local toxicity. Local anesthetic agents, depending on the concentration, can be directly toxic to tissue. Also, there are theoretical concerns that the use of a vasoconstrictor in an anesthetic solution may reduce blood flow that could increase wound healing time and vulnerability of the wound to infection. However, this concept has never been formally demonstrated.

Systemic toxicity. Systemic toxicity of local anesthetics occurs when a sufficient quantity of the drug accumulates in the body so that sodium channel blockade occurs in the heart or brain. There is a dose-related clinical progression of local anesthetic toxicity, from subtle neurologic symptoms to seizures to cardiovascular collapse.

TABLE 6.7 Guidelines for Maximum Doses of Commonly Used Local Anesthesia Agents[a]

Agent	Without Epinephrine (mg/kg)	With Epinephrine (mg/kg)
Lidocaine HCl[b]	3–5	7
Mepivacaine HCl	8	7[c]
Bupivacaine HCl[d]	1.5	3

[a]All maximum doses should be reduced 20% to 25% in very young, old, and very sick patients.
[b]A lidocaine level of 0.5 to 2.0 g/mL may be reached for every 100 mg of lidocaine infiltrated for blocks.
[c]Epinephrine adds to the potential cardiac toxicity of this drug.
[d]Not to be used for pudendal blocks or IV regional anesthesia; not recommended for children younger than 12 years.
Adapted from Stewart RD: Local anesthesia. In Paris PM, Stewart RD, editors: Pain management in emergency medicine, Norwalk, CT, 1988, Appleton & Lange.

All local anesthetics produce systemic toxicity at sufficiently high blood or CNS concentration. Each local anesthetic has a range of therapeutic safety beyond which systemic toxicity is more likely to occur (Table 6.7). Overdosage of local anesthetics may occur more commonly in patients with large wounds and patients with a low body mass index.

The more lipophilic anesthetic agents (e.g., etidocaine, bupivacaine) are more cardiotoxic. Cardiac toxicity may also occur if epinephrine-containing anesthetics are inadvertently injected intravenously. Special care should be exercised in children and when performing blocks known to produce high blood levels of the anesthetic agent (e.g., intercostal). In pediatric patients, the maximum agent dose should be calculated before administration.

A wide variety of symptoms may be experienced from local anesthetic toxicity. These include lightheadedness, headache, tinnitus, paresthesias, muscle spasm, and confusion. In addition, benzocaine has been associated with methemoglobinemia. The degree to which CNS symptoms are experienced is directly related to the blood level of the local anesthetic.

CNS toxicity from anesthetic agents may result in seizures. A typical clinical progression usually begins with circumoral paresthesias, dysarthria, and tinnitus or similar auditory phenomenon. These events may be followed by a decreased level of consciousness progressing to confusion, seizures, and coma. Longer-acting, more potent agents (e.g., bupivacaine, etidocaine) are more likely than lidocaine to cause CNS symptoms at lower blood levels. Local anesthetic-induced seizures should be treated with IV benzodiazepines and may be refractory to normal dosing of neuroleptic medications.

Local anesthetic agents also have direct effects on cardiac automaticity, conductivity, contractility, and vascular tone. Management of cardiovascular collapse caused by toxic levels of local anesthetic agents should follow standard advanced cardiac life support guidelines. Unless the overdose is massive, the toxicity should be relatively short-lived, given the redistribution of the lipophilic agents.

Reducing the pain of local anesthetic injection. Many techniques can be used to reduce the pain of anesthetic injection (Box 6.7). Distraction by manual methods such as scratching, jiggling, or repetitively pinching the skin during needle puncture or injection reduces the discomfort experienced during local anesthetic injection. Injecting the agent slowly is the principal method to reduce injection pain. Injection into the edges of a wound is less painful than injection through intact skin. Warming the anesthetic and applying a topical anesthetic agent can also decrease the initial sensation associated with needle injection.

BOX 6.7 Techniques to Reduce the Pain of Injection

- Buffering of local anesthetic agents
- Counterirritation
- Slower rate of injection
- Use of topical anesthetics
- Warming of solution
- Distraction techniques

The addition of sodium bicarbonate to lidocaine before injection reduces anesthetic injection pain. A standard solution of sodium bicarbonate (8.4% in 50 mL) can be added to a syringe containing lidocaine in a ratio of 1 : 10 (e.g., 1 mL bicarbonate to 10 mL lidocaine, or 0.5 mL to 5 mL). Buffered lidocaine can be stocked in the ED and is effective for up to 1 week.

Topical Anesthesia

Topical anesthetics are generally of two types, those that can be applied to intact skin and those used on open skin. Topical agents are particularly useful in pediatric patients intimidated by needles. These agents may help decrease the intensity of superficial stimuli. The long application time and limited analgesia are the principal drawbacks of these strategies. In some patients, however, the strategy of applying the topical anesthetic and delaying the procedure until there will be less pain can be a useful tool in controlling pain and the response to subsequent interventions.

Topical anesthetics applied to intact skin

Eutectic mixture of local anesthetics. A eutectic mixture of local anesthetics (EMLA) is a mixture of lidocaine and prilocaine in an alkaline oil mixture in which the anesthetics are primarily in their nonionized form. This format allows diffusion through intact skin. The term *eutectic* refers to mixtures that result in a melting point higher than that of either agent alone.

For clinical use, an EMLA mixture should be applied to the desired area with an occlusive dressing 30 to 60 minutes before the procedure is performed. Heating EMLA for 20 minutes improves analgesia but is less effective than a routine 60-minute application, with or without heat. The duration of action after a 60-minute application is 1 to 5 hours.

Indications for the use of EMLA include venipuncture, arterial puncture, lumbar puncture, or arthrocentesis when a 30- to 60-minute delay in performing the procedure is not an impediment. EMLA can be applied in triage, particularly for pediatric patients, with an IV started later in the ED with little or no pain.

Ethyl chloride and fluoromethane sprays. Ethyl chloride and fluoromethane sprays are occasionally used for superficial analgesia. The agents evaporate quickly and cool the skin, providing brief (<1-minute) local anesthesia due to the sensation. The induced analgesia is brief. Any injection or incision should be made immediately after the application of the agent.

Agents applied to mucosal surfaces

Cocaine. Cocaine is unique among local anesthetic agents, given that it is a potent vasoconstrictor in addition to being an anesthetic that can be applied to mucosal surfaces. Cocaine is frequently used in the nose, for which a 4% (40 mg/mL) solution provides rapid anesthesia for the treatment of epistaxis and other nasal procedures. Although the maximum safe dose is unknown, no more than 200 mg is typically applied in adults. Cocaine should not be used in patients with known coronary artery disease due to the potential for coronary artery vasoconstriction.

Lidocaine. Both 2% and 4% lidocaine solutions are available in a viscous matrix for mucosal surfaces. Gel lidocaine can be used in nasal procedures, including the passing of nasogastric tubes and gastric lavage tubes. It can also be used for urethral anesthesia during Foley catheter placement. To be effective, lidocaine gel preparations must be injected into the urethra with a catheter tip syringe and be in contact with the area for 5 to 20 minutes. Lidocaine spray (2–10%) is useful for upper airway anesthesia, including intranasal use for nasogastric tube insertion.

Tetracaine. Tetracaine is a potent ester used for surface anesthesia of the cornea. Tetracaine stings when placed in the eye, but only for 10 to 15 seconds, after which there is excellent corneal anesthesia.

Benzocaine. Almost insoluble in water, benzocaine remains on mucous membranes in the mouth and is commonly used to provide superficial analgesia for oral procedures and pain.

Agents applied to open skin: lidocaine, epinephrine, and tetracaine. The combination of lidocaine, epinephrine, and tetracaine, 5 to 10 mL, may be applied to an open wound using sterile cotton, which is then covered and held in place for 10 to 20 minutes. Anesthesia has been described in approximately 85% of cases of wounds of the scalp and face and a lower percentage of extremity wounds. Application of the solution to mucous membranes (eye, intranasal) can result in toxic blood levels of tetracaine and should be avoided.

Nonpharmacologic Interventions

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) systems use electrical stimulation to induce analgesia, likely through the activation of descending sensory pathways and modulation of nociceptive signals at the level of the spinal cord (see Figs. 6.5 and 6.6). TENS units include a pulse generator, amplifier, and electrodes. Studies have demonstrated varying degrees of effectiveness. These devices are rarely indicated for use in the ED.

Out-of-Hospital Analgesia

Out-of-hospital clinicians frequently encounter patients with painful conditions. Patients obtain pain relief more quickly when pain medications are initiated by out-of-hospital personnel, although pain control in this setting is challenging to perform adequately.

The out-of-hospital environment is less controlled than the ED, and information regarding a patient's underlying condition is more limited, making the safe administration of pain medications more difficult. As in the ED, establishing rapport with the patient, providing calm reassurance, and using careful movement and handling, including proper splinting, are the first steps to which pharmacologic support can be added. Pain can be assessed in the out-of-hospital setting using numeric and verbal rating scales, the same as would occur in the ED.

Protocols for the administration of fentanyl and morphine are available in most emergency medical services systems and are usually limited to single-dose therapy prior to obtaining orders from the medical control physician. Morphine, 0.1 mg/kg, is safe for out-of-hospital use and should be considered the first-line agent for severe pain, as it is in the ED.

OUTCOMES: TREATMENT ENDPOINTS

Pain is a subjective experience. In the ED, management of acute pain should specify an initial dose, with a repeat dose and interval determined through a specific desired endpoint, such as pain reduction measured by a standardized assessment tool (see Fig. 6.7). A reasonable endpoint is to achieve sufficient pain relief for the patient to be able to doze or carry on a normal conversation with clinicians or family members.

CHAPTER 6: QUESTIONS AND ANSWERS

1. Which of the following statements is true regarding pain transmission?

a. Cardiac pain is transmitted via the sympathetic system.
b. Central post-stroke neuropathic pain is associated with parietal infarcts.
c. Descending modulation of pain is mediated primarily through γ-aminobutyric acid (GABA).
d. Peripheral neurotransmitters include prostaglandins, histamines, and substance P.

Answer: A. As a general rule, all visceral pain is carried via sympathetic afferents to ganglia and then to the spinal cord. Prostaglandins, substance P, and histamine sensitize peripheral afferents but are not neurotransmitters. The dorsal column tracts can down-modulate ascending pain signals. Central post-stroke pain is clinically seen most often after thalamic strokes. Descending tracts that modulate pain processing at the dorsal horn use norepinephrine and serotonin, with the effect of the former being most important regarding analgesia.

2. Which of the following analgesics is matched with the correct feature?

a. Fentanyl—prolonged QT interval on electrocardiography
b. Hydromorphone—active metabolites
c. Meperidine—muscle rigidity
d. Oxycodone—serotonin syndrome

Answer: D. Oxycodone has been associated with serotonin syndrome when coadministered with selective serotonin reuptake inhibitor (SSRI) medications. This is due to an active metabolite it shares with morphine, hydromorphone, hydrocodone, and codeine. The following are the other correct associations:

Meperidine—anticholinergic toxicity, active metabolites
Fentanyl—muscle rigidity (chest wall)
Hydromorphone—inactive metabolite

3. A 32-year-old male patient undergoing treatment for an ankle sprain returns to the emergency department (ED) because of inadequate pain relief from the medicines he was prescribed. He is currently taking oxycodone, 10 mg PO every 4 hours, and ibuprofen, 400 mg every 4 hours. What is the next most appropriate medicine to add to his pain treatment regimen?

a. Add acetaminophen, 650 mg q4h.
b. Add tramadol, 50 mg PO q4h.
c. Increase ibuprofen to 800 mg.
d. Increase oxycodone to 15 mg.

Answer: A. Acetaminophen provides additive analgesia to nonsteroidal antiinflammatory drugs (NSAIDs) and opioids, with few adverse effects at low doses, and it should be incorporated in acute pain treatment when not contraindicated. The pain-relieving effects of ibuprofen have not been shown to be greater when 800 mg is used versus 400 mg, so increasing the dose of ibuprofen is unlikely to improve pain relief and will increase the risk of adverse effects of the NSAIDs. An increased dose of oxycodone would result in improved pain relief but increases the risk of adverse effects; it should be tried after other nonopioid treatments have failed. In this case, acetaminophen should be attempted first before increasing the oxycodone dose. Tramadol would not be indicated before acetaminophen because of its high rate of dizziness and nausea.

7

Procedural Sedation and Analgesia

Steven A. Godwin and Andrew Schmidt

KEY CONCEPTS

- Safe, effective procedural sedation and analgesia requires high-level experience and sound protocols for patient selection and patient monitoring.
- After procedural sedation, patients should be discharged with and remain in the company of a responsible adult for 4 to 8 h after recovery.
- Propofol is the agent of choice for deep sedation in the emergency department but requires supplementation with an opioid analgesic when a painful procedure is planned.
- The absence of a preprocedure fasting period is not a contraindication to procedural sedation for an emergent or time-sensitive condition.
- Pulse oximetry is mandatory during sedation, and end-tidal CO_2 should be monitored if moderate or deep sedation is planned. Oxygen should be administered to patients undergoing procedural sedation.

FOUNDATIONS

Background and Importance

The performance of diagnostic and therapeutic procedures is common in emergency care. Many of these interventions are often associated with significant pain and anxiety. Procedural sedation and analgesia (PSA) is a fundamental and required skill for emergency clinicians and an integral part of the core training of emergency medicine residents. This chapter will focus primarily on PSA in the adult population; Chapter 157 provides specific guidance for PSA for children.

PSA improves patient care and satisfaction by relieving pain and anxiety and facilitating successful therapeutic or diagnostic procedures.[1,2] These include fracture or joint reduction, incision and drainage of abscesses, cardioversion, tube thoracostomy, lumbar puncture, complex wound repair, and imaging studies in uncooperative patients.

Many of the agents used for PSA have the potential to cause significant respiratory, cardiovascular, or central nervous system (CNS) depression. The Joint Commission (TJC), Centers for Medicare and Medicaid Services (CMS), American College of Emergency Physicians (ACEP), and American Society of Anesthesiologists (ASA) have produced expert consensus and evidence-based guidelines concerning the use of PSA (Box 7.1).[1–3] Although controversy continues about credentialing and oversight of PSA outside the operating room at some institutions, the advent of these guidelines has led to PSA becoming a common emergency department (ED) procedure. The adoption of PSA as a standard procedure in the ED has been further enhanced by the availability of shorter-acting more effective drugs, and noninvasive monitoring devices.

With the wide variety of patient populations and procedural needs, the ability to individualize PSA for each situation is a necessary skill. Knowledge of the characteristics of each sedative is essential but identifying patient characteristics that may increase the risk of adverse events during sedation is more critical in ensuring a safe and patient-centered sedation. This can be best achieved through detailed preprocedural patient assessment, protocols delineating the required personnel and equipment, specific drugs used (including their routes of administration, dosages, effects, interactions, and complications), considerations for special at-risk populations, and patient monitoring, recovery, and discharge criteria.

The following terms are important for understanding the concepts presented in this chapter:

Anxiolysis is a state of decreased apprehension concerning a particular situation in which the patient's level of awareness does not change.

Analgesia refers to the relief of pain without the intentional alteration of mental status, such as occurs in sedation. An altered mental state may be a secondary effect of the medications administered for this purpose.

Dissociation is a trancelike cataleptic state induced by an agent such as ketamine and characterized by analgesia and amnesia. Protective reflexes, spontaneous respirations, and cardiopulmonary stability are retained. Sedation is a controlled reduction of environmental awareness.

Procedural sedation and analgesia is a technique of administering a sedative or dissociative agent, along with an analgesic, to induce a state that allows the patient to tolerate painful procedures while maintaining adequate spontaneous cardiorespiratory function. It is intended to result in a depressed level of consciousness that allows the patient to maintain oxygenation and airway control independently and continuously. The drugs, doses, and techniques used are not likely to produce a loss of the protective airway reflexes.

ASA currently recognizes a continuum of depth of sedation, consisting of four subgroups (Fig. 7.1)—minimal sedation, moderate sedation, deep sedation, and general anesthesia.[3] A fifth category, dissociative sedation, has been adopted by ACEP (Table 7.1).[1]

Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive functions and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate sedation and analgesia (formerly called *conscious sedation*) refers to a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, auditory only or accompanied by light tactile stimulation. Reflex withdrawal from the painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is always maintained.

Dissociative sedation is a trancelike cataleptic state induced by the dissociative agent ketamine; it is characterized by analgesia and amnesia while protective airway reflexes, spontaneous respirations, and cardiopulmonary stability are maintained.

Deep sedation and analgesia describes a drug-induced depression of consciousness during which patients cannot be easily aroused but

respond purposefully after repeated or painful stimulation. The ability to maintain ventilatory function independently may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even with painful stimulation. The ability to maintain ventilatory function independently is impaired. Patients typically require assistance in maintaining a patent airway, and positive-pressure ventilation is required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

The progression from minimal sedation to general anesthesia is a dynamic continuum that lacks distinct separation between stages. The transition from one level of sedation to the next is often difficult to predict and varies from patient to patient. The sedation continuum is not drug-specific, and levels from mild sedation to general anesthesia can be achieved with virtually all the PSA agents. Because of this, emergency clinicians administering PSA should be able to treat patients who are in at least one level greater than the intended level of sedation.

Anatomy, Physiology, and Pathophysiology

Pain experienced by sick and injured patients is the result of multiple pathways in the body. In general, a painful stimulus activates bodily receptors, which then initiates biochemical signals through peripheral and central neural pathways, ultimately ending in the interpretation and perception of pain in the brain. The pharmacologic treatment of this pain comes in many different forms, ranging from local or regional anesthetics directly injected into the affected area, to more systemic-acting analgesics, and finally to sedating or dissociating medications aimed at suppressing the overall central awareness of pain.

Each class of medication utilized in PSA has its own mechanisms of action to treat the perception of pain. The most well-known class of analgesics covered in this chapter is opioids. These medications act on systemic opioid receptors, inhibiting the central pain pathway, while also providing some level of sedation. More pure sedatives, like benzodiazepines, etomidate, and propofol, primarily act on central γ-aminobutyric acid (GABA) receptors, resulting in a decreased level of consciousness and a loss of awareness and of a sense of pain, instead of suppression of pain reception. Dexmedetomidine, another sedative, works on a different class of receptors known as alpha2-adrenoceptors, providing sedation and mild analgesia. Finally, ketamine, a potent analgesic and dissociative agent, produces its actions through antagonism of N-methyl-D-aspartate (NMDA) receptors. By understanding the mechanism of each medication, clinicians can develop a multimodal approach to PSA to ensure comfort and safety.

MANAGEMENT

Decision Making

The approach to procedural sedation requires evaluating conditions that may enhance or impede the effectiveness of procedural sedation. These factors include patient assessment, including the consideration of preprocedural fasting, appropriate personnel, supplies, and equipment, patient monitoring, and postprocedural recovery.

Patient Assessment

Although no outcome-based studies have demonstrated a clear benefit from presedation evaluation beyond vital signs, mental status, and

BOX 7.1 American College of Emergency Policy Statement on Procedural Sedation in the Emergency Department[a]

The American College of Emergency Physicians recommends the following:

- Emergency physicians who have received the appropriate training and skills necessary to safely provide procedural sedation, such as board certification (ABEM/ABOEM) in emergency medicine or graduates of an ACGME accredited emergency medicine program, should be credentialed without additional requirements for procedural sedation.
- The decision to provide sedation and selection of the specific pharmacologic agents should be individualized for each patient by the emergency clinician and should not be otherwise restricted.
- Emergency physicians and staff are expected to be familiar with the pharmaceutical agents they use and be prepared to manage their potential complications.
- To minimize complications, the appropriate drugs and dosages must be chosen and administered in an appropriately monitored setting. Patient evaluation should be performed before, during, and after their use.
- Institutional and departmental guidelines related to the sedation of patients should include the selection and preparation of patients, informed consent, equipment and monitoring requirements, hospital staff training and competency verification, criteria for discharge, and continuous quality improvement.

[a] June 2017.

Adapted from American College of Emergency Physicians Policy Statement: Procedural sedation in the emergency department. June 2017.

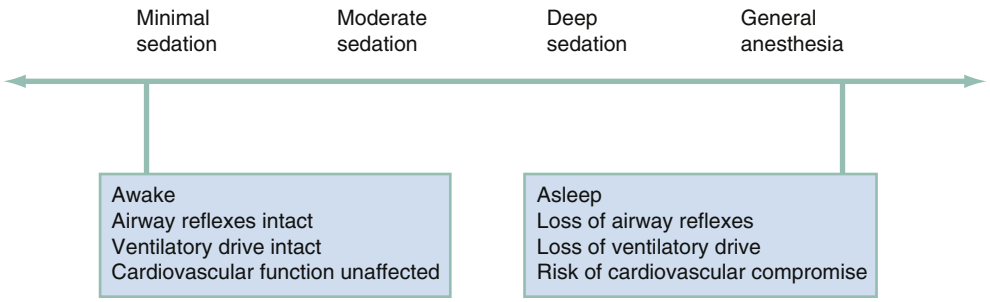

Fig. 7.1 Schematic Representation of the Sedation Continuum. As increasing doses of nondissociative agents are given, patients move along the sedation continuum, experiencing a progressive decline in their level of consciousness and an increased risk of adverse respiratory and cardiovascular events. If medication administration continues, the patient will ultimately reach a state of general anesthesia, with loss of protective airway reflexes and ventilatory drive. The transition from one level of sedation to the next is often difficult to predict and varies from patient to patient.

TABLE 7.1 Definition of Levels of Sedation and Analgesia

Parameter	Minimal Sedation (Anxiolysis)	Moderate Sedation and Analgesia (Conscious Sedation)	Deep Sedation and Analgesia	Dissociative Sedation	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation	Purposeful response to repeated or painful stimulation	Unarousable, even with painful stimulus	Unarousable, even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Adequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	Elevated	May be impaired

TABLE 7.2 American Society of Anesthesiologists Physical Status Classification

Class	Description	Examples	Sedation Risk
I	Normal, healthy patient	No past medical history	Minimal
II	Mild systemic disease without functional limitations	Mild asthma, controlled diabetes	Low
III	Severe systemic disease with functional limitations	Pneumonia, poorly controlled seizure disorder	Intermediate
IV	Severe systemic disease that is a constant threat to life	Advanced cardiac disease, renal failure, sepsis	High
V	Moribund patient who may not survive without procedure	Septic shock, severe trauma	Extremely high

airway and cardiopulmonary assessment, consensus guidelines have suggested that there may be an increased risk of adverse events in subsets of patients. These include patients at the extremes of age, patients with anatomic features predictive of challenging intubation or rescue bag-mask ventilation, and those with underlying significant disease states or impaired cardiopulmonary physiology. A patient's general physical status is conventionally categorized according to the ASA's classification system (Table 7.2).[4] Most practice guidelines require a history and focused physical examination be performed and documented before PSA. No routine diagnostic testing is needed before PSA, other than diagnostic testing driven by the patient's current status, including comorbidities.

The patient's age, current illness or injury for which PSA is intended, comorbidities, previous experiences or problems with PSA or general anesthesia, drug allergies and current medications, and tobacco, drug, and alcohol use are reviewed and recorded. A directed physical examination focuses on the vital signs, heart and lungs, and evaluation of the airway to identify anatomic features of a potentially difficult airway (see Chapter 1).

A discussion including the risks, benefits, and potential side effects of PSA should be held with patients or their families before the procedure. Written consent is preferred unless this is not possible due to the patient's clinical condition or access to the patient's medical surrogate.

Not every patient is an appropriate candidate for PSA in the ED. Therefore, patient selection is essential for the safety of the sedation. Depending on the clinical circumstances, a patient with an anticipated difficult airway or ASA classification of III or IV may require additional clinical resources. These can include additional nursing support or additional providers with expertise in procedural sedation, including emergency clinicians or an anesthesiologist. At times, it may even be advisable to undertake the procedure in the operating room with anesthesia.

Preprocedural Fasting

Evidence supporting preprocedural fasting in PSA has been extrapolated from the literature on general anesthesia. To date, there have been no published outcome-based studies demonstrating an increased risk of aspiration after a liquid or solid meal and no studies showing a benefit of fasting before PSA. Additionally, while anesthesia guidelines provide more conservative fasting recommendations, procedures deemed to be urgent or emergent should not be delayed based on fasting time.[5]

In 2014, ACEP endorsed a level B recommendation regarding preprocedural fasting. It stated that clinicians should not delay procedural sedation in adult or pediatric patients in the ED based on fasting time. The recommendation further noted that preprocedural fasting for any duration has not demonstrated a reduction in the risk of emesis or aspiration during procedural sedation and analgesia. A large 2018 pediatric study found no association between fasting time and serious adverse events, including clinically apparent aspiration.[6]

Subsequent expert consensus statements emphasize considering the patient's risk factors for aspiration, including severe underlying illness, obstructive sleep apnea, obesity, age less than 12 months, upper endoscopy as the procedure requiring sedation, or bowel obstruction, and incorporating this information into the choice of sedative agents and depth of sedation.[1,2]

Personnel

TJC and most institutional policies have suggested that PSA providers should have adequate training to administer the agents effectively and safely. This includes the skill to assess risk, dose, and administer medications appropriately, monitor the patient's response to the medications, and manage all potential complications, in particular airway complications.[2] This generally implies that PSA in the ED should be supervised by an emergency clinician or other appropriately trained and credentialed physician. It is also recommended that a qualified support person (e.g., nurse, respiratory therapist) able to recognize and respond to the complications of PSA be present for continuous monitoring of the patient. Although they may assist with minor interruptible tasks, they should focus on the patient's status and not have any other responsibilities that would interfere with monitoring and documentation from the start of the procedure to completion of the recovery phase.

BOX 7.2 Equipment for Procedural Sedation and Analgesia

High-flow oxygen source
Suction
Airway management equipment
Monitoring equipment
Pulse oximeter
ECG monitor, defibrillator, transcutaneous pacemaker
Blood pressure monitor
Capnography[a]
Vascular access equipment
Reversal agents
Resuscitation drugs
Adequate staff

[a] Capnography carries a level B recommendation by the American College of Emergency Physicians for use as an adjunct to pulse oximetry and clinical assessment to detect early hypoventilation. It is also recommended by the American Society of Anesthesiologists for monitoring the presence of exhaled carbon dioxide during moderate or deep sedation, in addition to the continual observation of qualitative clinical signs of adequate ventilation.
ECG, Electrocardiogram.

Devices and Techniques

Supplies and Equipment

PSA may result in an allergic reaction, oversedation, respiratory depression or, rarely, cardiopulmonary arrest. The incidence of these complications depends on patient selection, drugs used, rate and dosage of administration, and specific patient sensitivities. Consequently, appropriate equipment to monitor the patient's condition continually, manage airway complications, allergic reactions, and drug overdoses, and treat respiratory or cardiopulmonary arrest should be readily available. Supportive equipment includes oxygen, suction, patient-monitoring devices, basic and advanced airway management equipment, a defibrillator, advanced life support medications, reversal or rescue agents, and vascular access equipment (Box 7.2).

With rare exceptions, PSA medications in adult patients should be administered via the intravenous (IV) route. Adults undergoing PSA in the ED should therefore have an IV line placed before the procedure. This need in children is less clear and depends on the presence of comorbid conditions and choice and route of drug to be administered. In children, if the procedure is likely to be lengthy or if multiple doses of drugs will be needed, a peripheral IV line is recommended.

While the requirement for supplemental oxygen, and its benefits during PSA, have not been well studied, emergency department data does suggest its use decreases the incidence of hypoxemic episodes during procedural sedation.[2,7] However, significant respiratory depression in these patients may not be detected because of their normal oxygen saturation. The routine use of capnography eliminates this issue, since ventilatory status is displayed continuously, and is recommended for any planned procedure using more than light levels of sedation or anxiolysis.

The most crucial aspect of monitoring during PSA is the visual observation and assessment of the patient, especially the response to medications and procedures. The patient's ability to follow commands in response to varied levels of stimulation is useful in quantifying the level of consciousness. Furthermore, the patient's ventilatory rate may be readily assessed by direct observation, although depth of respiration or tidal volume is harder to estimate clinically. Pulse oximetry is a reliable and essential monitoring modality. Other components of monitoring, which should be documented, include determination of respiratory rate, heart rate, blood pressure, oxygen saturation, cardiac rhythm, and capnography.

ASA and Joint Commission standards have historically required responsive-based assessments for documenting depth of sedation and a measure for assessing patient comfort. A 2019 ACEP practice guideline on unscheduled procedural sedation challenges this concept as an adequate metric and encourages strong consideration for the incorporation of ventilation-focused assessments as a measure of sedation adequacy. The consensus guideline recommends focusing on respiratory capacity instead of responsiveness alone as a means to enhance patient safety across sedative agents.[2]

Although there is no outcome-based evidence that cardiac monitoring during PSA is of any benefit, it is certainly not harmful, is routinely available, and may be beneficial in some instances. It should be used routinely in older patients and patients with a history of cardiovascular disease, hypertension, or dysrhythmia. Although in young, healthy patients, continuous pulse oximetry alone may be safe (as this will also display the heart rate), we recommend that cardiac rhythm monitoring, if available, should be used in all adult cases.

Capnography (or capnometry) measures end-tidal carbon dioxide (CO_2) partial pressure and has been shown to detect cases of inadequate ventilation earlier than clinical assessment or detection of hypoxemia by oximetry. While the pooled evidence for capnography has not shown a benefit in patient outcomes, studies have demonstrated that its use can significantly reduce hypoxemic events during procedures.[8,9] This, in addition to its lack of harm, ease of use, and increasingly low cost have resulted in most sedation oversight organizations recommending its use. In its 2018 guidelines, the ASA recommended continually monitoring ventilatory function with capnography unless precluded or invalidated by the nature of the patient, procedure, or equipment.[3] The 2014 ACEP guidelines, further supported by more recent organizational statements, endorsed a level B recommendation that capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry or clinical assessment alone in patients undergoing procedural sedation and analgesia in the ED.[1,2]

We recommend that continuous capnography be used when deep sedation is planned due to the inherent risk of respiratory depression. Although optional when only light sedation or anxiolysis is planned, capnography may enhance patient safety by allowing the observer to recognize unintended oversedation and depression of respiratory rate or volume more rapidly.

The bispectral index (BIS) is monitored via a noninvasive device attached to the patient's forehead and determines the depth of sedation level via frontal lobe electroencephalographic measurements. It has been used in the operating room as an objective measure of sedation depth. Though ED studies have revealed a correlation between BIS readings and objective patient sedation levels, no reliable advantage or beneficial role has been demonstrated to support its routine use in PSA monitoring.[10]

When transporting patients outside the ED for diagnostic procedures requiring PSA, every attempt should be made to provide the same level of monitoring during the transport and procedure as would be used within the department.

The highest risk of serious adverse events generally occurs within 5 to 20 minutes of receiving the last dose of IV medication and at the completion of procedures, when the patient remains sedated but is no longer receiving the painful stimulus. Similarly, patients undergoing lengthy procedures in which deeper sedation is desired to reduce

motion (e.g., magnetic resonance imaging [MRI]) are also at an increased risk. Patients should be monitored closely at these times, and this should continue until clinical recovery has occurred.

Recovery

Monitoring should continue until patients are spontaneously awake and able to function independently. The duration of recovery is variable and depends on both the agents used and the depth of sedation. Drowsy patients should not be left unattended, and appropriate measures to prevent falls should be taken.

Post-procedure Recovery and Discharge

Before discharge, baseline cognitive and motor functions such as the ability to follow commands, speech, ambulation, and sitting should be verified. Vital signs and respiratory status should be back to baseline and within normal limits. Residual pain should be addressed. Nausea should be minimal, and vomiting should be resolved. It is preferable that all patients, including adults, be sent home with a responsible adult but, if this is not possible, the patient should remain in the ED until a normal baseline has been achieved.

Patients should be advised not to drive or participate in other dangerous activities for 12 to 24 hours. Despite the short clinical duration of most of the agents used, some patients may exhibit subtle signs of cognitive deficits and mild drowsiness. Therefore, we recommended that they remain in the company of a responsible adult at home for 4 to 8 hours. For children, light play at home should be the extent of activities, with no bicycle riding, swimming, or other complex motor activity until the next day. An antiemetic and progressive diet is helpful if nausea or vomiting is experienced. Standard discharge instructions should also be provided for the presenting complaint as well as for the sedation performed, and all patients should be instructed to immediately return if any confusion or respiratory symptoms arise.

Pharmacology

In selecting agents, clinicians must balance the desired effects, risks and benefits, and logistics of administration for each situation. The 2019 ACEP practice guideline on unscheduled procedural sedation calls for focusing on the sedation depth and ventilatory status of each individual patient as opposed to a specific agent.[2] The clinician should have a clear understanding of the purpose of PSA so he or she can relate it to the procedure being performed. When the procedure is unpleasant but not painful (e.g., endoscopy), pure sedation may be the desired endpoint, and agents such as benzodiazepines, etomidate, or propofol are sometimes used alone. These agents do not provide pain relief and should not be used as the sole agent when pain management is also desired. Analgesic agents such as opioids or nitrous oxide are often added to a sedative agent to provide analgesia for painful procedures. In contrast, ketamine, as a dissociative agent, may be an excellent single drug choice for painful or stimulating procedures. Usually, a combination of analgesic and sedative agents is required. Caution is indicated, however, because their side effects are frequently potentiated when given in combination.

The specific agents for PSA and dosage recommendations for adult patients are provided in Table 7.3. Their benefits and adverse effects are provided in Table 7.4. Individual agents are discussed in greater detail in the following sections.

Routes of Administration

The decision regarding the optimal route of administration should be determined by the procedure and requirements of the specific patient. In general, IV titration to the desired level of sedation and analgesia produces the most rapid, safest, and most predictable results. Drugs given by the intramuscular (IM), oral, transmucosal, intranasal (IN), or rectal routes generally have a slower onset of action, are difficult to titrate, have unpredictable results, and may lead to prolonged sedation. These routes are rarely used for PSA in adults.

In pediatric patients, however, the benefits of IV drug administration may be outweighed by the difficulty and distress to the patient in obtaining IV access. In this situation, drugs given by the alternative routes may be preferred (see Chapter 157). For example, ketamine and midazolam have been shown to provide consistent and predictable results in children through IM or IN routes.[11] Evidence describing the use of inhaled nitrous oxide for PSA in the emergency department primarily involves pediatric patients. It has a predictable behavior when

TABLE 7.3 Procedural Sedation and Analgesia Agents—Recommended Adult Starting Doses

Agent	Class	Main Effect	Route of Administration	Usual Starting Dose
Fentanyl	Opioid	Analgesia	Intravenous	1 mcg/kg
Morphine	Opioid	Analgesia	Intravenous	0.1 mg/kg
Midazolam	Benzodiazepine	Sedation, amnesia	Intravenous	0.05 mg/kg
		Amnesia	Intramuscular	
Ketamine	Phencyclidine derivative	Dissociation, analgesia, sedation, amnesia	Intravenous Intramuscular	1–2 mg/kg 2–5 mg/kg
Etomidate	Imidazole derivative	Sedation, amnesia	Intravenous	0.1 mg/kg
Propofol	Alkylphenol derivative	Sedation, amnesia, antiemetic	Intravenous	1–2 mg/kg
Alfentanil	Opioid analogue	Analgesia	Intravenous	3–8 mcg/kg over 3 min, then 3 mcg/kg q5–20 min
Remifentanil	Semisynthetic mu opioid receptor	Analgesia	Intravenous	0.1–0.15 mcg/kg/min infusion Supplemental boluses: 1- to 2-mcg/kg increments
Dexmedetomidine	α_2-Adrenergic agonist	Analgesia, sedation	Intravenous	0.5–1 mcg/kg over 10 min, then 0.2–1 mcg/kg/h. Titration should be slow, about every 30 min.

TABLE 7.4 Procedural Sedation and Analgesia Agents—Benefits and Adverse Effects

Agent	Route(s) of Administration	Onset (min)	Duration (min)	Advantages	Adverse Effects
Fentanyl	Intravenous, transmucosal	1–2	30–40	Rapid onset	Respiratory depression
		10–30	60–120	Short duration ↓Histamine release Minimal CV effects	Rigid chest syndrome
Morphine	Intravenous	5–10	240–360	Longer lasting	Hypotension Respiratory depression
Midazolam	Intravenous, intramuscular, oral, rectal, intranasal	1–2	30–60	Rapid onset	Respiratory depression
		15–30	60–90	Easy to titrate	
		10–30	60–90	Multiple routes	
		10–15	45–60		
Ketamine	Intravenous, intramuscular, oral, rectal, intranasal	1	15–45	Airway reflexes maintained	Emergence phenomena
		5	15–30	No respiratory depression	Emesis
		30–45	120–240	Predictable	Laryngospasm
		5–10	15–30		↑ICP and ↑IOP
		5–10	30–120		Hypertension Tachycardia
Etomidate	Intravenous	<1	5–10	Rapid onset Short duration Minimal CV effects Cerebroprotective	Respiratory depression Myoclonus Adrenal suppression
Propofol	Intravenous	<1	10–20	Rapid onset Short duration Antiemetic Cerebroprotective	Respiratory depression Hypotension Injection pain
Ketofol	Intravenous	1–3	10–15	Rapid onset Reduction in repeat dosing Reduction in emesis	Recovery agitation Respiratory depression Increased HR
Alfentanil	Intravenous	Immediate	10–30	Rapid onset Short duration Minimal CV effects	Respiratory depression and which can be increased with used as supplement to propofol
Remifentanil	Intravenous	3–6	5–10	Rapid onset Short duration Minimal CV effects	Respiratory depression
Dexmedetomidine	Intravenous	10–15 after initial loading infusion	5–8 half-life; 2-h terminal elimination	Short duration Minimal ventilatory effects	Bradycardia Hypotension

CV, Cardiovascular; *HR,* heart rate; *ICP,* intracranial pressure; *IOP,* intraocular pressure.

used as a sole inhalational PSA agent in children but is also frequently used as an analgesic adjunct to a sedating agent. Within this population, it has been found to be a safe and effective adjunct, especially in minor procedures utilizing local anesthesia.[12,13] However, it does require the appropriate scavenging equipment and safety protocols for providers utilizing these systems.

IV medications should be administered slowly to minimize hypotension or respiratory depression. It is important to allow adequate time between doses to achieve and assess peak effect before an additional dose is given. Lower initial doses should be chosen in sensitive patients or when drugs from multiple classes are being administered. Ketamine is considered the exception because, unlike the other agents described, it possesses a threshold response rather than an additive dose-response continuum. Smaller doses of ketamine cause analgesia and disorientation. Dissociation occurs when a dosage threshold of 1 to 1.5 mg/kg IV in adult patients or 1.5 to 2.0 mg/kg in younger pediatric patients is reached. Higher doses have not been shown to enhance or deepen its dissociative effects.

Opioids

Parenteral opioids are commonly used as analgesics before painful procedures are performed. For PSA, an opioid is rarely optimal as a single agent, and most emergency clinicians combine an opioid with a sedative-amnestic agent to balance sedation-amnesia and analgesia with the least likelihood of respiratory depression. One preferred method of establishing adequate analgesia for a painful procedure when using combined agents is addressing the pain requirements initially in the medication sequencing and then adding the anxiolytic for sedation.

The most commonly used opioids in the ED for PSA are fentanyl and morphine. These are often combined with benzodiazepines such as midazolam for moderate sedation and are used in smaller doses to provide analgesia during deep sedation with etomidate or propofol. An important consideration when co-administering opioids with other sedating medications is the combined effects on respiration and blood pressure. The pharmacokinetics of the opioid, specifically onset of action and maximal effect, should be considered during PSA. The respiratory depression created by any one agent is exaggerated when multiple agents are administered closely together. Patients who receive opioids less than 30 minutes before the start of a sedation have a small increased risk of adverse events, including hypoxemia.[14]

Fentanyl

Fentanyl has many advantages as an analgesic agent for PSA, given its rapid onset of action, short duration of activity, lack of histamine release, and favorable cardiovascular profile. Fentanyl rapidly crosses the blood-brain barrier and produces analgesia in as little as 90 seconds. Serum levels rapidly decline from peak concentrations because of extensive tissue uptake followed by hepatic metabolism. It has a duration of action of 30 to 40 minutes; the peak respiratory depressant effect of a single IV dose of fentanyl is 5 to 15 minutes following injection. These properties permit the titration of multiple small doses to the desired clinical effect. Because fentanyl readily creates a reservoir in adipose tissue, accumulated large doses may result in a progressively increased duration of effect, although this does not generally occur in doses less than 10 mcg/kg.

For deep sedation, a single dose of 0.5 to 2 mcg/kg of fentanyl is often given before the sedating agent. After adequate pain relief has been achieved, a smaller dose of a sedative agent may then be added and titrated to effect to minimize respiratory depression.

For moderate sedation, fentanyl can be titrated, along with a sedative agent such as midazolam, depending on whether the emergency clinician assesses that more sedation (midazolam) or analgesia (fentanyl) is required. Dosage should begin at 1 mcg/kg and be slowly titrated upward every 2 to 4 minutes, until the desired level of analgesia has been achieved. Sufficient analgesia for painful procedures under moderate sedation usually is accomplished with doses of 2 to 3 mcg/kg and under deep sedation with 1 to 2 mcg/kg. Lower doses should be used in older patients or when other CNS depressants have been previously administered (e.g., ethanol).

Respiratory depression is more likely at higher doses, when the drug is given rapidly, or when combined with other CNS depressants, such as benzodiazepines or alcohol. Other side effects may include vomiting and pruritus, although these are less common than with other opioids. Hypotension and bradycardia are rare but may occur with high doses. These adverse effects may be readily reversed by naloxone. Chest wall rigidity and glottic spasm, which may make ventilation difficult, are unique complications seen when high doses (anesthetic) of fentanyl (generally >7 mcg/kg) are given rapidly. These doses are not used for PSA. In the rare event of chest wall rigidity, symptoms may not reliably be antagonized by naloxone and may necessitate neuromuscular blockade and intubation to enable adequate ventilation.

Morphine

Morphine is poorly lipid-soluble and penetrates the blood-brain barrier more slowly after small bolus injections. Onset of action is 5 to 10 minutes, and a period of 10 to 30 minutes is required before its peak effects are seen, although, when used for PSA, morphine performs similarly to fentanyl, with comparable recovery times. A general starting dosage of 0.1 mg/kg is commonly used and then titrated to the desired effect, as with fentanyl. Morphine has much more histamine release and is more likely to produce hypotension, especially in preload-dependent patients. This fact, combined with its slow peak onset time, makes it a less ideal opioid for PSA use. It has potential similar to other opioids for producing respiratory depression, especially when used with other CNS depressants, such as benzodiazepines. Morphine undergoes hepatic metabolism to an active metabolite, followed by renal excretion. Insufficiency of either organ system may lead to increased serum half-life.

Benzodiazepines

Benzodiazepines are potent amnestic, hypnotic, and anxiolytic medications. They also have anticonvulsant and muscle relaxant properties but do not have analgesic effects. Because of this, they are commonly co-administered with an analgesic agent, such as fentanyl or morphine. They may be given IV, IM, via the oral (PO) or IN route or per rectum (PR) but are virtually always used via the IV route for PSA in adults. Midazolam is the most commonly used agent because of its favorable pharmacokinetics.

Midazolam

Midazolam has many benefits for PSA, given its rapid onset of action and short duration of action, compared with other benzodiazepines. Its stronger amnestic properties are an advantage over other benzodiazepines. The starting IV dose is 0.05 mg/kg. Children may need slightly higher doses. The onset of sedation is generally within 1 to 2 minutes, and the duration of action is 30 to 60 minutes. Alternatives to an IV route are often used in children, including IM, PR, IN, and PO routes. Midazolam has been shown to be an extremely safe and effective agent for PSA, both alone and when used in combination with fentanyl.

Side effects include dose-dependent hypoventilation and hypoxemia. Apnea and hypotension are uncommon but occur more often at high doses or when other CNS depressants, such as opioids, are used. Headache, nausea, emesis, coughing, and hiccups have been shown to occur, although rarely. Lower doses should be used for older adults or when other analgesics are given concomitantly. Prolonged effects may be seen in older adults or those with liver dysfunction owing to decreased hepatic or first-pass metabolism. Midazolam is highly lipophilic, and its effects may be significantly amplified in obese patients, resulting in an increased plasma half-life of up to 8 hours with high or repetitive doses. Chronic alcohol users who do not have liver dysfunction may require relatively high doses of midazolam to achieve the same clinical effects due to cross-tolerance.

Ketamine

Ketamine is a well-studied, safe, and predictable agent for use in PSA. It is a derivative of the street drug phencyclidine and is classified as a dissociative agent. It causes disruption between the thalamoneocortical and limbic systems, preventing the higher centers from perceiving visual, auditory, or painful stimuli. Because of this, ketamine leads to profound analgesia, amnesia, and catalepsis. It does not produce unconsciousness, but rather a trancelike state. Patients often experience nystagmus, roving eye movements, and random movements of the extremities, unrelated to painful stimuli. Parents who observe a procedure in which ketamine is used may be disturbed and should be forewarned.

Ketamine has several advantages over other PSA agents. The most notable are its profound analgesic effect and lack of significant respiratory depression. The protective airway reflexes, such as coughing, swallowing, and muscular tone of the tongue and pharynx, are preserved or slightly enhanced. Its use further leads to a blockade of catecholamine reuptake, and blood pressure is generally well supported. It also induces bronchial smooth muscle relaxation and is well tolerated in patients with reactive airway disease. It has a fast onset and offset and

is predictable when given by the IV or IM route. After administration, it is rapidly distributed and taken up by the cerebral tissues. The effects are maintained until the drug redistributes into the peripheral tissues and is metabolized by the liver. As a result, repeat doses are well tolerated in more prolonged procedures. However, emergency clinicians should be aware that repeat doses might lead to longer recovery times and an increased incidence of emesis.

Ketamine may be given by multiple routes but is administered almost exclusively by the IV route in adults. After an IV dose of 1 to 2 mg/kg, a dissociative state results in approximately 1 minute, with duration of action of approximately 15 to 30 minutes. Complete recovery generally requires 1 to 2 hours. Similar cataleptic results may be seen with IM administration of 4 to 5 mg/kg in approximately 5 minutes, with effects lasting 15 to 30 minutes. For pediatric sedation, ketamine is generally administered by the IV or IM route but may also be given via the PO, PR, or IN route. These other routes are infrequently used because of variable onset of action, slow offset, and less predictable results.

The most common side effect seen with ketamine is the emergence phenomenon seen in approximately 15% of patients. The symptoms are often mild and may include unpleasant vivid dreams with nighttime awakenings or hallucinations. Less than 1% to 2% of patients have significant emergence agitation. This is more commonly seen in female patients, adolescents or adults, and in those with underlying psychiatric disorders. There is minimal evidence to support concomitant use of midazolam or haloperidol to reduce the emergence phenomenon.[15] Given the short-term and relatively benign effects of emergence, coupled with the desire to minimize unnecessary polypharmacy during sedation, this practice is not recommended unless it is for the specific treatment of preprocedural anxiety.

Benzodiazepines are useful for treating an emergence phenomenon if it occurs during the recovery phase. Emesis is a common side effect, and concomitant dosing with an antiemetic has been shown to reduce its incidence. Other side effects seen with ketamine use during sedation include transient apnea and laryngospasm; these are rare but have been suggested to be more common with rapid IV administration or larger doses. Doses given slowly, at a rate of 0.5 mg/kg/min, may further limit these events.

Ketamine also stimulates tracheobronchial and salivary secretions. In any patient undergoing airway examination (e.g., flexible video laryngoscopy), pretreatment with glycopyrrolate, 0.01 mg/kg given 10 minutes before the ketamine, may be beneficial. Because airway reflexes are maintained, airway compromise generally is not a concern in other patients. Prophylactic pretreatment with anticholinergics is unnecessary, and this practice is no longer recommended. Post-recovery nausea and vomiting are also frequently seen but are generally short-lived and respond well to typical antiemetics, such as ondansetron.

In patients with known or suspected significant cardiovascular or coronary artery disease, the potential for ketamine to induce catecholamine-mediated hypertension and tachycardia should be considered when weighing the risks and benefits of its use. Finally, given its potential for increasing intraocular pressure as well as inducing nausea and vomiting, alternative agents should be considered when planning for sedation in patients with known or suspected ocular globe ruptures.

Sedative-Hypnotics

Etomidate. Etomidate is a short-acting, sedative-hypnotic agent structurally unrelated to the other PSA agents, with no analgesic properties. It exhibits a very rapid onset of sedation and hypnosis by enhancing neurotransmission at GABA receptors. Etomidate has been used for deep sedation because of its rapid onset, short duration of action and, most importantly, minimal effects on cardiovascular function.

After IV administration, sedation occurs in approximately 1 minute, and patients recover in 5 to 10 minutes. Etomidate induces deep sedation that borders on general anesthesia with higher doses and may be more challenging to titrate than the other sedative-hypnotics. It is generally administered IV, with an initial dose of 0.1 mg/kg given slowly over 1 to 2 minutes. Additional doses of 0.05 to 0.1 mg/kg may be administered every 2 to 3 minutes until the desired level of sedation has been achieved. Smaller initial doses should be considered when etomidate is combined with analgesic agents or given to older adults. Because it has little effect on the cardiovascular system and is cerebroprotective, it is an excellent choice for patients at risk for hemodynamic instability or increased intracranial pressure.

Adverse effects that may limit its usefulness include apnea, respiratory depression, myoclonus, nausea, and vomiting. These side effects are more common with rapid IV administration, when higher doses are used, and in older patients. Myoclonus is the most common side effect and is typically described as mild and brief but, at times, may be severe enough to interfere with the procedure. Although respiratory depression is rare and generally transient, few patients may require brief periods of assisted ventilation. Vomiting is unlikely with doses administered in the ED. Etomidate transiently suppresses endogenous glucocorticoid production by inhibiting 11-β-hydroxylase activity, but this is clinically irrelevant with a single sedating dose.

Propofol. Propofol is another short-acting sedative-hypnotic that is structurally unrelated to the other PSA drugs, with no analgesic properties. It has an extremely rapid onset, short duration of action, and predictable efficacy for inducing deep sedation.

Sedation clears quickly and completely after only a few minutes, permitting superior titration and earlier recovery and discharge. Propofol also possesses potent antiemetic properties and decreases intracranial pressure. Because of this, propofol is a highly desirable and widely used agent for deep sedation in the ED. It does not provide analgesia, however, and should be preceded by an opioid or regional nerve block for painful procedures. As with all sedative agents, the addition of an opioid may increase the risk of deeper than anticipated sedation, respiratory depression, apnea, and hypotension, and smaller starting doses are recommended.

Propofol is administered with an initial IV bolus dose of 1 mg/kg, although a lower starting dose of 0.5 mg/kg can be used for patients with poor cardiovascular reserve or those who received significant presedation opioid analgesia. Propofol is then titrated every 1 to 3 minutes by 0.25- to 0.5-mg/kg aliquots to the desired sedation level. Children may require slightly higher weight-adjusted doses than adults. The onset of sedation occurs in less than 1 minute, and patient recovery occurs in 10 to 20 minutes. For procedures lasting longer than this, additional boluses of 0.5 mg/kg may be administered, or a continuous infusion of 6 to 9 mg/kg/h may be titrated to the desired level of sedation.[16]

Adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Other agents, such as opioids, may intensify these effects. In most cases, apnea is transient, and patients do not experience a significant decrease in their oxyhemoglobin level before recovering their respiratory function. This underscores the value of supplemental oxygen administration during sedation. If the oxygen saturation decreases to the low 90s, the patient may require a brief period of assisted ventilation. Often, a simple jaw thrust can improve oxygenation and ventilation if there is evidence of acute airway obstruction due to relaxed glossal or hypopharyngeal musculature.

Propofol commonly results in a transient decrease in systolic and diastolic blood pressures, which rarely necessitates fluid administration and is well tolerated by healthy patients. The hypotensive effect is exaggerated in older adults and in patients with hypovolemia, and the initial dose of propofol should be reduced to 0.25 to 0.5 mg/kg in

such patients. Pain associated with propofol injection occurs in most patients and can be reduced with small infusions of IV lidocaine before its administration. Despite these concerns, propofol has been shown to be reliable and safe when used with proper monitoring in the ED setting.[16]

Ketamine plus propofol. Ketamine is commonly combined with propofol (known as "ketofol") for PSA. The two are thought to have synergistic effects that balance each other's deficits while decreasing the overall dose of propofol. Ketamine provides the analgesic effects that propofol lacks, while ketamine's cardiorespiratory stimulating effects provide a balance to the respiratory depression and hypotension caused by propofol. Also, vomiting and recovery hallucinations from ketamine are potentially mitigated by the antiemetic and hypnotic effects of propofol.

Though no study to date has shown definitive evidence to help providers choose between ketofol or propofol alone, a trend toward improved provider and patient satisfaction as well as decreased adverse respiratory events has been reported when using ketofol.[17–19] Patients receiving ketofol frequently require less redosing due to the extended effects of the ketamine to maintain a similar depth of sedation. Clinicians should consider this strategy in cases where propofol is desired as a sedative agent, but the patient may be at a higher risk of respiratory depression or hemodynamic instability.

Ultra–fast-acting agents. Emergency department experience with agents such as alfentanil and remifentanil for PSA is limited. Alfentanil is an ultra–short-acting analogue of fentanyl that has been described for PSA in the ED. This agent has been used in anesthesia and is safe and effective when added to propofol for PSA in the ED; the combination has not been shown to provide any additional benefit over more standard agents. Emergency clinicians should be aware that patients who receive supplemental alfentanil may require additional stimulation to induce ventilation during ED PSA and may have extended recovery periods. Although alfentanil is safe when added to propofol, the combination has not been shown to provide any additional benefit.

Remifentanil is an ester derivative of fentanyl and also has ultra–short-acting sedative and analgesic properties. Traditionally used in general anesthesia for sedation and analgesia, it has been described in brief reports for ED PSA. It has the advantage of being metabolized by esterases present in interstitial tissues and red blood cells, and therefore its metabolism is independent of hepatic or renal dysfunction. It can cause significant respiratory depression, but the patient is still often responsive to verbal commands.

Dexmedetomidine is a newer sedative agent for use in the ED. It acts as a highly selective α_2-adrenergic agonist with sedative, anxiolytic, and analgesic properties. Dexmedetomidine induces natural sleep to create its sedative effects. It has been mainly administered via infusion and has been used safely and successfully to facilitate flexible fiberoptic and video intubation, gastrointestinal (GI) procedures, and cardioversions. More intensive care unit (ICU) reports have demonstrated its use as a preferred sedative agent for mechanically ventilated patients. While high-quality ED data are lacking, a 2019 randomized control trial found that it outperformed a combination of midazolam and fentanyl in terms of the level of analgesia and onset of sedation, without increased adverse events, during procedural sedation for shoulder reduction.[20] Given its α_2-adrenergic effects, the primary side effects are bradycardia and hypotension.

Reversal and Rescue Agents. Careful titration of medications to the desired level of sedation is generally the goal in PSA. At times, however, unanticipated deeper levels of sedation may be reached, and respiratory depression or apnea may occur. Airway repositioning, supplemental oxygen, and bag-valve-mask ventilation may be required. If these periods are prolonged, partial or complete reversal of agents such as opioids or benzodiazepines may be necessary. Elective reversal of PSA after completion of the procedure is not recommended. When reversal agents exist, it is advised that they be immediately available for use during PSA if required.

Naloxone. Naloxone is a competitive antagonist of opioids and has been effectively used for the reversal of opioid-induced respiratory depression during PSA. It has a rapid onset of action and a mean plasma half-life of approximately 45 minutes, although its clinical effects last only 15 to 30 minutes. Resedation is generally not a problem for patients who have been given short-acting opioids such as fentanyl or morphine in doses recommended for PSA. Nevertheless, these patients should be observed for a minimum of 1 hour after the administration of naloxone. It is vital for patients who have received large doses of fentanyl to ensure that redistribution of fentanyl within the body does not result in a sedation relapse.

Naloxone may be administered via the IV, IM, subcutaneous, intranasal, or endotracheal route, but it is commonly given by IV. The smallest dose necessary to restore respiratory effort should be used because the reversal of the opioid's respiratory depressant effect is matched by reversal of the analgesia. The initial dosage depends on the patient and the specific goals desired. For partial reversal, titrated doses of 0.1 to 0.2 mg may be used every 1 to 2 minutes to desired effect. Complete reversal is rarely desirable and requires doses of 1 to 2 mg. Similar doses may be used for children. In opioid-dependent patients, these doses may precipitate an acute withdrawal state, and smaller initial doses should be considered. Large doses of naloxone may also make postprocedural pain challenging to control. Naloxone use has little risk, but pulmonary edema, seizure, and dysrhythmia rarely have been reported.

Flumazenil. Flumazenil is a competitive antagonist of benzodiazepines. Although it reverses the sedation effect of benzodiazepines, it is not as effective for reversing respiratory depression. In general, when oversedation occurs, brief support of ventilation permits the patient to recover sufficient spontaneous respiration without the need for reversal. Flumazenil has a rapid onset of action in 1 to 2 minutes, peak effect in 5 to 10 minutes, and individually variable clinical duration of 30 to 90 minutes. Continuous patient monitoring must be ensured when flumazenil is used to reverse respiratory depression associated with longer-lasting benzodiazepines because resedation is likely. Flumazenil has also been shown to be effective in reversing paradoxical excitement in children.

It is generally titrated in doses of 0.1 to 0.2 mg IV every 1 to 2 minutes to the desired effect. A maximum dose of 1 mg is generally sufficient. Common pediatric doses of 0.02 mg/kg are generally used, with a maximum of 0.2 mg. It should be used with extreme caution in patients with benzodiazepine dependence or a history of seizures because it may precipitate life-threatening status epilepticus refractory to standard treatments. Routine reversal of benzodiazepines is not recommended.

Drug Selection and Administration

When choosing a strategy for PSA, it is important to consider the type of procedure being performed (painful or not), length of the procedure, specific procedural requirements (anxiolysis vs. immobility), and whether sedation may need to be prolonged (Table 7.5). The need for IV access generally is an issue only in small children. Planned adjuncts, such as topical, local, or regional anesthesia, are also considered. Patient factors, including age, medications, alcohol and drug use, and comorbid conditions, are considered when selecting the agent and initial dose. Procedures necessitating sedation may be broadly divided into three categories—nonpainful procedures requiring immobilization (e.g., CT, MRI); low-pain, high-anxiety procedures (e.g., laceration repair, lumbar puncture); and highly painful, high-anxiety procedures (e.g., fracture or joint reduction, tube thoracostomy, abscess drainage, cardioversion).

TABLE 7.5 Adult Drug Selection Strategies

Procedure Type	Examples	Recommendation	Alternatives	Comments
Nonpainful	Radiologic imaging	Midazolam (intravenous)	Propofol (intravenous)	Midazolam has considerable support and safety.
Low pain, high anxiety	Central line placement Lumbar puncture	Midazolam (intravenous)	Propofol (intravenous) Ketamine (intravenous)	Analgesia may be accomplished frequently with local or topical agents.
High pain, high anxiety	Fracture or joint reduction Abscess drainage Burn debridement Cardioversion Chest tube placement	Midazolam + fentanyl (intravenous) Propofol + fentanyl (intravenous) Ketamine (intravenous, intramuscular)	Etomidate + fentanyl (intravenous) Propofol + ketamine (intravenous)	There are far more data supporting the safety of fentanyl and midazolam, although the other choices have significant support.

For brief nonpainful procedures requiring complete immobilization, IV midazolam and propofol are excellent choices, and etomidate is a reasonable alternative. For longer procedures, oral or rectal midazolam is reasonable.

For briefly painful procedures requiring minimal to moderate sedation, and when topical or local anesthetics may be used (e.g., to reduce a glenohumeral dislocation for which intraarticular lidocaine will be used), midazolam is a reliable and safe choice. IV propofol, preceded by a modest dose of fentanyl, is an excellent choice for brief painful procedures requiring deep sedation (e.g., cardioversion, joint reduction, other highly painful procedures). Ketamine by the IV and IM routes has been extensively studied in children and is highly effective, with a large margin of safety for children and adults. The same may be said for IV midazolam plus fentanyl in the adult and pediatric populations.

CHAPTER 7: QUESTIONS AND ANSWERS

1. When do most adverse events associated with emergency department procedural sedation occur?

- **a.** During the manipulation or intervention
- **b.** 5 to 20 minutes after the last sedative dose
- **c.** 20 to 30 minutes after the last sedative dose
- **d.** 30 to 60 minutes after the last sedative dose

Answer: b. High-risk times are 5 to 20 minutes after the last medication administration and at the completion of the procedure, when there is no longer a painful stimulus but the patient remains sedated.

2. Which of the following statements is most accurate regarding the use of fentanyl for procedural sedation?

- **a.** Chest wall rigidity is a common occurrence but may be reversed with naloxone.
- **b.** For deep sedation, a single dose of 1 to 2 mcg/kg IV is often given before sedation to achieve good pain control. A smaller dose of sedative agent may then be added and titrated to effect.
- **c.** Rapid IV administration is generally safe.
- **d.** Respiratory depression is less likely with fentanyl than with an equipotent dose of morphine.

Answer: b. For deep sedation, less respiratory depression is generally observed if a single pain-relieving dose of fentanyl is used before sedation, followed by small titrated doses of a sedative agent. Sufficient analgesia is generally attained with fentanyl dosages of 1 to 2 µg/kg IV. Rapid IV administration of large doses is more likely to precipitate respiratory depression or arrest. Chest wall rigidity is very rarely seen and generally only with large, rapid, IV boluses of more than 7 µg/kg IV. If severe chest wall rigidity syndrome is precipitated, it often requires paralysis to ventilate the patient adequately. It is not reversed with naloxone. Equivalent dosages of morphine show more histamine release and hypotension than fentanyl but have similar respiratory depression potential.

3. Which of the following statements regarding the use of ketamine is false?

- **a.** Benzodiazepine coadministration has not been shown to reduce the incidence of emergence phenomenon in children.
- **b.** Despite increased secretions, airway reflexes are generally well maintained.
- **c.** Hypotension is common.
- **d.** Profound analgesic and sedative effects occur with minimal respiratory depression.

Answer: c. Ketamine increases the release of catecholamines on administration and supports blood pressure well. It also decreases smooth muscle tone in the bronchial tree and may have a benefit in patients with reactive airways disease. Several studies have failed to show benefit with the concurrent administration of low to moderate dosages of benzodiazepines in preventing emergence phenomenon in children. These studies have shown a slightly increased risk of side effects. Their routine use is discouraged and should be reserved for the actual treatment of severe emergency phenomena.

4. Which of the following statements regarding the use of propofol is true?
   - **a.** Propofol has a long duration of action and provides significant analgesia.
   - **b.** Propofol has significant antiemetic properties.
   - **c.** Propofol increases intracranial pressure.
   - **d.** Propofol is well tolerated in volume-depleted patients.

Answer: b. Propofol is a short-acting, sedative-hypnotic, cerebroprotective agent with no analgesic but profound antiemetic properties. Its adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Preload-dependent patients are particularly susceptible to hypotension. Its combined use with ketamine is common. The two agents are thought to have synergistic effects that balance each other's deficits. Their combined use has been shown to improve provider satisfaction, sedation quality, and decrease emesis but has not been shown to be clinically superior to either agent used alone in regard to respiratory depression, airway complications, or improved recovery times.

5. Which of the following statements is true regarding the need for fasting before procedural sedation?
   - **a.** A 6-hour period of fasting is required after the ingestion of liquids or solids before procedural sedation.
   - **b.** Preprocedural fasting is required in all cases.
   - **c.** The recommendation for preprocedural fasting is based on controlled trials involving patients undergoing procedural sedation.
   - **d.** The risk of vomiting and loss of the airway protective reflexes is low during procedural sedation.

Answer: d. The American Society of Anesthesiologists (ASA) currently recommends a period of 2 hours after ingestion of clear liquids, 4 hours after ingestion of breast milk, and 6 hours after the ingestion of other liquids or solids before the performance of procedural sedation. This recommendation is based on expert consensus and has been extrapolated from data on patients receiving general anesthesia and manipulation of the airway during intubation and extubation. There are no published studies showing an increased risk of aspiration after a liquid or solid meal nor benefits of fasting before procedural sedation. Large studies have shown no clinically significant differences with airway complications, emesis, or other adverse effects among groups of patients stratified by their preprocedural fasting status. The risks of procedural sedation should be balanced against the risks of delaying a time-sensitive procedure.

8

Fever in the Adult Patient

Frederick C. Blum and Michelle H. Biros

KEY CONCEPTS

- Younger adults with fever usually have benign self-limited disease with low mortality. The challenge in this group is to identify rare causes of fever such as meningitis or septic condition when confronted with a predominance of self-limited viral and focal bacterial illness.
- For older patients (greater than 65 years), immune-compromised patients, or those with chronic disease, fever indicates a high risk for serious disease. Temperature elevation may be minimal in these patients, who often are unable to mount a significant febrile response to serious infection. Bacterial infection is the most common cause of fever in these patients. Three body systems—the respiratory tract, urinary tract, and skin and soft tissue—are the target for more than 80% of these infections.
- Atypical symptoms of illness are common in older febrile patients. Altered mental status, difficulty with ambulation, frequent falls, and general functional decline may be the only signs of serious infection in older patients.
- The white blood cell count is not a discriminatory test for patients with fever, may incorrectly indicate serious infection when none is present, or may be normal in the presence of life-threatening infection.
- In febrile patients with serious signs and symptoms, early empirical antibiotic therapy is often indicated as is treatment for severe acute respiratory syndrome (SARS)-2 coronavirus (COVID-19) and as appropriate influenza. The choice of antivirals, antibiotics, and other therapies are based on the likely cause of the fever as well as concomitant conditions, such as absolute neutropenia and end-stage renal disease.

FOUNDATIONS

Epidemiology

Morbidity and mortality rates from febrile illnesses vary dramatically with age. Younger adults with fever usually have benign self-limited disease with low mortality. The challenge in this group is to identify rare causes of fever such as meningitis or sepsis when confronted with a predominance of self-limited viral and focal bacterial diseases. Patients older than 65 years, or those with chronic disease who have fever, represent a group at higher risk for serious disease with higher rates of morbidity and mortality. For example, the incidence of community-acquired pneumonia is 2.6 times greater in adults 65 to 79 compared with younger adults, and in those over 79 years, it is seven times greater.[1] The relative mortality and morbidity rates for any given infection are much higher in the geriatric population; more than 50% of sepsis cases occur in patients older than 65 years, with a resultant mortality up to 26%.[2] Even viral illnesses that are generally not fatal, such as influenza or COVID-19, can be lethal in older adults.[3] Three body systems—the respiratory tract, urinary tract, and skin and soft tissue—are the target for more than 80% of these infections.[2]

Pathophysiology

Body temperature is normally controlled within a narrow range by the preoptic area of the hypothalamus. In the anterior hypothalamus, neurons directly sense the blood temperature. Temperature is subsequently controlled by a combination of vasomotor changes, shivering, changes in metabolic heat production, and behavioral changes. Normal temperature range is usually 36.0°C to 37.8°C (96.8°F to 100.0°F). There is a circadian rhythm within this range, with lower temperatures in the morning and higher temperatures in the late afternoon. Fever occurs when this normal range is reset to a higher value.

There is no consensus on the threshold core temperature that defines fever. The Centers for Disease Control and Prevention define fever as a core temperature greater than 38.0°C (100.4°F) in the absence of fever-reducing medication. However, most authorities agree that a core body temperature of 38.3°C (100.9°F) represents a significant fever. Fever is distinct from hyperthermia. Hyperthermia is an elevation of the temperature related to the inability of the body to dissipate heat; fever is the elevation of body temperature caused by thermoregulatory pathways in response to infections and certain other medical circumstances (Box 8.1). Most cases of temperatures higher than 41.0°C (105.8°F) are a result of hyperthermia, but febrile illness may also be considered.

Fever may be produced by a number of endogenous and exogenous substances termed *pyrogens*. Endogenous pyrogens include a variety of cytokines released by leukocytes in response to infectious, inflammatory, and neoplastic processes. Exogenous pyrogens include a large number of bacterial and viral products and toxins. Toxins induce fever by stimulating cells of the immune system to release endogenous pyrogens. These cytokines, such as interleukin-1 (IL-1), IL-6, tumor necrosis factor, and interferon, travel to the hypothalamus and induce the production of prostaglandin E_2 (PGE_2).

PGE_2 raises the set point of the temperature range by a combination of effects, including peripheral vasoconstriction, increased metabolic heat production, shivering, and behavioral changes that conserve heat. Fever is maintained as long as the levels of endogenous pyrogens and PGE_2 are high. There is also a variety of other humoral and neural pathways that modulate this basic response. Cyclooxygenase

BOX 8.1 Differential Diagnosis—Noninfectious Causes of Fever

Critical Diagnoses
Acute myocardial infarction
Pulmonary embolism or infarction
Intracranial hemorrhage
Cerebrovascular accident
Neuroleptic malignant syndrome
Thyroid storm
Acute adrenal insufficiency
Transfusion reaction
Pulmonary edema

Emergent Diagnoses
Congestive heart failure
Dehydration
Recent seizure
Sickle cell disease
Transplant rejection
Pancreatitis
Deep vein thrombosis

Nonemergent Diagnoses
Drug fever
Malignancy
Gout
Sarcoidosis
Crohn disease
Postmyocardiotomy syndrome

inhibitors, such as aspirin, decrease fever by blocking the production of PGE_2. Age, malnutrition, immunosuppression, and chronic disease may also blunt the febrile response.

Moderate elevations of the body temperature may serve to aid host defenses by increasing chemotaxis, decreasing microbial replication, and improving lymphocyte function. Elevated temperatures may directly inhibit the growth of certain bacteria and viruses.[4] Fever also results in certain increased physiologic effects to the host, including increased oxygen consumption, metabolic demands, protein breakdown, and gluconeogenesis. These effects are particularly problematic in older adults who typically have a smaller margin of reserve for any given body system. Older adults have a blunted febrile response and a lower baseline temperature than younger adults. Some authorities therefore suggest that the threshold for the definition of fever should be considered lower (i.e., 100.4°F) in frail older adults than in younger persons.[5]

The therapeutic benefit of treating febrile patients with antipyretics is controversial and may depend on individual patient factors. For example, some studies indicate that febrile intensive care unit (ICU) patients with sepsis have reduced mortality if allowed to maintain an elevated temperature but that this may not be the case for febrile ICU patients without sepsis.[6] A recent meta-analysis of antipyretic treatment of septic patients showed no mortality benefit at 28 days, but early mortality (14 days) was significantly lower in febrile patients treated with antipyretic therapies.[3] Treatment of fevers makes patients feel more comfortable, however, and because of the detrimental effects of the increased metabolic demands caused by high fevers, it is recommended that patients with temperatures greater than 41°C be treated with antipyretics.

The initial step in the process of fever is resetting the thermostatic set point in the hypothalamus to a higher temperature while the actual body temperature remains normal. This mismatch of the thermostat with the "sensed" body temperature causes the patient to feel chilled (chills). The patient remains chilled until the body temperature rises to near the (elevated) hypothalamic set point. At this point, the patient no longer experiences chills and feels euthermic—but may feel fatigued or ill—but, to the caregiver, the skin temperature or thermometer reading is now elevated. The sequence of chills followed by febrile illness is the basis of the (incorrect) popular belief that getting chilled leads to infection, such as pneumonia. When the thermostatic set point is reduced to normal, the patient suddenly feels hot and sweats until the body temperature falls to match the set point, now normal.

Diagnostic Approach

Differential Considerations

The complete differential diagnosis for the patient in the emergency department (ED) with fever is extensive. The major infectious and noninfectious causes are summarized in Table 8.1 and Box 8.1, respectively. The vast majority of serious causes are infectious in origin. Immediate threats to life are from decompensated shock (usually septic), respiratory failure (related to shock or pneumonia), or central nervous system infection (meningitis). Some critical noninfectious causes of fever also exist (see Box 8.1), but these are relatively rare and frequently do not occur with fever as the primary symptom.

A primary medical decision in acute febrile illness is based on assessment of the patient's stability (Fig. 8.1). Patients with life-threatening signs and symptoms, including significant alterations in mental status, respiratory distress, and cardiovascular instability require rapid resuscitation. Prompt airway management and initiation of monitoring, intravenous access, fluid resuscitation, supplemental oxygen, and respiratory support are often necessary, despite incomplete information concerning the cause of the fever. Sustained temperatures above 41.0°C are rare but can be damaging to neural tissue and require rapid cooling (e.g., misting, fans, cooling blankets).

In the younger, otherwise healthy patient with fever, immediate threats to life such as toxic or septic shock, meningitis, meningococcemia, and peritonitis should be considered and treated empirically. In older, chronically ill patients with fever, most of the serious illnesses originate from infections in the respiratory tract, genitourinary tract, and skin and soft tissues. Meningitis, although less common, can also be a significant cause of morbidity and mortality in this group.

Pivotal Findings

Although the differential diagnosis of fever is broad, most of the treatable causes are of infectious origin. Most of these causes of fever may be diagnosed by careful history and physical examination. Age and the presence of underlying medical conditions can substantially influence the evaluation and subsequent decision making regarding management.

An approach to the diagnosis and management of the healthy, otherwise stable adult patient with acute febrile illness is shown in Fig. 8.2. In younger and otherwise healthy adults, self-limited, localized bacterial infections or benign systemic viral infections are usually the cause of fever. Assessment of risk for acute viral illness, such as influenza and COVID-19, should be made based on comorbid conditions and diagnostic testing and subsequent treatment based on overall risk for complications. The challenge with this group is to identify the rare life-threatening illness, such as meningococcemia, meningitis, or systemic methicillin-resistant *Staphylococcus aureus* (MRSA) infection.

In the older or chronically ill population, fever is frequently a sign of severe illness. Usually, the cause is infectious. In addition to the most common infectious causes of illness (e.g., respiratory, urinary, or skin sources), infections such as meningitis, cholecystitis, appendicitis, and

TABLE 8.1 Differential Diagnoses—Infectious Causes

Organ System	Critical Diagnoses	Emergent Diagnoses	Nonemergent Diagnoses
Respiratory	Bacterial pneumonia with respiratory failure	Bacterial pneumonia, peritonsillar abscess, retropharyngeal abscess, epiglottitis	Otitis media, sinusitis, pharyngitis, bronchitis, influenza, tuberculosis, COVID-19
Cardiovascular		Endocarditis, pericarditis	
Gastrointestinal	Peritonitis	Appendicitis, cholecystitis, diverticulitis, intraabdominal abscess	Colitis or enteritis
Genitourinary		Pyelonephritis, tubo-ovarian abscess, pelvic inflammatory disease	Cystitis, epididymitis, prostatitis
Neurologic	Meningitis, cavernous sinus, thrombosis	Encephalitis, brain abscess	
Skin and soft tissue		Cellulitis, infected decubitus ulcer, soft tissue abscess	
Systemic	Sepsis or septic shock, meningococcemia	Influenza, COVID-19	

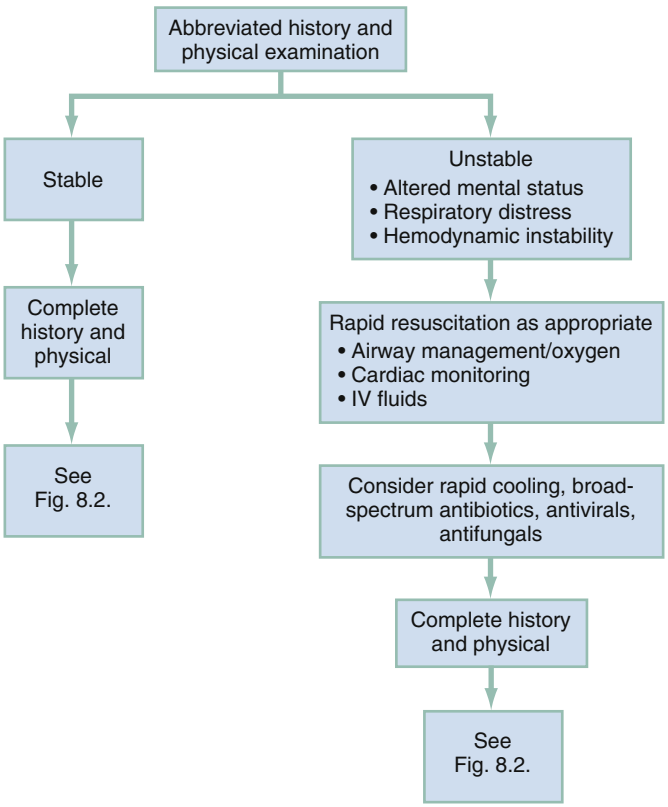

Fig. 8.1 Approach to the Critically Ill Febrile Adult Patient. *IV,* Intravenous.

diverticulitis are considered and may cause atypical signs and symptoms in older adults or immunosuppressed patients. In these populations, subtle changes in behavior may be the only sign of severe infection. Abnormal vital signs, especially significant tachypnea and hypotension, may portend a complicated and severe course.

Symptoms

The onset of the fever, its duration and magnitude, and any associated symptoms help identify possible causes and severity of illness. Localizing symptoms such as dysuria or productive cough are especially helpful. The timing of the fever and its patterns may implicate certain diseases (e.g., malaria). Recent or remote travel, chronic illnesses, past surgeries, hospitalizations, and treatment modalities may raise the suspicion of exotic or nosocomial infections. The presence of prosthetic heart valves or any indwelling device may be critical to the diagnosis. Exposure to other ill persons may impact differential considerations and management.

Community-acquired MRSA is a common cause of skin infections, as recognized in the last decade. Recently, gram-negative and mixed pathogen (gram negative and gram-positive) infections have increased; consideration of this may alter management when antibiotics are being considered for skin and soft tissue infections (SSTIs).[7] For all skin infections, it is important to seek a history of skin infections in close family members or other close contacts, as exposure to a colonized patient is a risk factor for development of SSTIs.

Also important in the medical history is a list of all the patient's medications, including any antipyretic medications, as recent use of antipyretic medications can mask a fever in a patient presenting to the ED. Family members are frequently an important source of information for older and very young patients.

Atypical symptoms of illness are common in older patients. Pneumonia or urinary tract infection in the older patient may be heralded only by a change in mental status, difficulty ambulating, or some other functional decline. Dysuria, frequency, and flank pain often are absent entirely in older adults with a urinary tract infection. Patients with pneumonia may inconsistently demonstrate productive cough or shortness of breath. Other frequent but nonspecific symptoms include anorexia, weight loss, weakness, lethargy, nausea, and recurrent falls. A history of cancer with recent chemotherapy or radiation therapy may be a clue to leukopenia or another immunosuppressed state. In older patients or those who have cognitive impairment, assessment of the patient's baseline mental and physical function often relies on the reports of others who know the patient well.

Signs

The presence and magnitude of fever are important elements of the examination, but the older, very young, or chronically ill patient may not mount a febrile response to significant infection. Temperatures may fluctuate and rechecks may be necessary. Although the most accurate measure of core body temperature is thought to be via the thermistor of a pulmonary artery catheter, central measurements of temperature are usually impractical in the ED; rectal temperature measurements or, when a Foley catheter is indicated, bladder thermistors are the most practical and accurate.[8] Axillary and tympanic temperatures may be unreliable compared to rectal temperature measurements, and may be altered by external conditions.

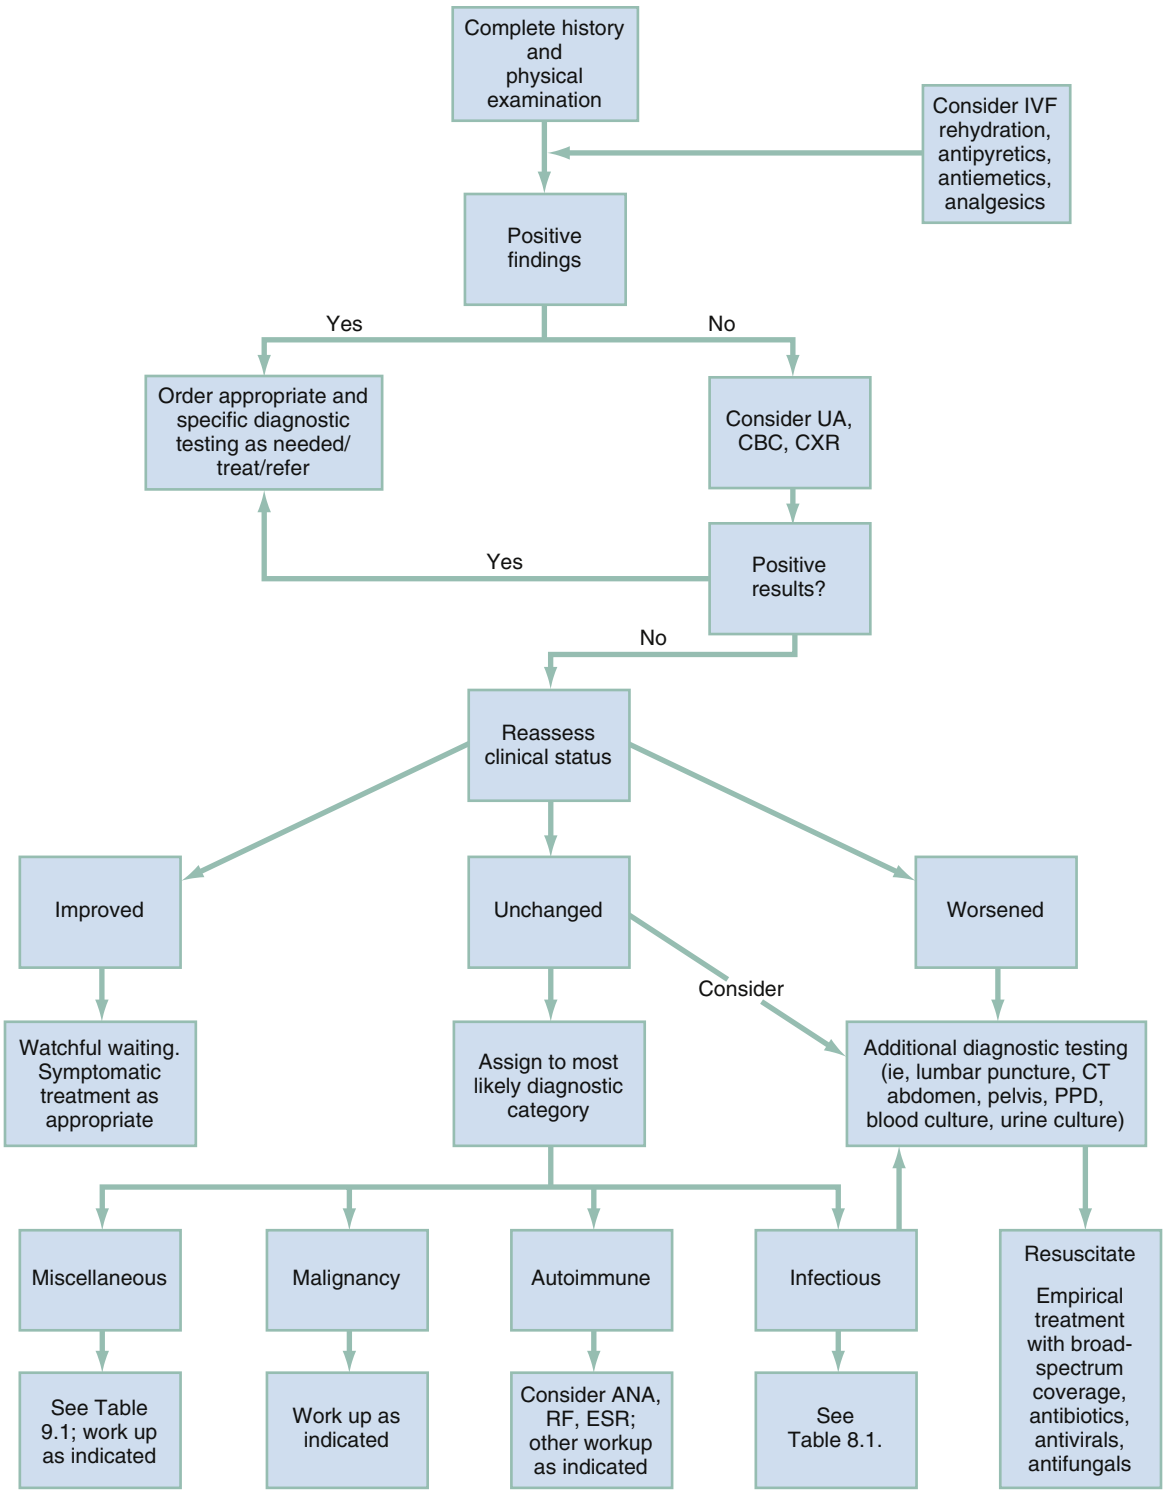

Fig. 8.2 Approach to the Stable Adult With an Acute Febrile Illness. *ANA,* Antinuclear antibody; *CBC,* complete blood count; *CT,* computed tomography; *CXR,* chest x-ray; *ESR,* erythrocyte sedimentation rate; *IVF,* intravenous fluids; *PPD,* purified protein derivative; *RF,* rheumatoid factor; *UA,* urinalysis. (Modified from Holder BM, Ledbetter C. Fever of unknown origin: an evidence-based approach. *Nurse Pract.* 2011;36:46–52.)

Oral temperatures may be transiently distorted by recent ingestion of hot or cold liquids, smoking, or hyperventilation. Rectal temperatures are typically 0.7°C to 1.0°C higher than oral temperatures.[8]

Fever is inconsistently associated with tachycardia and tachypnea. As a rough estimate, the heart rate may increase by 10 beats/min for each 0.55°C- (1°F-) rise in temperature. Relative bradycardia may be caused by medications such as beta blockers, but also can suggest factitious or drug-related fevers, typhoid fever, brucellosis, or leptospirosis. Frank bradycardia may occur with rheumatic fever, Lyme disease, viral myocarditis, and endocarditis. The respiratory rate may increase 2 to 4 breaths/min/°C in febrile illness. More significant tachypnea may be caused by respiratory infection or the acidosis related to shock.

In many patients, the examination is directed by the patient's localization of symptoms. The head and neck examination may identify treatable foci of infection, such as otitis media, sinusitis, pharyngitis, peritonsillar abscess, retropharyngeal abscess, and dental infections. A muffled, so-called hot potato voice with severe sore throat may be a clue to adult epiglottitis or upper airway abscess. Fundoscopy rarely may reveal evidence of disseminated candidiasis, miliary tuberculosis, endocarditis, toxoplasmosis, or leukemia.

The neck is examined for lymphadenopathy, masses, or thyroid pathology (thyromegaly or mass). Nuchal rigidity or pain on flexion of the neck is a useful sign for meningismus if present, but this may not be a prominent finding in many patients, particularly the very young or debilitated patient, even if meningitis is present.

The lungs are examined for rales, pleural rubs, or dullness to percussion. Localized rales or rhonchi may be subtle clues to the presence of pneumonia. The presence of concomitant chronic obstructive pulmonary disease or congestive heart failure, as well as poor respiratory effort, may hamper the diagnosis of pneumonia in older adults. The heart is examined for pericardial rubs or new murmurs.

The abdominal examination may be deceptively benign in older patients, patients with diabetes, or patients taking immunosuppressive drugs or steroids. When indicated by history or other findings, a rectal examination should be performed to check for evidence of enteritis, perirectal abscess, or prostatitis. The external genitalia examination may reveal evidence of a Bartholin abscess, urethral or vaginal discharge, or evidence of epididymitis or orchitis. In women, symptoms of lower abdominal pain, vaginal discharge, and dyspareunia suggest the need for a pelvic examination to evaluate for pelvic inflammatory disease or tubo-ovarian abscess.

The skin and extremities should be evaluated for rash, petechiae, joint inflammation, or evidence of soft tissue infection. In the absence of trauma, tenderness over the long bones or the spine may be evidence of osteomyelitis or neoplastic processes. Older adults and bedridden patients should be checked for the presence of pressure sores or decubitus ulcers.

Ancillary Testing

Ancillary testing is directed by the history and physical examination. The two most useful ancillary tests, especially in older patients, are urinalysis and chest radiography. Chest radiographs are often helpful in the diagnosis of pulmonary infection but may be difficult to interpret in the patient with concurrent chronic obstructive pulmonary disease, congestive heart failure, dehydration, or other chronic lung disease. Urinalysis, although not foolproof, is highly accurate for detecting urinary tract infection, especially in men. Although the white blood cell count has often been used in the evaluation of febrile patients, it lacks the degree of sensitivity and specificity to be of discriminatory value. The white blood cell count may incorrectly indicate serious infection when none is present or may be normal in the presence of life-threatening infection.[5] Other indirect tests of infection and inflammation, such as the erythrocyte sedimentation rate, C reactive protein, and procalcitonin can provide useful information but are plagued with irregular sensitivity and poor specificity. Gram staining of appropriate specimens may be helpful, and cultures may be ordered, although the results do not often influence emergency evaluation and treatment. With the broad scope of causes of SSTI (MRSA, gram negative, and mixed organism infections), it has become increasingly important to obtain cultures from soft tissue skin abscesses in patients considered at risk for significant SSTI.[8] In older or chronically ill patients with acute fever of unclear origin, blood and urine cultures are frequently appropriate. Outpatient blood cultures should rarely be done. Polymerase chain reaction (PCR) testing for respiratory illness including COVID-19 may be done based on the clinical presentation. A patient ill enough to require blood cultures from the ED generally requires hospitalization and empirical antibiotic coverage. Cerebrospinal fluid evaluation should be considered when mental status changes are evident, or if headache, meningismus, or other unexplained neurologic symptoms are present and cannot be clearly accounted for by infection outside the central nervous system. Thyroid function studies may be helpful when thyroid storm is suspected. Arterial or venous blood gas studies may help identify patients with critical disease who require prompt treatment.

Plain films of the abdomen are rarely indicated. Abdominal computed tomography (CT) is helpful if appendicitis, diverticulitis, cholecystitis, intestinal obstruction, perforated hollow viscus, or intraabdominal abscess is suspected. Ultrasonography may be helpful in the patient with potential cholecystitis.

Cranial CT scanning may be indicated before lumbar puncture in febrile patients with focal neurologic findings or a suspected embolic source, such as endocarditis, to exclude mass lesions such as a tumor or brain abscess. Neither CT scanning nor lumbar puncture should delay administration of antibiotics in patients with suspected meningitis.

Diagnostic Algorithm

The differential diagnoses of infectious causes of fever are summarized in Table 8.1. The differential diagnoses of noninfectious causes of fever are listed in Box 8.1. However, differences in patient characteristics can cause different manifestations of the same illness. For example, pneumonia or a urinary tract infection manifests in and is tolerated by an 80-year-old very differently from that of a young adult. A careful history and physical examination, along with strategic ancillary testing, will allow the emergency clinician to determine when a critical condition is present and will determine the operational tempo of subsequent evaluation and treatment.

EMPIRICAL MANAGEMENT

Temperatures higher than 41.0°C can result in damage to neuronal tissue and require prompt and vigorous treatment with antipyretics and external cooling measures. Heat illness, a spectrum of disorders due to environmental heat exposure, can result in extreme hyperpyrexia and lead to heat stroke. Urgent external cooling with fans, mist, and other modalities are required and are discussed in Chapter 129. Although the therapeutic benefit of lowering fever is controversial, it does not appear harmful and patients often feel better when their temperature is lowered.[4,6-9] Rectal and intravenous acetaminophen is as effective as oral acetaminophen and may be used in patients who are unable to take oral medication.

Patients with signs and symptoms of sepsis require prompt evaluation and treatment. Sepsis is characterized by the systemic inflammatory response syndrome (SIRS) to an infectious threat. SIRS is defined by the presence of two or more of these criteria: temperature greater than 38°C or less than 36°C; heart rate greater than 90 beats/min; respiratory rate greater than 20 breaths/min or $Paco_2$ less than 32 mm Hg; and leukocyte count greater than 12,000/μL, less than 4000/μL, or more than 10% immature (band) forms. The reliability of SIRS has increasingly been questioned and low specificity of SIRS has limited its utility as a screening tool for sepsis. Patients with sepsis or septic shock require vigorous management, including intravenous fluid administration and prompt antibiotic therapy. The current guidelines utilize the quick Sequential Organ Failure Assessment (qSOFA) (respiratory rate of 22/min or greater, altered mentation, or systolic blood pressure of 100 mm Hg or less) as a rapid ED bedside assessment to identify patients with two or more of these features as more likely to have poor outcomes (see Chapter 127).[10]

Patients with evidence of respiratory failure from shock or pneumonia often need ventilator support. Soft tissue infections of the head and neck may compromise the airway because of mechanical obstruction. These may require acute intervention to provide a secure airway.

In many cases, early empirical antibiotic therapy is appropriate. The choice of antibiotics is based on the likely cause of the fever, as well as concomitant conditions, such as absolute neutropenia and end-stage renal disease. If a specific infection is subsequently identified, antibiotic therapy should be specific to that infection. With clinically severe illness in the absence of a clear source of infection, broad-spectrum coverage of gram-positive and gram-negative aerobic and anaerobic bacteria is indicated. In acutely ill febrile patients, especially those who are immunocompromised, antiviral and antifungal treatment are also frequently indicated.

DISPOSITION

Localized bacterial infections can often be treated with outpatient oral antibiotics. Relatively young, healthy patients with systemic viral illness can also be treated on an outpatient basis. These illnesses are often accompanied by vomiting and poor oral intake, and treatment in the ED with antipyretics, anti-nausea medications, and intravenous hydration may help prepare the patient for a successful outpatient course.

When no clear infection is identified in febrile older patients or those with chronic illness, such as diabetes or chronic renal failure, admission to the hospital may be necessary to elucidate the possible causes and clinical course. In this subset of patients, a diligent search for evidence of bacterial infection is required. Also, admission to an inpatient unit or ED observation unit may be advisable when fever or other systemic symptoms accompany an SSTI infection. In patients with unexplained severe febrile illness, blood and urine cultures and broad-spectrum antibiotics are indicated to treat possible life-threatening infection until a specific disease process or pathogen is identified. Indwelling devices, such as percutaneous intravenous access ports, frequently require culture and may need to be removed. Neutropenic patients with fever require prompt treatment with broad-spectrum parenteral antibiotics, pending results of cultures. Patients with unstable vital signs or life-threatening infections may require admission to a special care unit if they cannot be adequately stabilized in the ED before admission.

CHAPTER 8: QUESTIONS AND ANSWERS

1. Which three body systems are the target of more than 80% of bacterial infections in patients older than 65 years?
   - **a.** Central nervous system, respiratory system, genitourinary system
   - **b.** Central nervous system, respiratory system, skin and soft tissue
   - **c.** Central nervous system, urinary system, skin and soft tissue
   - **d.** Respiratory system, genitourinary system, skin and soft tissue

Answer: d. Patients older than 65 years who present with fever represent a group at high risk for serious disease. Morbidity and mortality in this group are significant. Between 70% and 90% are hospitalized, and 7% to 9% die within 1 month of admission. Infection is the most common cause of fever in these patients, and most of these infections are bacterial in nature. More than 80% of these infections originate from the respiratory system, genitourinary system, and skin and soft tissue.

2. A 65-year-old man presents after "briefly collapsing" at a nearby bus stop. On arrival, he is confused, opens his eyes spontaneously, and follows simple commands. A medical information card found in his wallet reveals a history of hypertension and gout. Vital signs reveal a blood pressure of 95/50 mm Hg, heart rate of 95 beats/min, respiratory rate of 24 breaths/min, temperature of 41.5°C, and arterial oxygen saturation (Sao_2) of 95%. His finger-stick glucose level is normal. Pertinent physical examination findings include pallor, dry mucous membranes, Glasgow Coma Score (GCS) of 14, and ataxia. An intravenous bolus of normal saline is started. Which of the following is the most appropriate next step in the management of this patient?
   - **a.** Administer broad-spectrum antibiotics.
   - **b.** Mist the patient with water and place him in front of a fan.
   - **c.** Obtain a head CT scan.
   - **d.** Perform a lumbar puncture.

Answer: b. In terms of initial resuscitative efforts, the most significant finding in this patient is a temperature of 41.5°C. Almost all cases of temperatures higher than 41.0°C (107°F) are due to hyperthermia rather than to fever. Sustained temperatures higher than 41.0°C (106°F) are rare but can be damaging to neural tissue and require rapid, aggressive, cooling measures, such as misting the patient with tepid water and placing him or her in front of a fan, immersion in cool water, or application of cooling blankets. Each of the other four options could potentially be performed during this patient's stay in the emergency department; however, the immediate focus is on temperature reduction.

3. Of the cases of functional decline in nursing home patients, 75% are due to which of the following?
   - **a.** Congestive heart failure
   - **b.** Coronary artery disease
   - **c.** Dementia
   - **d.** Infection

Answer: d. Of the cases of functional decline (e.g., difficulty ambulating, anorexia, decreased activity, new urinary incontinence) in nursing home patients, 75% are due to infection.

4. An 85-year-old man is brought to the emergency department (ED) by his daughter, who says that he has had a fever and has been eating less than normal for 2 days. The patient has a history of hypertension and severe dementia. He can provide no useful information. His present temperature was recorded by the triage nurse to be 38.5°C (101°F). The remainder of his vital signs are within normal limits. The only abnormal findings on physical examination are slightly dry mucous membranes, confusion, and poor social interaction. The daughter confirms his mental status to be at baseline. Which of the following are the two most important ancillary tests to perform in this patient?
   - **a.** Blood culture and urine culture
   - **b.** Urinalysis and chest radiography
   - **c.** Urinalysis and white blood cell count
   - **d.** White blood cell count and chest radiography

Answer: b. The two most important ancillary tests in the evaluation of fever in the adult patient, and especially in older patients, who frequently have atypical presentations, are urinalysis and chest radiography. Chest radiographs are often helpful in the diagnosis of pulmonary infection but may be difficult to interpret in the patient with chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), or other chronic lung disease. Urinalysis, although not foolproof, is highly accurate for urinary tract infection, especially in men. Although the white blood cell count is almost universally used in the evaluation of febrile patients, it lacks sufficient sensitivity and specificity to be of discriminatory value. Cultures are ordered in selected patients; however, the delay in obtaining results precludes any influence in emergency evaluation and treatment. Other tests that have relevance in select patients with fever include Gram staining, cerebrospinal fluid (CSF) analysis, thyroid function studies, ultrasonography, and computed tomography (CT) of the abdomen or head.

9

Weakness

Andrew J. Eyre

KEY CONCEPTS

- Weakness is a common complaint among emergency department (ED) patients, with a preponderance in elders and those with chronic disease, and therefore may require a broad approach to investigating underlying causes.
- Patients may use the term weakness to reflect a variety of vague symptoms including decreased motor strength, fatigue, poor energy, dyspnea, or even depression.
- Global weakness is typically caused by a systemic condition while a focal neurologic deficit or pattern can often be traced to a specific lesion within the central or peripheral nervous systems.
- Although not always detectable in the acute period, lesions to the upper motor neurons (UMNs) tend to produce signs that include spasticity to extension in the upper extremities, spasticity to flexion in the lower extremities, hyperreflexia, pronator drift, and Hoffmann and Babinski signs.
- Lesions to lower motor neurons (LMNs) typically result in flaccidity, decreased reflexes, fasciculations, or muscle cramps.

FOUNDATIONS

Epidemiology

Weakness, a common ED complaint, can reflect a vast array of pathology with varying degrees of severity. Patients may use to the term *weakness* to describe either focal or systemic complaints and often use the broader description of weakness to convey otherwise vague or subjective symptoms, such as fatigue, lethargy, or general malaise. As a result, weakness as chief or associated complaint can be quite challenging, both from a diagnostic and therapeutic perspective.

Up to 10% of ED visits are for generalized weakness, with a preponderance of the complaint among elders. Over half of these patients are identified as having a serious condition, and the diagnoses span cardiovascular, hematologic, neurologic, toxicologic, psychiatric, endocrine, pulmonary, metabolic, and infectious causes.[1]

This chapter focuses on the initial evaluation of the generalized complaint of weakness and the specific evaluation of acute neuromuscular weakness. The latter may be focal or generalized and may originate in central or peripheral nerves, the neuromuscular junction (NMJ), or myofibers themselves. Other chapters in this text provide additional information regarding the diagnosis and management of specific neurologic causes of weakness including the brain and cranial nerves (CNs; see Chapter 91), spinal cord (see Chapter 92), and peripheral nerves (see Chapter 93), as well as neuromuscular disorders (see Chapter 94).

Pathophysiology

There are many diagnostic considerations for the patient presenting with diffuse weakness (Box 9.1). While a singular cause of weakness may be identified, elders and patients with multiple medical problems may have numerous factors contributing to weakness. Alterations in plasma volume, electrolyte imbalance, anemia, decreased cardiac function, drop in systemic vascular resistance, increased metabolic demand (infection, toxin, endocrinopathy), and mitochondrial dysfunction (severe sepsis) can all produce non-localized weakness. A global depression in central nervous system (CNS) activity from sedative effects or stimulant withdrawal can also present as generalized weakness. Focal weakness confined to one area in the face or body (left, right, distal, or proximal) typically indicates a localized neurological issue corresponding to a specific area of the central or peripheral nervous systems (PNSs).

Lesions involving the motor areas of the cerebral hemispheres may cause unilateral weakness, and lesions in the cerebral cortex outside the motor area may cause receptive or expressive aphasias and complex cerebral motor deficits such as apraxia. Peripherally, the spinal nerves extend from the anterior horn of the spinal cord and represent the anatomic origins of the lower motor neuron (LMN). The neuroanatomic distinction between LMNs and upper motor neurons (UMNs) is essential in localizing lesions.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis for generalized weakness is broad. Consideration of systemic causes such as infectious, neurological, toxicologic, metabolic, and physiological causes is important (see Box 9.1). The first step is to address potential life threats, major systemic conditions, and disorders requiring emergent intervention. A detailed history should elucidate the nature, onset, and progression of symptoms, exacerbating or alleviating factors, and fluctuations in severity that may help discern if weakness is a result of cardiovascular disease, pulmonary insufficiency, metabolic disturbance, concurrent infection, toxic ingestion, medication imbalance, or malignancy. Medication reactions or interactions are an important consideration in patients taking multiple medications. A thorough review of systems should also be performed to identify associated signs or symptoms that may help to form a unifying diagnosis. For example, a review of systems might reveal orthopnea and symptoms of congestive heart failure in the fatigued patient with significant cardiac disease, chronic blood loss in the anemic patient, or incontinence in an older adult with a urinary tract infection. Elders often present with less localizing symptoms of infection, such as dysuria or frequency in the case of a possible urinary tract infection, and require a broad diagnostic approach, including laboratory and radiological studies.

Vital sign abnormalities, including bradycardia, tachycardia, tachypnea, fever, hypothermia, or hypotension should prompt immediate intervention and a search for a systemic cause of the weakness. A

BOX 9.1 Nonneurologic Weakness

- Alterations in plasma volume (dehydration)
- Alterations in plasma composition (glucose, electrolytes)
- Derangement in circulating red blood cells (anemia or polycythemia)
- Decrease in cardiac pump function (myocardial ischemia)
- Decrease in systemic vascular resistance (vasodilatory shock from any cause)
- Increased metabolic demand (local or systemic infection, endocrinopathy, toxin)
- Mitochondrial dysfunction (severe sepsis or toxin-mediated)
- Global depression of the central nervous system (sedatives, stimulant withdrawal)

general detailed physical examination, including evaluation of the skin and mucous membranes, may provide evidence of systemic disease. A cardiovascular examination can give the clinician a sense of the adequacy of circulation. A carefully performed neurologic examination is important to determine the occasionally subtle presentations of focal central or PNS lesions.

If history, physical examination, and ancillary testing do not identify a systemic cause of weakness, the investigation should broaden to include consideration of neural or primary muscular causes for weakness. Focal causes of weakness include central and peripheral neurological disease. Conditions involving UMNs tend to produce signs that include spasticity to extension in the upper extremities, spasticity to flexion in the lower extremities, hyperreflexia, pronator drift, and Hoffmann and Babinski signs. UMN signs signify a lesion within the cerebral cortex or corticospinal tract (CST) of the brainstem or spinal cord. Although these findings are not always detectable in the acute period, the presence of even one of them suggests pathology within the CNS. Weakness caused by LMN dysfunction is often accompanied by flaccidity, decreased reflexes, fasciculations, or muscle cramps. Lesions in the anterior horn of the spinal cord and its axonal extensions at the nerve root and peripheral nerve produce these findings.

Diagnostic Algorithm

Critical and Emergent Diagnoses

Fig. 9.1 describes the approach to evaluating acute weakness. Generalized weakness can be explored by systematic consideration of the cardiac, neurological, metabolic, and infectious etiologies that can manifest as generalized weakness. This includes an evaluation of cardiac function, including consideration of acute reduction in cardiac output or worsening contractility leading to congestive heart failure.[1,2] Further evaluation of circulation should include assessment of hemoglobin, oxygen saturation, and systemic vascular tone. Next, assess plasma volume and its composition to evaluate dehydration and altered nutrient (glucose), electrolyte (Na, K, Ca), or waste product (CO_2, urea, bilirubin, ketoacid, ammonia, etc.) levels which can produce diffuse weakness. If substrate delivery and plasma composition appear sufficient, consider disturbances of cellular metabolic machinery secondary to an endocrinopathy, toxin, or mitochondrial dysfunction in the setting of infection. In particular, consideration of infectious causes of generalized weakness should include bacterial, viral, and rickettsial infections that may not be evident from initial laboratory results.

Neurologic examination focuses on identifying acute findings that could support CNS impairment, including acute cerebrovascular events. Although generalized weakness can present deceptively as a focal deficit, particularly in areas already weakened by prior neurologic insult, focal findings, such as lateralizing weakness, numbness, gait instability, or CN defects, should prompt a more detailed exploration of a potential neurologic cause.

After evaluating the potential systemic causes of weakness, the practitioner should then address the specific causes of the focal loss of muscle power. This requires elucidating the pattern of a patient's weakness from the cortical neuron down through the CNS, PNS, NMJ, and myofibers. Table 9.1 lists the most important critical and emergent causes of acute neuromuscular weakness. Common clinical patterns of weakness can be classified and assessed as discussed in the following sections.

Specific Presentations of Neuromuscular Disorders

Unilateral Weakness

Combination of arm, hand, or leg with ipsilateral facial involvement. Weakness involving the combination of arm, hand, or leg with ipsilateral facial involvement is generally caused by a lesion in the contralateral cerebral cortex or the CSTs coursing down the corona radiata and forming the internal capsule. Mild forms can be limited to a loss of dexterity and coordination with hand movements. Moderate loss of power is termed *paresis,* while complete loss of motion is termed *plegia*. UMN signs are useful corroborative findings but may not always be present, especially in the acute phase. Sensory disturbances commonly occur over the areas of weakness. Evaluate for associated neglect, visual field loss, or expressive or receptive aphasia to localize the problem to the cortex.

Patients with equal loss of strength to the face, hand, and leg are more likely to have a subcortical lesion disrupting all these fibers as they funnel close together in the internal capsule. Concomitant headache is concerning for brain hemorrhage or mass lesion, although complex migraines can produce focal neurologic deficits.[1] Sudden onset of this weakness pattern often suggests hemorrhage or acute ischemia, whereas a gradual onset may be seen in demyelination (e.g., multiple sclerosis, acute demyelinating encephalomyelitis) or neoplasm.[1]

Combination of arm, hand, or leg with contralateral facial involvement. Weakness involving the combination of arm, hand, or leg with contralateral facial involvement indicates a brainstem lesion. A careful CN examination can provide more clues. If the patient has contralateral facial findings, there will likely be ptosis (CN III or sympathetic fibers) or a facial droop with forehead involvement (CN VII nucleus). Signs of CN V, VI, VIII, IX, or XII dysfunction will help localize to a particular level within the brainstem. Cerebellar findings or nystagmus may also be present on examination. Sensory disturbances can parallel the weakness, and some patients will report double vision, trouble swallowing, slurred speech, vertigo, or nausea and vomiting. The CST courses ventrally through the brainstem, and extremity weakness with UMN signs in the involved limbs may accompany brainstem lesions. Depressed consciousness can also occur if the brainstem reticular activating system is involved. The two main underlying processes that cause unilateral extremity weakness with contralateral facial involvement are vertebrobasilar insufficiency and demyelinating diseases.

Combination of arm, hand, or leg without facial involvement. Weakness involving the combination of arm, hand, or leg without facial involvement is most likely to be a result of one of the following three processes:

- A lesion in the medial, contralateral, cerebral homunculus (over the area where the lower extremity is represented)
- A discrete internal capsule or brainstem lesion involving only the corticospinal rather than the corticobulbar tracts
- Brown-Séquard internal capsule or brainstem lesion if the patient also has contralateral hemibody pain and temperature sensory disturbances below the level of motor weakness.

Importantly, however, before a patient is placed in this category, a careful examination of facial symmetry is required to determine that subtle facial droop or effacement of the nasolabial fold is not present.

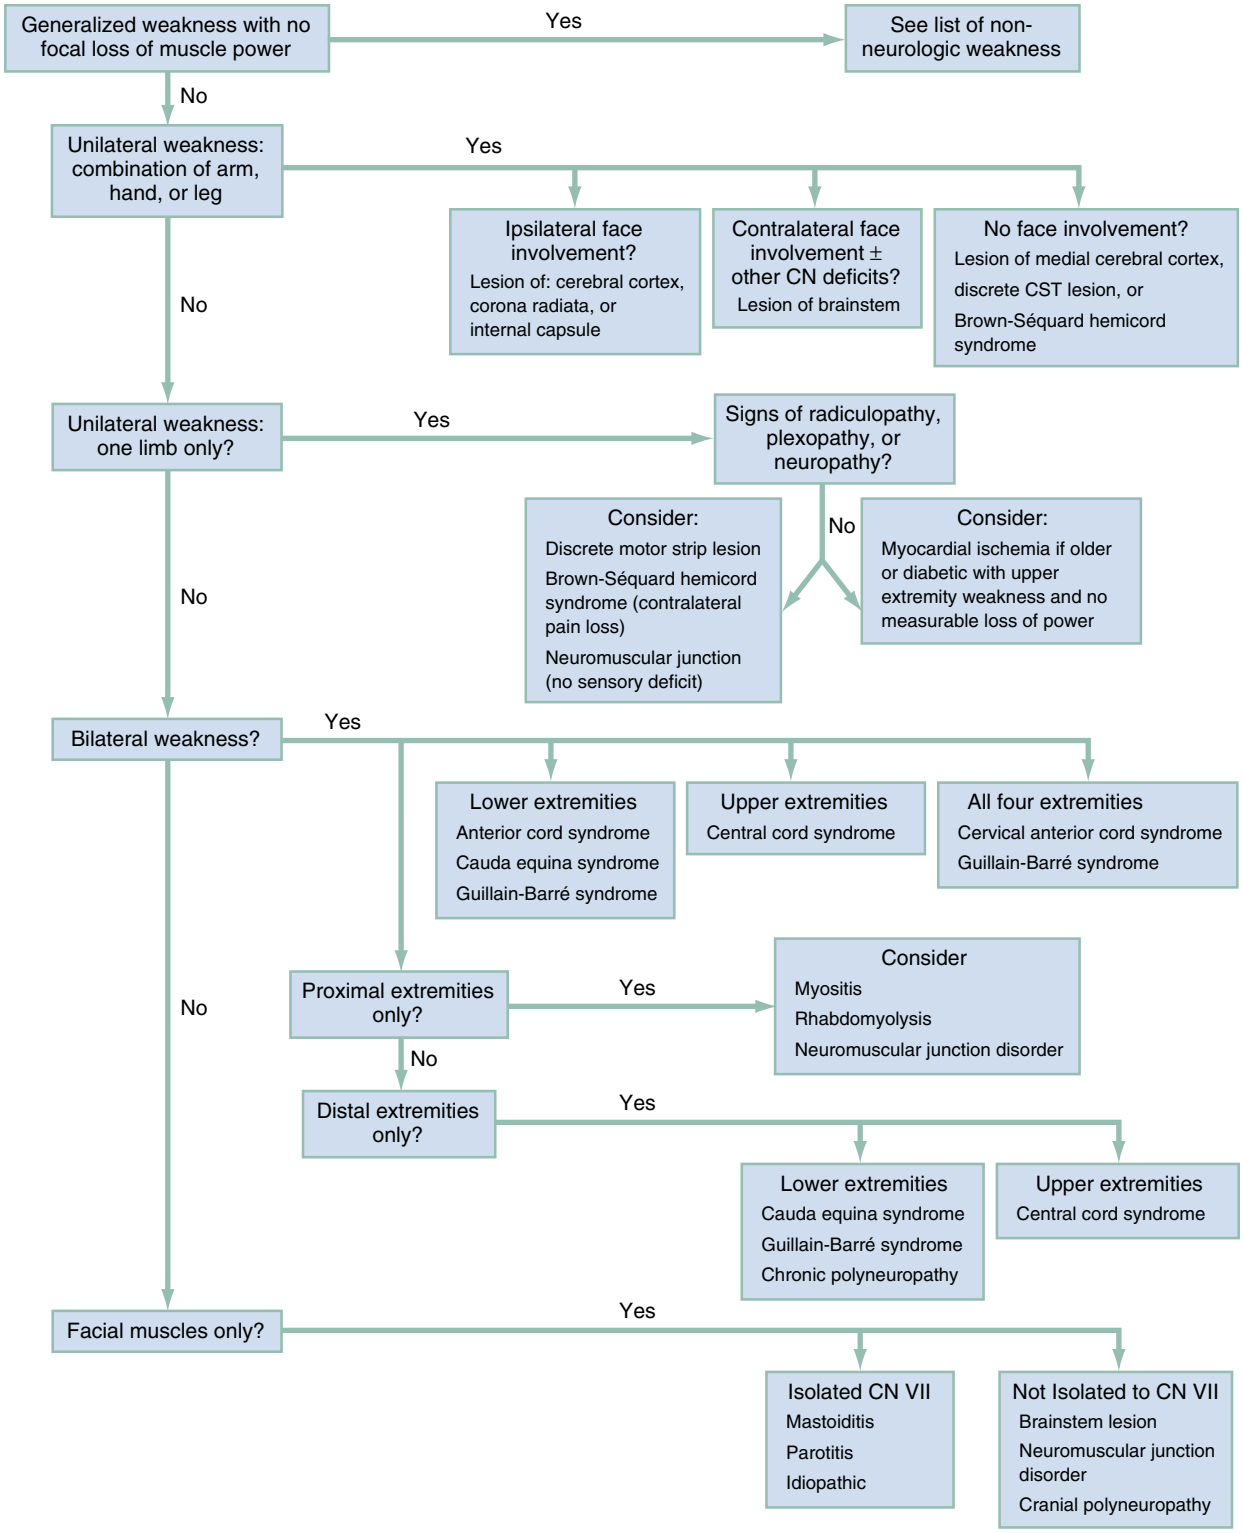

Fig. 9.1 Common Clinical Patterns of Weakness, Classified and Assessed. *CN*, Cranial nerve.

Isolated extremity weakness (monoparesis or monoplegia). Isolated weakness of one extremity is usually caused by a spinal cord or peripheral nerve lesion. Examination for UMN signs in the affected limb will help uncover rare monomelic presentations of CNS lesions. If UMN signs such as hyperreflexia or spasticity are present, a careful evaluation is performed for facial weakness or involvement of the contralateral or other ipsilateral limb as indicative of a central process. If weakness is in the entirety of one lower limb, one should ensure that the patient does not have a contralateral pinprick level indicative of Brown-Séquard hemicord syndrome. Monomelic weakness is often the result of a radiculopathy, plexopathy, peripheral neuropathy, or NMJ disorder. See Table 9.1 for emergent and critical PNS diagnoses.

TABLE 9.1 Critical and Emergent Causes of Neuromuscular Weakness

Diagnosis	Features
Critical Diagnoses	
Cerebral cortex or subcortical	Ischemic or hemorrhagic cerebrovascular accident (CVA)
Brainstem	Ischemic or hemorrhagic CVA
Spinal cord	Ischemia, compression (disk, abscess, or hematoma)
Peripheral nerve	Acute demyelination (Guillain-Barré syndrome)
Neuromuscular junction	Myasthenic or cholinergic crisis Botulism Tick paralysis Organophosphate poisoning
Muscle	Rhabdomyolysis
Emergent Diagnoses	
Cerebral cortex or subcortical	Tumor, abscess, demyelination
Brainstem	Demyelination
Spinal cord	Demyelination (transverse myelitis) Compression (disk, spondylosis)
Peripheral nerve	Compressive plexopathy (hematoma, aneurysm) Paraneoplastic vasculitis uremia
Muscle	Inflammatory myositis

The examination for monomelic weakness presentations includes detailed strength testing and determination of whether weakness localizes to one ventral nerve root myotome or one particular peripheral nerve within the limb. Reflexes with a peripheral nerve disorder will be diminished, not hyperactive. Although radiculopathies can occasionally be purely motor, most peripheral lesions have some sensory component to their presentation; therefore, a careful sensory examination in the distribution of dorsal nerve root dermatomes and peripheral nerves is essential. See Box 9.2 for a list of nonemergent causes of peripheral neuropathy.

NMJ disorders are considered when suspicion is low for a UMN source of isolated extremity weakness, reflexes are intact, and there are no sensory deficits to suggest a nerve or root problem. In such cases, the weakness is often mild, fluctuating, and worse later in the day. It usually involves the proximal arm or leg muscles, wrist extensors, finger extensors, or ankle dorsiflexors. NMJ disorder–induced weakness with only monomelic symptoms will be an uncommon diagnosis in the ED.

Bilateral Weakness

Lower extremities only (paraparesis or paraplegia). When weakness involves the lower extremities only, the first consideration is a spinal cord lesion. If this is the case, UMN signs may be absent in the acute period. Because the lateral spinothalamic tracts (LSTs) run in proximity to the CST, patients with bilateral lower extremity weakness frequently have alterations to their perception of pain or temperature. Examination may reveal a loss of pinprick sensation to a particular spinal level within the thoracic cord or terminal first lumbar segment. The lesion may be as high as T2 without producing upper extremity findings.

The main causes of anterior cord syndrome are external compression, ischemia, or demyelination. In the absence of UMN signs or a clear thoracic pinprick level, evaluation of perianal sensation, rectal tone, and urinary retention can identify deficits that point to cauda equina syndrome, compression of peripheral nerve roots running below the termination of the spinal cord. If the physical examination does not support a cord syndrome or cauda equina compression, the patient may have a peripheral neuropathy affecting the longest nerve tracts first. The acute presentation that is most concerning is Guillain-Barré syndrome (GBS). Rapid demyelination of peripheral nerves can result in symmetric weakness ascending from the feet. Sensory findings parallel the weakness, and reflexes should be decreased at some point in the patient's clinical course. (1)

BOX 9.2 Nonemergent Causes of Peripheral Neuropathy

Connective tissue disorder
External compression (entrapment syndrome, compressive plexopathy)
Endocrinopathy (diabetes)
Paraneoplastic syndromes
Toxins (alcohol)
Trauma
Vitamin deficiency

Upper extremities only. When weakness involves the upper extremities only, the lesion is localized within the central portion of the cervical spinal cord where corticospinal fibers designated for hand and arm strength are located. The patient may have pinprick sensory loss over the upper extremities from the involvement of crossing sensory axons destined for the contralateral LST. However, light touch sensation, mediated by the posterior columns, should remain intact. Common causes of central cord syndrome include cervical spine hyperextension injuries and syringomyelia.

All four extremities without facial involvement (quadriparesis or quadriplegia). When weakness involves all four extremities without facial involvement, the primary concern is a cervical spinal cord injury or process, but the patient is first assessed for medical conditions that produce global weakness. The more dense the extremity weakness, the more likely it is that the patient has a cervical spinal cord problem. Although all four extremities will test poorly for muscle strength, there is frequently some discrepancy between the lower and upper limbs in quadriparesis.

Determination of sensory dermatomes by pinprick testing in the arms and hands, along with strength testing of specific myotomes, will allow localization of the level within the cervical spinal cord. One physical examination confounder in disorders that cause cord compression or ischemia is that upper extremity myotomes corresponding to the site of spine involvement will actually have LMN signs of flaccid weakness and decreased reflexes because anterior cells are involved at this particular level. However, UMN signs may be elicited below that level. A C5 lesion, for example, can cause diminished biceps reflexes but exaggerated triceps and patellar reflexes. Bilateral extremity weakness may occur in patients with GBS that has ascended from the lower extremity peripheral nerve myelin sheaths to the upper extremities. In this case, the lower limbs are usually weaker than the upper limbs.

Proximal portions of extremities only. Weakness confined to the proximal portions of the upper extremities only points to a myofiber disorder, provided that there are no UMN signs or sensory deficits. Patients may report general fatigue or trouble raising the arms above the head, climbing stairs, or rising from a chair. The common acute and progressive causes of proximal muscular weakness are inflammatory diseases such as polymyositis or dermatomyositis, or necrosis, as in rhabdomyolysis from 3-hydroxy-3-methylglutaryl-coenzyme A

(HMG-CoA) reductase inhibitors. Muscles are commonly but not always tender to palpation. Myositis patients can also have dysarthria and dysphagia from weakness of the pharyngeal muscles. Airway protective mechanisms may eventually be compromised.

Chronic or recurrent myofiber pathology includes abnormalities to anchoring proteins supporting fibrils to the cytoskeleton and cell membrane (e.g., muscular dystrophies), dysfunctional ion channels responsible for depolarization of the muscle fiber cell (channelopathies such as hyperkalemic and hypokalemic periodic paralysis), or impaired ability to use carbohydrate and lipid energy sources (e.g., metabolic myopathies, mitochondrial myopathies). The presentation of these varied conditions ranges from insidious and progressive to sudden onset and episodic. Occasionally, a patient with an NMJ disorder will demonstrate proximal extremity or neck muscle weakness mimicking myofiber disease.

Distal portions of extremities only. Weakness involving the distal portions of the extremities only is almost always caused by a peripheral neuropathy (see Box 9.2). Patients will have weakness and poor coordination with fine movements of their feet or hands. If this type of distal weakness is present in both lower extremities only, the patient will most likely have a chronic peripheral neuropathy or an acute demyelinating neuropathy (GBS). The patient will also have some sensory disturbance over the feet. Examination for perianal sensory deficits or issues with fecal or urine continence will help exclude the compressive polyradiculopathy of cauda equina syndrome as a cause of bilateral distal lower extremity weakness. If only the fingers and hands are involved, evaluation for central cord syndrome is performed. Bilateral lower cervical radiculopathies or symmetrical polyneuropathies are possible but much less likely.

Facial Weakness Without Extremity Involvement

Isolated facial weakness will appear in one of two forms.

Unilateral facial droop. Isolated, unilateral weakness of the upper and lower halves of the face is caused by a CN VII problem. Causes for an isolated CN VII neuropathy are Bell palsy, mastoiditis, and parotitis. The examination must confirm that there is no extremity involvement and that other CNs, cerebellar testing results, and visual fields are normal. This will ensure that a brainstem lesion is not causing the weakness.

Facial weakness not limited to cranial nerve VII. Facial weakness not limited to CN VII will be associated with some combination of ptosis, binocular diplopia, dysarthria, or dysphagia. It can be caused by a brainstem lesion, multiple cranial neuropathies, or NMJ problem. If there are no cerebellar findings, visual field deficits, sensory disturbances, or extremity UMN signs, posterior cerebral circulation and brainstem disorders are less likely, and an NMJ disorder is more likely. Dysfunction of one or more ocular, facial, or pharyngeal muscles will be the most common presentation for NMJ pathology. The history may indicate that the facial weakness is acute and progressive (botulism) or chronic and fluctuating (myasthenia gravis). Signs of these diseases can be determined by examining extraocular motion, facial expression, and soft palate rise. Generalized fatigue is often reported, and neck, extremity, and respiratory muscle weakness caused by involvement of these neuromuscular units may be present on examination.

Patients with an abnormality of the presynaptic release of acetylcholine (e.g., botulism, Eaton-Lambert syndrome, organophosphate poisoning) can have autonomic ganglia involvement and hence abnormal pupillary response to light, dry mouth, fluctuations in heart rate and blood pressure, anhidrosis, or gastrointestinal and bladder dysmotility.

Facial weakness from cranial polyneuropathy manifests with more than one CN deficit not localizing to a brainstem level and without any other long tract signs. These patients may have a variant of GBS or irritation of multiple CNs after they have exited the brainstem and pierced through inflamed meninges or malignant skull base metastases.

EMPIRIC MANAGEMENT

The management of neuromuscular weakness is based on evaluating the underlying cause and managing the acute complications of weakness. Airway protection in obtunded patients or those with upper airway compromise is paramount. Neck and pharyngeal muscle weakness, for example, may herald a risk for aspiration or airway obstruction. Diaphragmatic weakness and inadequate hypopharyngeal muscle control or respiratory muscle fatigue should prompt definitive airway protection by endotracheal intubation. During rapid sequence intubation (RSI), succinylcholine should be avoided in suspected cases of progressive denervation of muscle of more than a 3-day duration due to receptor upregulation and the risk for severe hyperkalemia. In this situation, we recommend rocuronium, a nondepolarizing neuromuscular blocking agent.

New quadriparesis or quadriplegia and hypotension without another cause is assumed to be caused by failure of autonomic sympathetic fibers in the cervical spinal cord. Consider a volume load and pressor support in addition to emergent imaging of this area. Although new weakness localizing to the spinal cord calls for immediate imaging, weakness from the spinal roots down does not always necessitate imaging in the ED unless cauda equina syndrome or other acute, emergent pathology is suspected.

Patients with suspected GBS need pulmonary function testing in addition to admission to a critical care setting for further management. An infectious or metabolic trigger is sought in patients with myasthenic crisis. If the patient is currently on acetylcholinesterase inhibitors, consideration should be given to a cholinergic crisis. Be aware of medications that may worsen weakness in patients with NMJ disease (e.g., aminoglycosides, quinolones, beta blockers). Rhabdomyolysis is treated with aggressive fluid resuscitation and intervention directed at the primary cause, if known.

In any patient with a sudden onset of focal weakness, a vascular cause (occlusion or hemorrhage) should be strongly considered until excluded by an adequate imaging study. The presence of a severe headache with unilateral weakness, or midline back pain with lower extremity weakness, alerts the clinician to a compressive space-occupying lesion of the CNS or spinal cord, respectively.

Patients with UMN signs have weakness that localizes to the spinal cord CST or above and are considered to have an emergent problem. They may be at risk for progression to sympathetic autonomic failure or obtundation from enlarging space-occupying spinal or cerebral lesions, respectively. The presence of anorectal or bladder insufficiency without another explanation suggests a UMN or cauda equina lesion. Laboratory tests are most useful for excluding non-neuromuscular causes of weakness (electrocardiography, measurement of hemoglobin, glucose, electrolytes, troponin, and lactate levels, urinalysis). Two exceptions are the creatinine kinase level in inflammatory myositis and potassium level in channelopathies.

DISPOSITION

Patients with generalized weakness should receive treatment and disposition based on the underlying diagnosis and anticipated clinical course, and the range of dispositions will vary based on etiology. Patients with identified central vascular lesions, thrombotic or hemorrhagic, should be aggressively managed in the inpatient setting. Patients with mild LMN or myofiber weakness of benign origin may

be discharged with close follow-up, provided that the condition is not thought to be progressing rapidly. Those with more severe or progressive LMN or myofiber weakness and any patient with new UMN weakness should be admitted for further testing. Patients with suspicion for ascending paralysis should be admitted to an ICU setting for close respiratory observation.

CHAPTER 9: QUESTIONS AND ANSWERS

1. A 65-year-old man with a history of atrial fibrillation, on warfarin, with a supratherapeutic international normalized ratio (INR) of 4, presents with sudden onset right leg weakness and back pain. On examination, he is tachycardic to 108 beats/min and has 3/5 weakness to the right hip flexors and extensors, knee flexors and extensors, as well as ankle dorsiflexion and great toe extension. However, ankle plantar flexion is preserved. His knee reflexes are absent, but Achilles reflexes are normal. He has a normal Babinski reflex and no spasticity. He has sensory deficits throughout the anterior and posterior parts of his proximal leg as well as the anterior lower leg and dorsum of the foot. His posterior lower leg and plantar surface, however, have normal sensation. Rectal tone is normal, and there is no urinary retention. What is the most likely diagnosis?

a. Anterior cord syndrome from epidural hematoma
b. Cauda equina syndrome
c. Guillain-Barré syndrome
d. Hemorrhagic anterior cerebral artery (ACA) distribution stroke
e. Retroperitoneal hematoma with lumbar plexopathy

Answer: e. This patient has a spontaneous retroperitoneal hematoma compressing the lumbar nerve plexus.

2. A 45-year-old man has had gradual onset of progressive weakness to his face and trouble swallowing for 2 days. On examination, he has bilateral ptosis with dilated, poorly reactive pupils, bilateral upper and lower facial muscle weakness, poor soft palate rise, and slurred speech. His oral mucosa is dry. Arms and legs have 5/5 strength. He has no sensory deficits. He has a palpable distended bladder. His symptoms have not abated since onset, and they are getting worse. What is the most likely diagnosis?

a. Brainstem stroke
b. Botulism
c. Muscular dystrophy
d. Myasthenia gravis
e. Organophosphate poisoning

Answer: b. This patient has acute onset of progressive neuromuscular junction weakness. He has autonomic findings of abnormal pupil response to light, dry oral mucosa from decreased salivary production, and a distended bladder. These imply that his problem is with the release of acetylcholine (ACh) rather than the nicotinic receptor. The latter would not have autonomic findings. The most appropriate cause of acute onset, progressive impairment in the release of ACh, as listed in the choices, is botulism.

3. A 23-year-old woman presents with the sudden onset of weakness of her face, arm, and leg 2 hours ago. On examination, she has weakness to her upper and lower face on the left. She cannot abduct her left eye. She has 3/5 strength to her upper and lower extremities on her right side. She has a right pronator drift and an upgoing toe on the right. Sensation is decreased in her right upper and lower extremities as well. There is no aphasia, neglect, or visual field deficit. What is the most likely diagnosis?

a. Midbrain stroke because of cardioembolic stroke
b. Middle cerebral artery (MCA) distribution stroke
c. Multiple sclerosis
d. Myasthenia gravis
e. Pons stroke because of vertebral dissection

Answer: e. This patient has acute onset of crossed face and extremity weakness, with upper motor neuron (UMN) signs in the extremities. Both upper and lower extremities are affected, which makes a corticospinal tract (CST) lesion more likely than a cerebral cortex lesion. Her left-sided facial weakness is representative of a peripheral cranial nerve (CN) VII that is actually due to infarction of the CN VII nucleus in the brainstem. The CN VI deficit on that side is due to proximity of this nucleus as well. The CST runs just anterior to these nuclei within the brainstem. These CN nuclei lie in the pons.

4. A 21-year-old man awoke this morning with weakness to his right hand and right foot. He admits to drinking heavily the night before and falling asleep on the floor. On examination, he appears well, with weakness to right wrist extension and thumb extension, as well as sensory deficits over the dorsal surface of his hand and first and third digits. He also has weakness to ankle dorsiflexion and great toe extension on the right. He has sensory deficits over the anterior lower leg and the dorsum of his foot. Biceps and ankle reflexes are intact, he has no pronator drift, and his toes are downgoing. What is the most likely diagnosis?

a. Brainstem stroke
b. Brown-Séquard syndrome
c. Compressive neuropathy
d. MCA distribution stroke
e. Polyradiculopathy secondary to disk disease

Answer: c. He has radial nerve and peroneal nerve palsies because of compression while lying passed out on the floor for an unspecified time.

5. A 70-year-old man has had trouble swallowing and progressive weakness of his hands over the past 2 months. On examination, his speech is slurred, his voice is nasal, and he has fasciculations to his face, tongue, and over his pectoralis muscles and deltoids bilaterally. He has 4/5 strength to shoulders, biceps, triceps, and hand grip bilaterally. Stiffness to extension is present at both elbows. He has bilateral pronator drift and 3+ biceps reflexes. He tends to smile inappropriately. He has no sensory symptoms. What is the most likely diagnosis?

a. Amyotrophic lateral sclerosis (ALS)
b. Brainstem stroke
c. Chronic demyelinating polyneuropathy
d. Parkinsonism
e. Polymyositis

Answer: a. This patient has lower motor neuron (LMN) signs (fasciculations) and UMN signs (pronator drift and increased reflexes) in similar distribution. The combination of upper and lower motor neuron involvement makes ALS the leading diagnosis among those listed. His dysphagia and inappropriate smiling are due to a release of the medulla from upper motor neuron regulation.

10

Cyanosis

Pranav Shetty and Madonna Fernández-Frackelton

KEY CONCEPTS

- Cyanosis occurs due to an absolute amount of desaturated hemoglobin (~5 g/dL) rather than a percentage; anemic patients exhibit cyanosis at a lower Pa_{O_2} than those with normal hemoglobin levels.
- Cyanosis is an insensitive indicator of tissue oxygenation; its presence suggests hypoxemia, but its absence does not exclude it.
- Central cyanosis is most commonly due to global arterial hypoxemia or abnormal hemoglobin forms; peripheral cyanosis is due to vasoconstriction or reduced flow of normally oxygenated hemoglobin to the peripheral tissues.
- Methemoglobin has a chocolate brown color, even when the blood is exposed to room air; pulse oximetry for patients with methemoglobinemia typically reads 85%, regardless of the Pa_{O_2} or Sa_{O_2}.
- Methemoglobinemia may be due to inherited congenital errors in enzyme function or acquired secondary to exposure to oxidizing agents such as certain drugs and toxins.
- Congenital heart disease is a diagnostic consideration in all infants presenting with cyanosis.
- Sulfhemoglobin is often reported as methemoglobin on CO-oximetry; patients with methemoglobinemia on CO-oximetry who do not respond to methylene blue treatment likely have sulfhemoglobinemia.
- Methylene blue is the treatment of choice for symptomatic methemoglobinemia or at levels of methemoglobin greater than 20%.
- All patients with a first episode of cyanosis or cyanosis of uncertain cause require hospitalization.

FOUNDATIONS

Cyanosis is a blue or purple appearance of the skin or mucous membranes. This clinical finding is most commonly caused by one of two pathologic processes: inadequately oxygenated blood containing deoxygenated hemoglobin or the presence of abnormal hemoglobin forms which are unable to bind oxygen or supply adequate oxygen to end organs and tissues.

Epidemiology

Cyanosis is a relatively rare presenting chief complaint in the emergency department (ED) and is usually noted in patients with a hypo-perfused state or known cardiopulmonary disease, including congenital heart disease. Although carbon monoxide poisoning and cyanide toxicity result in inadequate hemoglobin oxygenation and/or tissue hypoxia, these entities typically do not present with the clinical finding of cyanosis and are discussed in other chapters (see Chapter 148).

Pathophysiology

Cyanosis is evident on physical examination when the absolute amount of desaturated (unoxygenated) hemoglobin in the circulating capillary blood is elevated to ~5 g/dL. It is not caused solely by a percentage of desaturated total hemoglobin mass or decreased amount of oxyhemoglobin. For this reason, patients with anemia exhibit cyanosis at lower arterial partial pressure of oxygen (Pa_{O_2}) and oxygen saturation (Sa_{O_2}) levels than those with normal hemoglobin, while patients with polycythemia may exhibit cyanosis at higher Pa_{O_2} and Sa_{O_2} levels. As such, cyanosis is an insensitive indicator of tissue oxygenation; its presence suggests hypoxemia, but its absence does not exclude it.

Primary causes of hypoxemia include ventilation-perfusion (V/Q) mismatch, hypoventilation, diffusion limitation, and low levels of inspired oxygen. V/Q mismatch is an imbalance between the ventilation and perfusion of alveolar-capillary units and is the most common cause of hypoxemia. High V/Q ratios (increased dead space) can be seen in diseases such as pulmonary emboli, emphysema, and pulmonary hypertension. Low V/Q ratios, with the most extreme example being a right-to-left shunt, occur in pneumonia, asthma, ARDS, and pulmonary edema. Anatomic right-to-left shunts are seen in developmental anomalies, such as congenital heart disease and patent ductus arteriosus. Hypoventilation lowers alveolar P_{O_2} and is most commonly caused by depressed central respiratory drive, respiratory muscle weakness, or morbid obesity. Diffusion limitation refers to the impaired diffusion of oxygen across the alveolar-capillary interface and is seen in diseases such as interstitial pulmonary fibrosis and chronic obstructive pulmonary disease (COPD). This may not cause hypoxemia at rest but may during exercise when the transit time for red blood cells (RBCs) in the pulmonary capillary bed is reduced. Lastly, low levels of inspired oxygen result in reduced alveolar P_{O_2} levels and are seen primarily at high altitude.[1]

Abnormal hemoglobin forms, most commonly methemoglobin, also contribute to cyanotic disease. Under normal conditions, RBCs contain hemoglobin with iron in the reduced ferrous state (Fe^{2+}). Ferrous iron binds oxygen readily to create oxyhemoglobin, and it reverts to the ferrous state when oxygen is released. The iron molecule may be oxidized to the ferric state (Fe^{3+}) spontaneously or by oxidative stress, producing methemoglobin. The ferric iron cannot bind oxygen, impairing the ability of hemoglobin to transport oxygen to the tissues. Any remaining ferrous (Fe^{2+}) binding sites on the hemoglobin molecule have a higher affinity for oxygen, shifting the oxygen-hemoglobin dissociation curve (Fig. 10.1) to the left, further resulting in tissue hypoxia and subsequent lactic acid production.[2]

Methemoglobin normally accounts for less than 1% of total hemoglobin. Cyanosis results when more than 1.5 g/dL of methemoglobin is present (~10% to 25% of the total hemoglobin). Methemoglobin has a dark purple or chocolate-brown color, even when exposed to room air. It is primarily reduced to ferrous (Fe^{2+}) hemoglobin by nicotinamide adenine dinucleotide + hydrogen (NADH)–cytochrome b5 reductase, an enzyme system present in RBCs. A secondary system dependent

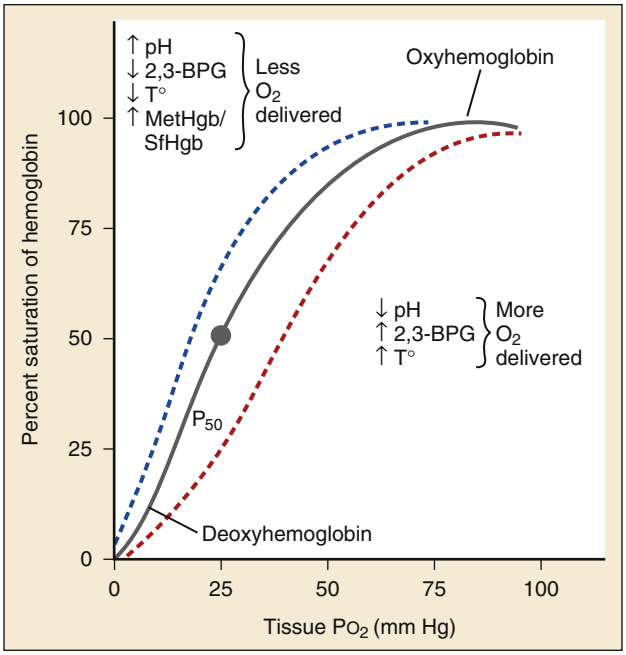

Fig. 10.1 Hemoglobin-Oxygen Dissociation Curve. The solid line represents percent of hemoglobin *(Hgb)* saturation at a given Pa_{O_2}. The *red dotted line* represents factors that favor O_2 delivery to the tissues, so that at a given Pa_{O_2}, the Hgb saturation drops and O_2 is released. Exercising muscle tissue creates an environment with lactic acid production and elevated temperature shifting the curve to the right, which favors the release of O_2. The *blue dotted line* represents a shift to the left with higher O_2 binding at any given Pa_{O_2}. Higher pH and lower temperatures, as in pulmonary capillary beds, favor more O_2 binding. Methemoglobin has a high affinity for oxygen molecules and does not readily release O_2 to the peripheral tissues. This shifts the normal oxygen dissociation curve to the left, resulting in hypoxia and lactic acid production. Lactic acid being produced in the tissues should facilitate O_2 release; however, the high affinity of methemoglobin for O_2 prevents this normal process. *2,3-BPG,* 2,3-Bisphosphoglycerate; *P_{50},* oxygen half- saturation pressure of hemoglobin; *P_{O_2},* partial pressure of oxygen; *T,* temperature. on nicotinamide adenine dinucleotide phosphate (NADPH) reductase uses glutathione and glucose-6-phosphate dehydrogenase (G6PD) to reduce methemoglobin to ferrous hemoglobin. This secondary pathway plays a minor physiologic role but is accelerated significantly by methylene blue.

Primary methemoglobinemia is the result of congenital errors in metabolism caused by diminished levels of NADH reductase or an abnormally functioning enzyme. Patients may have stable compensated cyanosis. Acquired methemoglobinemia occurs when methemoglobin production exceeds the capacity of NADH reductase activity; this is usually a result of a drug reaction.[3] The most common medications that cause methemoglobinemia are local anesthetics, both injected and topical, phenazopyridine, nitroglycerin, and metoclopramide. See Box 10.1 for additional causes. Newborns are at increased risk for methemoglobinemia due to relatively low NADH reductase activity compared with that of adults.

DIAGNOSTIC APPROACH

Differential considerations for patients with cyanosis are listed in Box 10.2.

BOX 10.1 Common Causes of Methemoglobinemia

Hereditary

Hemoglobin M
NADH methemoglobin reductase deficiency (homozygote and heterozygote)

Acquired

Medications

Amyl nitrite
Antineoplastics (e.g., cyclophosphamide, ifosfamide, flutamide)
Dapsone
Local anesthetics (e.g., benzocaine, lidocaine, prilocaine)
Metoclopramide
Nitroglycerin
Nitroprusside
Phenacetin
Phenazopyridine (Pyridium)
Quinones (e.g., chloroquine, primaquine)
Rasburicase
Sulfonamides (e.g., sulfanilamide, sulfathiazide, sulfapyridine, sulfamethoxazole)

Chemical Agents

Aniline dye derivatives (e.g., shoe dyes, marking inks)
Butyl nitrite
Chlorobenzene
Fire (heat-induced denaturation)
Food high in nitrates
Isobutyl nitrite
Naphthalene (mothballs)
Nitrophenol
Nitrous gases (seen in arc welders)
Paraquat
Silver nitrate
Trinitrotoluene
Well water (nitrates)

Pediatric Cases

Reduced NADH methemoglobin reductase activity in infants (<4 months)
Seen in association with low birth weight, prematurity, dehydration, acidosis, diarrhea, and hyperchloremia

Modified from Goldfrank LR. *Toxicologic Emergencies*. 9th ed. New York: McGraw-Hill; 2010.
NADH, nicotinamide adenine dinucleotide + hydrogen.

Pivotal Findings

Presentation and Symptoms

Common symptoms associated with cyanosis include dyspnea, fatigue, chest discomfort, and decreased exercise tolerance. The onset, duration, time of day of symptoms, and any previous episodes should be noted. Patients with methemoglobin levels less than 20% are often asymptomatic, although cyanosis may be noted. With levels of 20% to 50%, patients may exhibit headaches, fatigue, weakness, dizziness, and dyspnea. Levels greater than 50% result in altered mental status, lethargy, and seizures, and levels greater than 70% are associated with death.[4]

Precipitating factors may include exposure to cold air or water, high altitude, or exercise in patients with a history of cardiopulmonary disease. Additional history should include known congenital heart disease or cardiopulmonary disease, hypercoagulable states, and family history of cyanotic or hematologic disease. A history of exposure to fumes or chemicals should be obtained, including aniline or azo dyes,

BOX 10.2 Differential Diagnosis of Cyanosis

I. Peripheral cyanosis
  A. Low cardiac output states
    1. Shock
    2. Left ventricular failure
    3. Hypovolemia
  B. Environmental exposure (cold)
  C. Arterial occlusion
    1. Thrombosis
    2. Embolism
    3. Vasospasm (Raynaud phenomenon)
    4. Peripheral vascular disease
  D. Venous obstruction
  E. Redistribution of blood flow from extremities
    1. Peripheral arteriovenous fistulae
II. Central cyanosis
  A. Decreased arterial oxygen saturation
    1. High altitude (>8000 ft)
    2. Impaired pulmonary function
      a. Hypoventilation
        1. Drug toxicity
        2. Respiratory muscle weakness
        3. Upper airway compromise
      b. Impaired oxygen diffusion
        1. Interstitial pulmonary fibrosis
        2. Emphysema
      c. Ventilation-perfusion mismatch
        1. Pulmonary embolism
        2. Pulmonary hypertension
      d. Right-to-left shunt
        1. Pneumonia
        2. Large pneumothorax
        3. Acute respiratory distress syndrome (ARDS)
  B. Anatomic shunts
    1. Pulmonary arteriovenous fistulae and intrapulmonary shunts
    2. Cyanotic congenital heart disease
      a. Endocardial cushion defects
      b. Ventricular septal defects
      c. Coarctation of aorta
      d. Tetralogy of Fallot
      e. Total anomalous pulmonary venous return, low pulse oximetry readings
      f. Hypoplastic left ventricle
      g. Pulmonary vein stenosis
      h. Tricuspid atresia and anomalies
      i. Premature closure of foramen ovale
      j. Dextrocardia
  C. Disorders of hemoglobin
    1. Methemoglobinemia
    2. Sulfhemoglobinemia
    3. Polycythemia

shoe polish, and nitrates. A drug history should be reviewed, including use of prescription and over-the-counter medications, supplements, and herbal or alternative preparations. The potential of pseudocyanosis resulting from exposure to dyeing agents, heavy metals, or topically absorbed pigments should be explored.

In infants, congenital heart disease is suggested by difficulty feeding, sweating, lethargy, poor weight gain, or respiratory distress. Episodic cyanotic events, or "tet spells," may be seen in children with tetralogy of Fallot: ventricular septal defect, overriding aorta, pulmonic stenosis or atresia, and right ventricular hypertrophy with outlet obstruction. These patients have cyanosis, tachypnea, and anxiety due to decreased pulmonary blood flow, with shunting of unoxygenated blood into the systemic circulation (see Chapter 165).

Signs

There is significant interobserver variability in detecting cyanosis on physical examination. Room lighting and temperature may affect examination of the skin and mucous membranes. A patient's natural skin tone, thickness, and pigmentation also may alter findings.

The physical manifestation of cyanosis can be divided into two broad categories: central cyanosis and peripheral cyanosis. Central cyanosis is best seen on perioral skin, oral mucosa, or conjunctivae, but may be seen over the entire body surface. Central cyanosis is often secondary to profound arterial hypoxemia or the presence of abnormal hemoglobin. Peripheral cyanosis affects distal capillary circulation and is typically seen in the extremities and nail beds. Peripheral cyanosis is often secondary to low cardiac output, vasoconstriction, or venous stasis which results in reduced forward blood flow, allowing for greater oxygen extraction by the tissues. Differential cyanosis may occur in the upper or lower (or the right or left) half of the body, with the remainder of the body appearing well oxygenated. This form of cyanosis is usually seen in patients with cyanotic heart disease with multiple anomalies.

Vital signs should be obtained from all patients. Temperature is typically normal while blood pressure and heart rate vary, depending on the cause and acuity of cyanosis. Interpretation of pulse oximetry is challenging in the setting of cyanosis. Assessment of peripheral pulses, capillary refill time, and nail bed color may help determine if poor circulation is the cause of low pulse oximetry. Pulse oximetry measures light absorption of oxyhemoglobin and deoxygenated (reduced) hemoglobin using two light wavelengths, 660 nm (red) and 940 nm (infrared). The ratio of these two readings is the basis of the pulse oximetry calculation. By default, standard pulse oximeters assume the absence of abnormal hemoglobin such as carboxyhemoglobin or methemoglobin. Methemoglobin absorbs well at both wavelengths, resulting in a saturation reading of approximately 85%, regardless of actual Pao_2 and Sao_2 values.[5]

Upper airway obstruction and other signs of respiratory insufficiency or compromise should be sought. Infants with cyanosis, increased respiratory depth, periodic apnea episodes, or diaphoresis with feeding may have congenital heart disease. Tachypnea (>60 breaths/min) in a newborn is nonspecific but may indicate a pulmonary disorder, congenital heart disease, infection, metabolic disorder, or gastrointestinal or central nervous system (CNS) pathology.

The general appearance and mental status should be noted. The head, eyes, ears, nose, and throat examination may reveal central cyanosis. Jugular venous distention may be seen on the neck examination in patients with pulmonary edema or pulmonary hypertension. A neurologic examination should focus on mental status, symmetry of motor and sensory function, and any gross deficit. The chest examination may reveal crackles, wheezing, or inadequate chest wall movement with respiration. Heart sounds should be assessed for tachycardia, abnormal rhythm, or gallops and the presence and quality of murmurs, especially in the newborn. Central pulse strength should be noted. The abdomen should be examined for the presence of hepatosplenomegaly, pulsatile mass, or abdominal bruit.

Extremity examination should evaluate for evidence of chronic vascular disease, such as hair loss and temperature difference. Clubbing of the nails may occur due to increased soft tissue and expansion of the capillary beds (Fig. 10.2). Clubbing may be idiopathic or hereditary,

Fig. 10.2 Symmetric Clubbing. Shown here are equal cyanosis and clubbing of the hands and feet resulting from transposition of the great vessels and a ventricular septal defect without patent ductus arteriosus.

but is usually the result of chronic hypoxemic states, such as cyanotic heart disease, infective endocarditis, pulmonary disease, and some gastrointestinal disorders (e.g., cirrhosis, Crohn disease, regional enteritis). Thrombotic events should also be considered in patients with skin and nail bed hemorrhages or end-organ damage (e.g., eye, kidney). Splinter hemorrhages are often associated with infective endocarditis but can be caused by a variety of conditions (e.g., systemic lupus erythematosus, scleroderma, rheumatoid arthritis).

Ancillary Testing

A complete blood count will assess for erythrocytosis, polycythemia, or anemia.[6] A peripheral smear assesses RBC morphology and fragments, as well as the white blood cell differential count. A D-dimer level may be indicated if pulmonary embolism (PE) is suspected.

In the case of methemoglobinemia the peripheral blood typically appears chocolate brown in color. Normally, a small drop of blood placed on a white sheet or filter paper will turn bright red when exposed to 100% oxygen. No change in color is highly suggestive of methemoglobinemia.[7]

Arterial blood gas testing assesses Pao_2 and Sao_2 levels (see Fig. 10.1). In methemoglobinemia, the Pao_2 and Sao_2 may be normal as the partial pressure of oxygen dissolved in the blood should not be affected in the absence of concomitant cardiopulmonary disease and the Sao_2 value is often calculated based on the measured Pao_2.[8] The oxygen saturation gap is the difference between the calculated theoretical hemoglobin saturation on blood gas analysis and that measured by pulse oximetry; an elevated gap is strongly suggestive of methemoglobinemia. CO-oximetry measurements should be ordered if carbon monoxide exposure or methemoglobinemia is suspected. Sulfhemoglobin is often reported as methemoglobin on CO-oximetry. If sulfhemoglobinemia is possible (exposure to sulfa-containing drugs), the sulfhemoglobin percentage should be specifically determined. Devices designed to measure methemoglobin levels noninvasively (e.g., pulse CO-oximetry) may be useful but have decreasing accuracy at lower Sao_2 levels (<95%) and higher methemoglobin levels (>14%).[5]

Imaging

A chest radiograph will evaluate lung fields for consolidation, infiltrates, effusions, and pulmonary edema. An abnormal cardiac silhouette and mediastinum may suggest congenital heart disease. If pulmonary embolus is suspected, a diagnostic strategy utilizing lower extremity venous Doppler ultrasound, computed tomography pulmonary angiography (CTPA), cardiac ultrasound, or, rarely, V/Q scanning should be pursued.

Electrocardiography and Echocardiography

An electrocardiogram should be obtained on all patients with a new presentation of cyanosis to assess for dysrhythmia and acute ischemic changes. Right axis deviation or right ventricular hypertrophy may be seen with significant cardiopulmonary disease (e.g., cor pulmonale, acute pulmonary hypertension). An echocardiogram may be useful in detecting septal defects in infants, valvular disease in infants and adults, and overall cardiac function.

DIAGNOSTIC ALGORITHM

Fig. 10.3 outlines an approach to the differential diagnosis of peripheral and central cyanosis. During the initial assessment, the emergency clinician should initiate oxygen therapy and follow steps to determine the cause of cyanosis. In peripheral cyanosis, improvement with oxygen suggests a low-flow state due to global under-perfusion such as with hypovolemia or cardiogenic shock. Lack of improvement with oxygen implies a focal vascular occlusion secondary to environmental exposures, arterial thrombosis/embolism, or Raynaud disease. In central cyanosis clinical improvement with oxygen suggests hypoxemia due to a diffusion impairment, hypoventilation, or V/Q mismatch resulting in increased dead space ventilation. Patients who do not respond to high-flow oxygen are more likely to have a right-to-left shunt such as from pulmonary consolidation or congenital heart disease.

The patient's respiratory status should be immediately assessed and tension pneumothorax, bronchospasm, or upper airway obstruction considered. Cardiac size and silhouette on a chest radiograph may suggest the presence of congenital heart disease or congestive heart failure. Acute cardiac dysfunction, such as from acute coronary syndrome can be assessed with an electrocardiogram. If heart size is normal, impaired pulmonary function, pulmonary embolus, or other noncardiac causes should be considered. If pulmonary embolus is suspected, CTPA is the diagnostic test of choice in the absence of contraindications. If a patient exhibits no respiratory distress and remains resistant to oxygen therapy, cardiac shunting or abnormal hemoglobin forms should be considered and treated accordingly.

Critical Diagnoses

Acute cardiovascular and respiratory compromise are considered in patients with cyanosis and symptoms or signs of shock. The differential diagnosis includes acute heart failure, acute coronary syndrome, and hypovolemic or cardiogenic shock. In addition, consider acute respiratory insufficiency or failure, upper airway obstruction, massive PE, decompensation in a patient with known congenital heart disease or pre-existing lung disease such as pulmonary fibrosis or COPD, or the first presentation of pediatric congenital heart disease.

Emergent Diagnoses

Methemoglobinemia is an infrequent cause of central cyanosis but should be considered in patients with no history or physical findings suggestive of cardiovascular or pulmonary disease.

Sulfhemoglobinemia is a rare cause of cyanosis, usually occurring after exposure to hydrogen sulfide from organic sources, medications

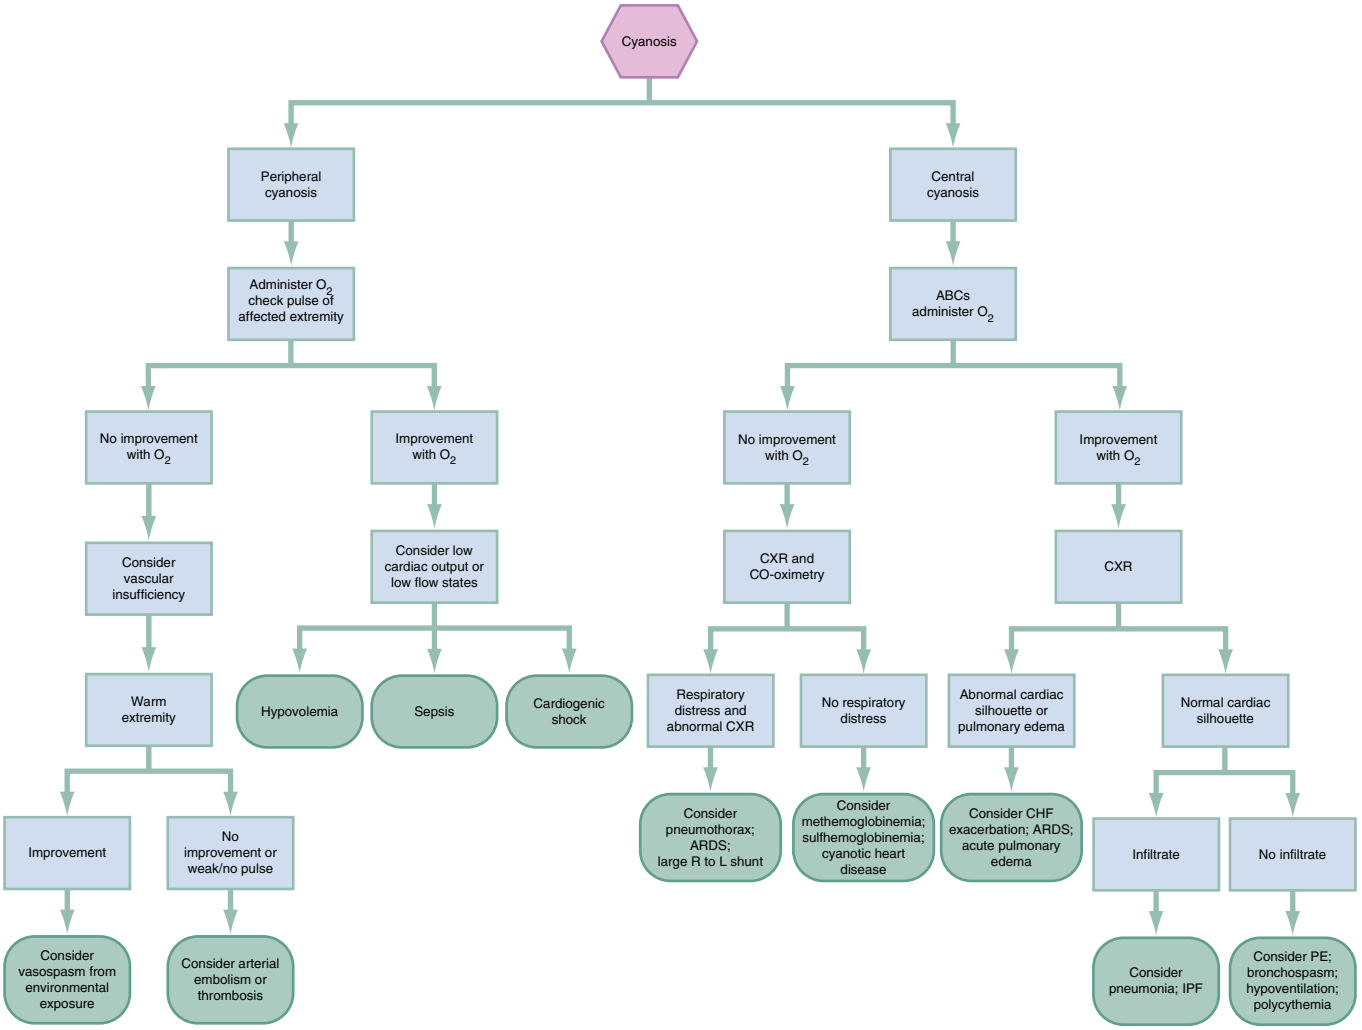

Fig. 10.3 Algorithmic Diagnostic Approach to Cyanosis. *ABCs,* Airway, breathing, circulation; *ARDS,* acute respiratory distress syndrome; *CHF,* congestive heart failure*; CXR,* chest radiograph; *IPF,* Interstitial Pulmonary Fibrosis; *IV,* intravenous; *O_2,* oxygen; *PE*, pulmonary embolism.

that are sulfonamide derivatives, or gastrointestinal sources (bacterial overgrowth). Sulfhemoglobinemia can cause cyanosis at levels as low as 0.5 mg/dL of blood, but the diagnosis may be challenging as some CO-oximeters will measure sulfhemoglobin as methemoglobin. Strong consideration should be given to sulfhemoglobin toxicity in patients with cyanotic findings and methemoglobin on CO-oximetry but who do not improve with methylene blue treatment, or when reported methemoglobin levels on CO-oximetry are not elevated enough to explain the low levels of oxyhemoglobin.[9,10]

Polycythemia is defined as an elevated RBC mass from one of three causes. Polycythemia vera is a disorder of bone marrow stem cells resulting in increased RBC mass, cyanosis predominately seen in the face and hands, and splenomegaly. Patients may demonstrate hyperviscosity syndrome. Secondary polycythemia occurs with an appropriate or inappropriate increase of erythropoietin, physiologic response to chronic hypoxemia (<92% oxygen saturation), cyanotic congenital heart disease, cigarette smoking, high-altitude exposures, or as a response to congenital methemoglobinemia.[11] Relative polycythemia is an increased RBC mass, often resulting from dehydration or reduced plasma volume.

Finally, vascular disease, such as Raynaud phenomenon, may cause peripheral cyanosis. Raynaud phenomenon occurs in 15% of the population, with a female predominance. Patients have an abnormal response to excessive cold or emotional stress, causing vasoconstriction, profound cold sensitivity, and recurrent events of sharply demarcated pallor or cyanosis of the digits (Fig. 10.4). Usually, the cutaneous arterial capillary beds of the fingers and toes are affected, but the tongue, ear, and other distal areas may also be affected.[12]

EMPIRIC MANAGEMENT

Fig. 10.5 outlines an approach to the management of peripheral and central cyanosis. Administration of high-flow oxygen is the first therapy for patients with central cyanosis; any clinical improvement, or lack thereof, should be noted. If the cyanosis improves with the administration of oxygen, consider arterial hypoxemia secondary to cardiopulmonary disease. If there is little to no improvement with oxygen, consider a right-to-left shunt causing hypoxemia or abnormal hemoglobin forms. In patients with cyanosis and concomitant respiratory distress or failure, airway management including positive pressure ventilation (PPV) and/or noninvasive PPV should be initiated.

Intravenous (IV) fluid resuscitation should be initiated in patients with hypovolemia. Treatment of congestive heart failure, arrhythmias, or poor cardiac output should occur as indicated. We recommend cardiology consultation for patients with congenital heart disease, who often have abnormal responses to oxygen and conventional fluid

Fig. 10.4 (A and B) Raynaud phenomenon due to cold exposure.

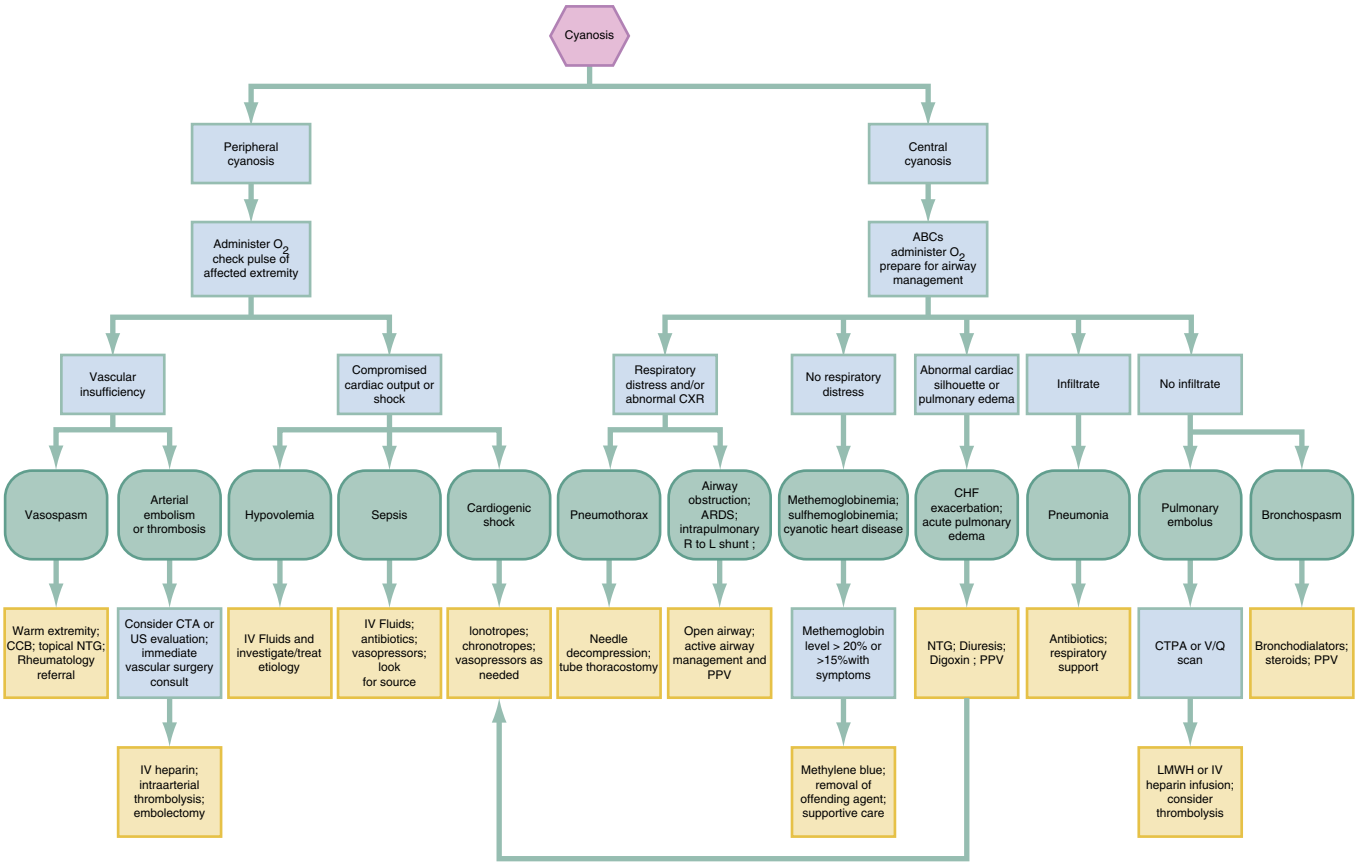

Fig. 10.5 Algorithmic Management Approach to Cyanosis. *ABCs,* Airway, breathing, circulation; *ARDS,* acute respiratory distress syndrome; *CCB,* calcium channel blocker; *CHF,* congestive heart failure; *CTA,* CT angiogram; *CTPA,* computed tomography pulmonary angiography; *CXR,* chest radiograph; *IV,* intravenous; *LMWH,* low-molecular-weight heparin; *NTG,* nitroglycerin; O_2, oxygen; *PE,* pulmonary embolus; *PPV,* positive pressure ventilation; *US,* ultrasound *V/Q,* ventilation-perfusion scan. Patients with chronic cyanotic heart disease may not require ICU care or even hospital admission. Disposition should be discussed with the patient's cardiologist. A V/Q scan may be obtained when CTPA is unavailable or contraindicated.

therapy. If oxygenation compromise is sufficient to cause ischemic chest pain, prompt correction of the underlying hemoglobin abnormality is undertaken simultaneously with conventional treatment of the ischemia. Although several specific treatments are discussed here, the cause of the cyanosis may be elusive, and hospitalization is required in all but chronic stable cases.

Methemoglobinemia and Sulfhemoglobinemia

If cutaneous exposure to an inciting agent (i.e., aniline dye) has recently occurred, surface decontamination with soap and water is recommended. Emergency personnel should use appropriate protective equipment. For asymptomatic patients with a methemoglobin level less than 20%, removal of the offending agent is usually the only necessary treatment; the methemoglobin level should return to normal within 24 to 36 hours, with a maximum of 100 mg. Urgent treatment with oxygen and methylene blue (1 to 2 mg/kg IV over 5 minutes) is indicated for patients with symptomatic hypoxia (e.g., dysrhythmias, angina, respiratory distress, seizures, coma) or methemoglobin levels greater than 30%. The response to treatment is usually rapid, within 15 minutes. In patients with continued symptoms or persistent methemoglobin levels greater than >30%, a repeat dose of 1 mg/kg can be administered.[13]

Methylene blue is relatively contraindicated in patients with known G6PD deficiency as it may result in massive hemolysis. In these patients, ascorbic acid may be used, however repeat doses are required with limited comparative effect.[14] Additionally, methylene blue is a potential teratogen and in pregnant patients, a risk-benefit analysis is warranted with consideration of supplemental therapies such as C-section delivery, hyperbaric oxygen, and exchange transfusion.[2] Consultation with the local poison control center may be of benefit.

Sulfhemoglobinemia is suggested when the laboratory reports an elevated methemoglobin level and the patient does not respond to methylene blue. Sulfhemoglobinemia is irreversible for the life of the erythrocyte and there is no known antidote. Treatment of sulfhemoglobinemia is supportive in addition to the removal of the causative agent. Exchange transfusion of RBCs has been described as a treatment,[15] but there are no controlled studies of this modality.

Other Causes of Cyanosis

Acute therapy for patients with symptomatic polycythemia with resultant hyperviscosity syndrome includes phlebotomy and volume expansion with isotonic crystalloid. The goal is to achieve a normal hematocrit (45%). Long-term therapy is focused on the underlying cause, and patients require referral to a hematologist.

Raynaud phenomenon is treated by warming the affected digits and extremities and protection from cold environments. Vasodilating agents (e.g., topical nitroglycerin, calcium channel blockers, endothelin receptor antagonists, phosphodiesterase inhibitors, botulinum toxin) may be useful in management.[12] If there is no improvement of localized peripheral cyanosis with warming and administration of 100% oxygen, arterial insufficiency or occlusion may be present. In cases of critical limb ischemia, IV heparin should be considered in consultation with a vascular surgeon. Vascular bypass, intraarterial thrombolysis, or stenting may be indicated. Embolic sources, such as endocarditis and abdominal aortic aneurysms, should also be considered.

PATIENT DISPOSITION

Admission

All patients with a first episode of cyanosis or an uncertain cause require hospitalization. Cardiology consultation and referral are recommended for children with a first episode of congestive heart failure and newly diagnosed or suspected congenital heart disease. Surgical consultation and intervention are indicated for acute arterial occlusion from embolic or thrombotic sources. Patients with symptomatic methemoglobinemia, a methemoglobin level over 15%, and those treated with methylene blue should be admitted for continued observation.

Discharge

Patients with peripheral cyanosis from vasospasm, those with asymptomatic methemoglobinemia less than 15% with removal of the offending agent, and stable patients with primary pulmonary disease may be treated as outpatients after several hours of monitoring in the ED. Follow-up should occur within 24 hours unless the patient has a previous diagnosis of chronic cyanosis. Instructions should clearly state that if the cyanosis worsens, or if dyspnea, altered mentation, or chest pain occurs after discharge, the patient should return immediately to the ED. Any identified precipitating agents should be removed.

CHAPTER 10: QUESTIONS AND ANSWERS

1. Which of the following statements regarding methemoglobin is true?

a. Methemoglobin begins to produce cyanosis when its concentration reaches 25% of total hemoglobin.
b. Methemoglobin changes from dark purple to light red when exposed to room air.
c. Methemoglobin normally accounts for 5% of total hemoglobin.
d. Methylene blue accelerates the reduction of methemoglobin to hemoglobin.
e. The primary method of reducing methemoglobin to hemoglobin is glucose-6-phosphate dehydrogenase (G6PD)–dependent.

Answer: d. Methemoglobin normally accounts for less than 1% of total hemoglobin. Cyanosis generally results when more than 10% to 15% of the total hemoglobin is methemoglobin (absolute level of 1.5 g/dL), which has a dark purple-brown color, even when exposed to room air. Methemoglobin is reduced to ferrous hemoglobin primarily by nicotinamide adenine dinucleotide (NADH)–cytochrome b5 reductase, an enzyme system present in red blood cells. A secondary nicotinamide adenine dinucleotide phosphate (NADPH)–dependent system uses glutathione and G6PD to reduce methemoglobin to hemoglobin. This secondary pathway normally plays a minor role but is accelerated by methylene blue.

2. Which of the following conditions produces central cyanosis?

a. Hypothermia
b. Raynaud phenomenon
c. Shock
d. Venous insufficiency
e. Ventricular septal defect

Answer: e. Central cyanosis is caused by decreased arterial oxygen saturation, often secondary to shunting of venous unsaturated hemoglobin into the arterial circulation, or the presence of abnormal hemoglobin. A ventricular septal defect causes shunting of deoxygenated blood from the right side of the heart to the left, with resultant decreased arterial oxygen saturation and central cyanosis. The remaining options would cause peripheral cyanosis.

3. In the cyanotic patient, clinical improvement with supplemental oxygen is most suggestive of which of the following underlying processes?

a. Arterial emboli
b. Congenital heart disease with right-to-left shunting
c. Hyperventilation
d. COPD
e. Methemoglobinemia

Answer: d. Clinical improvement with oxygen suggests diffusion impairment, hypoventilation, or an increased V/Q ratio due to mismatch. Patients who do not respond to oxygen are more likely to have decreased V/Q ratio abnormalities, such as shunting from pulmonary consolidation or congenital heart disease with right-to-left shunting, or abnormal hemoglobin. Arterial emboli will generally not be affected by supplemental oxygen.

4. Soon after receiving topical upper airway anesthesia with benzocaine, a patient becomes tachypneic and complains of chest pain. The patient is noted to be cyanotic. Supportive measures are initiated, and CO-oximetry reveals a methemoglobin level of 40%. Which of the following should be administered?

a. Benadryl
b. Hyperbaric oxygen
c. Methylene blue
d. Nitroglycerin
e. Thrombolytics

Answer: c. Local anesthetics such as benzocaine, lidocaine, and prilocaine can cause an acquired methemoglobinemia. Urgent treatment with oxygen and methylene blue is indicated in such patients, especially when accompanied by symptomatic hypoxia (e.g., dysrhythmias, angina, respiratory distress, seizures, coma) and methemoglobin levels greater than 20%.

5. An otherwise healthy 35-year-old woman presents with headache, mild shortness of breath, and central cyanosis. She is currently taking trimethoprim-sulfamethoxazole and phenazopyridine for

CHAPTER 10: QUESTIONS AND ANSWERS—cont'd

a urinary tract infection. She does not improve with supplemental oxygen. Her chest radiograph is normal. CO-oximetry shows a methemoglobin level of 28%. Her medications are withheld. The patient shows no improvement after 2 mg/kg of methylene blue is administered. Ongoing management should include which of the following treatments?

a. Calcium channel blockers
b. Hydroxocobalamin
c. Phlebotomy
d. Sodium thiosulfate
e. Supportive care

Answer: e. This patient likely has sulfhemoglobinemia, a rare complication of the medication phenazopyridine (Pyridium), as well as sulfa-containing drugs such as trimethoprim-sulfamethoxazole. Standard CO-oximetry will often report sulfhemoglobin as methemoglobin. Both sulfamethoxazole and phenazopyridine can also cause methemoglobinemia. Patients with an elevated methemoglobin level and no response to methylene blue likely have sulfhemoglobinemia, which is less severe than methemoglobinemia and only requires supportive care and removal of the offending agent. Phlebotomy is the treatment for polycythemia. Sodium thiosulfate and hydroxocobalamin are both used to treat cyanide toxicity, and calcium channel blockers may be used to treat peripheral cyanosis resulting from vasospasm (Raynaud phenomenon).

11

Syncope

Marc Probst

KEY CONCEPTS

- Syncope is defined as a sudden, spontaneous loss of consciousness and postural tone with rapid, complete, and spontaneous recovery. This loss of consciousness typically lasts seconds to minutes and is not followed by a persistent alteration in mental status.
- Syncope is caused by a transient global cerebral hypoperfusion. It is the final common pathway for a wide variety of underlying causes, and requires a systematic approach to diagnosis.
- Pre-syncope, or near-syncope, is defined as the sudden onset of a sense of impending or incomplete loss of consciousness.
- Most syncopal episodes have benign causes, but serious underlying conditions are possible. The causes of syncope can be organized into the following three categories: (i) cardiac, (ii) reflex (includes vasovagal syncope), (iii) orthostatic.
- National guidelines recommend a 12-lead electrocardiogram for all patients with syncope but most patients without serious underlying disease will have a normal or nondiagnostic electrocardiogram (ECG).
- National guidelines do not recommend routine laboratory testing or imaging (e.g., chest x-ray, neuroimaging, echocardiogram) and these tests should be obtained only when history or physical examination suggests such evaluation.
- Hospitalization or placement in an observation unit after emergency department (ED) evaluation for syncope is based on the specific, identified cause (e.g., gastrointestinal hemorrhage, malignant arrhythmia, pulmonary embolism).
- Patients with a clear description of reflex syncope (e.g., vasovagal syncope) without serious underlying disease are generally appropriately discharged directly from the ED.
- Several syncope clinical risk scores have been developed for ED use, but none have been definitively shown to outperform unaided clinical gestalt with respect to risk stratification and resource utilization.

FOUNDATIONS

Epidemiology

Syncope is a common clinical entity with a lifetime prevalence between 20% and 40%, and is slightly more common in women than in men.[1] The age distribution for syncope is bimodal, with a peak in early adulthood, around age 20 years, and a second peak in later adulthood, around and after age 60 years. Pre-syncope is a less common complaint than syncope for emergency department (ED) visits, perhaps because many patients with pre-syncope do not seek evaluation. Pre-syncope and syncope are associated with similar clinical outcomes at 30 days.[2]

Pathophysiology

Syncope is defined as a transient, spontaneous loss of consciousness and postural tone with rapid, complete, and spontaneous recovery, caused by global cerebral hypoperfusion, generally from a drop in cardiac output or systemic blood pressure. Loss of consciousness typically lasts seconds to minutes and is not followed by a persistent alteration in mental status. (For a discussion of the approach to altered mental status, see Chapter 12.) Approximately 8 to 10 seconds of hypoperfusion to both cerebral cortices and the brainstem reticular activating system will result in transient loss of consciousness and the inevitable loss of postural tone. Syncope is the final common pathway for a wide variety of underlying causes, (e.g., dehydration, hemorrhage, cardiac arrhythmia, structural heart disease) making for a broad differential diagnosis.

DIAGNOSTIC APPROACH

Differential Considerations

The causes of syncope can be organized into three broad categories:

(i) Reflex
(ii) Orthostatic
(iii) Cardiac (see Box 11.1).

Reflex syncope, also known as neurally mediated syncope, is the most common cause of syncope, particularly among younger patients. It is caused by inappropriate vasodilation, bradycardia, or both, and includes vasovagal syncope, carotid sinus syndrome, and situational syncope. Vasovagal syncope is commonly encountered in the ED and is typically characterized by a prodrome of some combination of the following associated symptoms: nausea, pallor, diaphoresis, lightheadedness, warmth, chills, and blurred or darkening vision. Common triggers include intense fear, emotion, anxiety, or pain; being in a warm, crowded place; prolonged standing; or other noxious stimuli, such as when a layperson encounters a traumatized traffic accident victim. Vasovagal syncope is a clinical diagnosis based on history, physical examination, and eyewitness accounts, if available. Carotid sinus syndrome is caused by carotid sinus hypersensitivity, which is defined as a pause of ≥3 seconds and/or a ≥50 mm Hg decrease in systolic blood pressure upon stimulation of the carotid sinus.[3] This entity is more common in older patients and in men. Situational syncope is defined by its close association with a specific action such as urination, defecation, recent or overeating, coughing, sneezing, swallowing, laughing, breath holding, or post-exercise. It can be preceded by the same prodromal symptoms as vasovagal syncope.

Orthostatic syncope, also known as postural hypotension, is defined by a decrease in blood pressure of at least 20 mm Hg systolic, and at least 10 mm Hg diastolic within 3 minutes of standing. This condition is associated with dehydration, blood loss, adverse medication effects, autonomic dysfunction, alcohol consumption, and older age. Syncope or pre-syncope will occur when the autonomic response is insufficient to counteract the drop in blood pressure associated with postural change. Measuring orthostatic vital signs in the ED setting is not generally useful since they do not appear to independently predict 30-day serious outcomes, nor do they reliably diagnose or exclude orthostatic

BOX 11.1 Cardiac Diagnoses Associated With Syncope

- Dysrhythmias: (See Box 11.2 for further detail)
  - Tachydysrhythmias
  - Bradydysrhythmias
- Structural causes:
  - Hypertrophic cardiomyopathy
  - Aortic stenosis
  - Severe pulmonic stenosis
  - Acute myocardial infarction/ischemia
  - Cardiac masses (e.g., atrial myxoma)
  - Pericardial tamponade
  - Prosthetic valve dysfunction
  - Ventricular assist device (VAD) dysfunction
- Cardiopulmonary causes:
  - Acute aortic dissection
  - Pulmonary embolism
  - Pulmonary hypertension

syncope, unless the vital sign changes upon standing reproduce the symptoms with which the patient presented.[4]

Cardiac syncope is divided into three general categories: Dysrhythmic, structural, and cardiopulmonary (see Box 11.1). This is the most serious form of syncope and must be distinguished from reflex or orthostatic syncope, when feasible. Cardiac dysrhythmias most often occur in patients with underlying structural heart disease, a prior diagnosis of a dysrhythmia syndrome, or a recent or acute myocardial infarction. Several dysrhythmias can lead to syncope or pre-syncope, including both brady- and tachydysrhythmias (see Box 11.2A). The symptoms caused by a given dysrhythmia will vary depending on the severity of the disruption of cardiac output and the patient's cardiovascular reserve. Patients with underlying heart disease, such as coronary artery disease (CAD), valvular disease, congenital heart disease, cardiomyopathy, or cardiac channelopathy (e.g., Brugada syndrome, long QT syndrome), are at higher risk for dysrhythmias. Various ECG findings are suggestive of such underlying heart disease (see Box 11.2B). Dysrhythmic syncope classically presents without a prodrome, although patients with tachydysrhythmias may report palpitations or chest discomfort prior to losing consciousness.

Structural heart disease has a significant morbidity and mortality without intervention, and also predisposes patients to serious dysrhythmia, making early diagnosis key to maximizing good outcomes. Structural causes of syncope include valvular disease (e.g., aortic stenosis), hypertrophic cardiomyopathy, pericardial tamponade, and atrial myxoma, among others (see Box 11.1).

Cardiopulmonary causes of syncope include conditions such as pulmonary embolism (PE), pulmonary hypertension, acute myocardial infarction (MI), and acute aortic dissection. Syncope is only a part of their presentation, and patients will have associated signs and symptoms of these conditions. Generally healthy patients with typical syncope and no findings suggestive of cardiopulmonary causes should not undergo specific testing, such as d-dimer assay or CT angiography. Routine testing of all ED syncope patients for PE, for example, with a d-dimer assay or CT pulmonary angiogram, is not indicated, and would lead to significant over-testing due to the low prevalence of this disease in this cohort.[5]

Cerebrovascular conditions associated with loss of consciousness should be considered, however, these will typically present with other cardinal signs and symptoms, and would generally not meet the strict definition of syncope. For example, a spontaneous subarachnoid hemorrhage (SAH) or basilar artery migraine could present with syncope

BOX 11.2A Dysrhythmias Potentially Associated With Syncope

- Atrioventricular (AV) Block
  - Mobitz type II second degree
  - Third degree (complete heart block)
- Sinus pause >3 s
- Sick sinus syndrome
- Persistent sinus bradycardia (<40 beats/min)
- Ventricular tachyarrhythmias
  - Monomorphic ventricular tachycardia
  - Polymorphic ventricular tachycardia (i.e., Torsades de pointes)
  - Ventricular fibrillation
- Supraventricular tachyarrhythmias
  - Atrial flutter/fibrillation
  - AV nodal reentry tachycardia
  - AV reentry tachycardia
- Alternating left and right bundle branch block
- Pacemaker or automatic implantable cardioverter-defibrillator malfunction with cardiac pauses

BOX 11.2B ECG Abnormalities Potentially Associated With Syncope

- Signs of acute myocardial ischemia (e.g., ST elevation/depression, T-wave inversions, new bundle branch block, new abnormal Q waves)
- Pre-excitation suggestive of Wolff-Parkinson-White syndrome
- Long QT interval suggestive of congenital or acquired form of the long QT syndrome (e.g., Jervell and Lange-Nielsen syndrome.)
- Short QT interval suggestive of short QT syndrome
- Right bundle branch block pattern with ST-elevation in leads V1–V3 suggestive of Brugada syndrome
- Inverted T waves in right precordial leads and epsilon waves suggestive of arrhythmogenic right ventricular cardiomyopathy
- Left ventricular hypertrophy, prominent abnormal Q waves, or deeply inverted T waves suggestive of hypertrophic cardiomyopathy
- Low voltages or electrical alternans suggestive of pericardial effusion
- Right ventricular strain pattern suggestive of pulmonary embolism

but would generally be preceded and accompanied by an acute headache, vertigo, or alteration in mental status. Acute stroke or transient ischemia attack does not cause syncope because it does not produce global hypoperfusion.

Syncope mimics are any of several conditions encountered in the ED that can mimic syncope, such as mechanical fall, intoxication, hypoglycemia, head trauma, and seizures (see Box 11.3). Differentiating these conditions from true syncope can be challenging, particularly without collateral history from witnesses. Seizures can be confused with syncope partly due to the fact that convulsions and incontinence, although classically associated with seizure, can also be seen with syncope as well. Rhythmic motor activity in the setting of syncope is often referred to as "convulsive syncope" and is usually brief (under 20 seconds). Unlike epileptic seizure, the motor activity and loss of consciousness of syncope are not associated with any post-ictal state.

Pivotal Findings

Taking a careful history is key to determining the etiology of the syncopal episode. In particular, the setting (e.g., bathroom after voiding, restaurant after a large meal, blood draw, crowded place), body position (e.g., seated, prone, standing, changing position), and context (e.g., exertion, emotional event, painful stimulus, fasting state) should

BOX 11.3 Syncope Mimics

- Seizure/epilepsy
- Hypoglycemia
- Hypoxemia
- Fall
- Concussion
- Intoxication (e.g., ethanol, opiates, carbon monoxide)
- Vertebrobasilar transient ischemic attack
- Cataplexy
- Drop attacks
- Psychogenic pseudo-syncope

BOX 11.4 Medications Associated With Orthostatic Hypotension

Vasodilators:
- Beta blockers, calcium channel blockers, nitrates, hydralazine, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, phenothiazines, phosphodiesterase inhibitors (e.g., sildenafil, tadalafil)
- Diuretics (e.g., hydrochlorothiazide, furosemide)
- Central antihypertensives (e.g., clonidine, methyldopa)
- QT-prolonging agents (e.g., amiodarone, flecainide, procainamide, quinidine, sotalol)

Psychoactive agents:
- Anticonvulsants (e.g., carbamazepine, phenytoin)
- Antipsychotic drugs (e.g., olanzapine, risperidone)
- Antiparkinsonian agents (e.g., levodopa, pramipexole)
- Central nervous system depressants (e.g., barbiturates, benzodiazepines)
- Antidepressants (e.g., monoamine oxidase inhibitors, Selective serotonin receptor reuptake inhibitors, trazodone, tricyclic antidepressants)
- Opiates analgesics (e.g., morphine)
- Sedating antihistamines (e.g., diphenhydramine)
- Cholinesterase inhibitors (e.g., donepezil, tacrine, galantamine)
- Alcohol
- Digitalis
- Neuropathic agents (e.g., vincristine)
- Bromocriptine

be established. Age, current medications, personal history of prior syncope, family history, and past medical history are important, as with any cardiopulmonary compliant. The risk of adverse events increases gradually with age, and is low under age 45 years. A careful medication history can also lead to a diagnosis of drug-related orthostatic hypotension (see Box 11.4). Any family history of sudden cardiac death, recurrent syncope, significant dysrhythmia, or early CAD should raise concern for cardiac syncope. Many comorbidities can place a patient at higher risk for adverse events, particularly a history of heart failure, CAD, dysrhythmia, or structural heart disease. Risk factors for PE should also be explored.

These clinical variables, along with associated signs or symptoms (see the following sections) can inform the pretest probability of cardiac, orthostatic, situational, or vasovagal syncope. For example, syncope occurring after quickly rising from supine to a standing position may indicate orthostatic hypotension. Syncope occurring during a blood draw likely represents a vasovagal episode. Syncope during or immediately after urination (micturition syncope), defecation (defecation syncope), eating a large meal (post-prandial syncope), coughing or swallowing may indicate a situational syncope. Syncope during exercise may prompt concern for cardiac outflow obstruction such as hypertrophic cardiomyopathy or aortic stenosis or inability to increase cardiac rate in response to exercise (e.g., heart block).

Any prior episodes and relevant previous testing (e.g., recent echocardiography, stress test) should be explored in an attempt to reduce low-value repeat testing. The clinical approach to pre-syncope is the same as for syncope—pre-syncope exists on a continuum with syncope, with similar rates of adverse events. Thorough ED evaluation fails to identify the etiology of syncope/pre-syncope roughly 50% of the time.

Symptoms

Several symptoms should be explored during the history-taking process including chest pain, dyspnea, palpitations, abdominal or back pain, vaginal bleeding, headache, and any associated neurologic symptoms. Chest pain could suggest a diagnosis of acute coronary syndrome with dysrhythmia, PE, or aortic dissection, while dyspnea could suggest PE or underlying heart failure. Palpitations may suggest a dysrhythmia. Abdominal or back pain could suggest a rupturing aortic aneurysm. Vaginal bleeding suggests possible ectopic pregnancy; severe headache may indicate SAH. Prodromal symptoms such as lightheadedness, warmth, nausea or vomiting, and pallor help make the diagnosis of vasovagal syncope.

Other symptoms may suggest the presence of a syncope mimic. A preceding aura or prolonged confusion/somnolence could indicate a seizure with a post-ictal state. Convulsions can occur with either syncope or seizure, but epileptic convulsions generally last longer (>20 myoclonic jerks).[6] A mechanical fall leading to blunt head trauma and loss of consciousness could represent a mild traumatic brain injury, and not syncope, although differentiating between the two can be difficult in practice, especially in older patients with cognitive deficits or in those whose head trauma induces retrograde amnesia.

Signs

The physical examination, which usually is normal, is generally not helpful in the evaluation of syncope. Hypotension may indicate volume loss from dehydration or hemorrhage. Otherwise, unexplained tachypnea, tachycardia, or hypoxia should prompt consideration of PE. Orthostatic blood pressure measurement is not helpful unless the patient's symptoms are reproduced in synchrony with the fall in blood pressure. Orthostatic hypotension has a sensitivity for hypovolemia of only approximately 70%.[6]

The cardiovascular examination may reveal cardiac murmurs indicative of structural heart disease (e.g., aortic stenosis) or reveal signs of new-onset heart failure (e.g., elevated jugular pressure, bilateral lower extremity edema, third heart sound, rales or wheezes on lung auscultation). A pulse deficit, in the correct context, may raise suspicion for aortic dissection. We do not recommend performing diagnostic carotid sinus massage in the ED due to the lack of high-quality evidence supporting its diagnostic utility in this setting. Carotid sinus massage (CSM) may be considered as part of an inpatient or observation unit evaluation of older patients (>40 years) with syncope associated with abrupt neck movement or neck pressure, and no identified underlying cause on detailed evaluation.

A neurologic examination, including a cognitive assessment, should be performed, and based on the definition of syncope, the patient should be neurologically at their baseline. Any sign of a new neurologic deficit should prompt consideration of an acute neurologic condition.

Examination of the head, neck, and extremities should be done to assess for signs of trauma, since syncope is often associated with fall. Rectal examination for gross blood or melena is recommended if gastrointestinal hemorrhage is suspected and the patient is not able to report recent stool characteristics.

Ancillary Testing

Electrocardiogram

The 12-lead ECG is the most commonly ordered test in the ED evaluation of syncope. Although it is rarely diagnostic, this test is safe, noninvasive, and relatively inexpensive. We recommend a 12-lead ECG in all cases of syncope except in otherwise healthy patients under age 40 with no significant conditions identified by careful history or physical examination, and with a history clearly consistent with vasovagal syncope. If there is uncertainty, we recommend obtaining a 12-lead ECG to evaluate for underlying conduction disturbance or occult myocardial injury. Dysrhythmias, preexcitation, and a shortened PR or prolonged corrected QT interval may be identified on the 12-lead ECG. Certain ECG abnormalities are considered highly likely to be casually related to the syncope, such as sinus bradycardia less than 40 beats/min or sinus pauses greater than 3 seconds, third-degree (complete) heart block, Mobitz II second-degree AV block, and others (see Box 11.2A). Other ECG abnormalities may raise concern for other serious underlying conditions (see Box 11.2B). For example, a pseudo-right bundle branch block in association with ST elevation in leads V_1 through V_3 suggests Brugada syndrome. Acute myocardial ischemia or cardiac hypertrophy may be revealed. An ECG showing a right ventricular strain pattern may suggest PE, whereas diffuse ST-elevation can help diagnose pericarditis, which may be accompanied by myocarditis. In patients over 40 years of age without a clear causative finding for syncope, continuous cardiac monitoring in the ED for 4 to 6 hours, both at rest and during light exertion, may be helpful in identifying dysrhythmias not evident on the initial ECG.[7]

Laboratory Testing

Routine laboratory testing, although often done for patients with syncope, is not supported by evidence and is not recommended in national guidelines. In patients with suspected anemia or blood loss from heavy menses or gastrointestinal hemorrhage, a complete blood count (CBC) may be useful. Electrolytes are not useful as a screening test in healthy patients but should be obtained when there is concern for elevated or low potassium, based on dietary habits (e.g., excessive consumption of black licorice causing hypokalemia) or medications (excessive or inadequate potassium supplementation in a patient taking a diuretic). Hyponatremia may arise in the context of polydipsia, particularly in patients on certain psychotropic medications, but is usually accompanied by some alteration of mental status.

Cardiac biomarkers are often obtained in the context of syncope, particularly in older adults. Troponin testing is indicated if acute MI is suspected though acute MI rarely presents with isolated syncope without other cardiopulmonary symptoms, particularly chest pain or shortness of breath.[8] Natriuretic peptide levels appear to have prognostic utility for predicting 30-day serious cardiac outcomes in adults with syncope.[9] A d-dimer assay should be reserved only for adult patients who have either signs and symptoms of PE (beyond isolated syncope), or significant risk factors for venous thromboembolism.

Urine Testing

All females of child-bearing age with irregular menses, abdominal pain or tenderness, or a suspicion of pregnancy should undergo urine testing for pregnancy. Ectopic pregnancy can present with syncope, which will be accompanied by abdominal findings suggesting the diagnosis and is easily excluded if the pregnancy test is negative.

Imaging

Chest Imaging

We do not recommend routine chest x-radiography for syncope patients, absent an indication on history or physical examination.

BOX 11.5 Critical Diagnoses Associated With Syncope

- Myocardial infarction
- Life-threatening dysrhythmias
- Acute aortic dissection
- Critical aortic stenosis
- Hypertrophic cardiomyopathy
- Pericardial tamponade
- Abdominal aortic aneurysm (ruptured)
- Massive pulmonary embolism
- Subarachnoid hemorrhage
- Toxic-metabolic derangements
- Severe hypovolemia or hemorrhage
- Ruptured ectopic pregnancy
- Sepsis

Absent these indications, the test is of low diagnostic yield, exposes the patient to unnecessary radiation, and is wasteful of time and resources. In patients with suggestive symptoms or findings, a chest x-ray may reveal an infectious process, cardiomegaly, or signs of heart failure, which may inform the diagnosis. Patients with associated signs and symptoms concerning for PE (e.g., tachycardia, hypoxia, tachypnea, chest pain, dyspnea) may require a CT pulmonary angiogram if the d-dimer is elevated or if they are sufficiently high-risk (see Chapter 74).

Neuroimaging

Patients with head trauma after syncope may require a CT scan of the head to assess for traumatic injury. Patients with altered mental status or new neurologic deficits would also require neuroimaging; however these would not be classified as syncope, by definition. Despite being of extremely low diagnostic yield, the head CT continues to be a costly and commonly ordered test.

Echocardiography

Bedside echocardiography is not routinely indicated for evaluation of syncope. In patients with known or suspected structural heart disease, bedside ultrasound can assess for right ventricular strain, pericardial effusion with tamponade, valvular disease, and other relevant structural findings. Similarly, echocardiography performed by a cardiologist may be indicated in select cases where the pre-test probability of structural heart disease is high based on past medical history, ECG, or cardiac biomarkers, but is otherwise of low diagnostic yield.[10] Clinicians in the ED should also consider assessing the abdominal aorta with bedside ultrasound in older patients with vascular risk factors, particularly those with abdominal or flank pain, given that a ruptured abdominal aortic aneurysm can present with syncope.

DIAGNOSTIC AND MANAGEMENT ALGORITHM

Patients presenting with syncope generally do not require immediate intervention or resuscitation. With these stable patients, the next consideration is whether ancillary testing beyond an ECG is indicated. In certain scenarios, such as clear vasovagal syncope, confirmed by history, in an otherwise healthy patient, there is no need for further testing (e.g., laboratory or radiology). Ancillary testing may be required to evaluate for serious diagnoses in certain patients with suggestive history or findings (see Boxes 11.5 and 11.6 for a list of serious diagnoses). Once ED testing is complete, either a diagnosis will be evident, or the episode will remain unexplained. There are numerous possible critical and emergent diagnoses that can present with syncope. For

BOX 11.6 Emergent Diagnoses Associated With Syncope

Systemic Hypoperfusion Resulting in Central Nervous System Dysfunction

Cardiovascular System–Mediated

Outflow Obstruction

Mitral, aortic, or pulmonic stenosis
Hypertrophic cardiomyopathy
Atrial myxoma
Pulmonary embolism
Pulmonary hypertension
Cardiac tamponade
Congenital heart disease

Reduced Cardiac Output

Tachycardia
- Supraventricular tachycardia
- Ventricular tachycardia
- Ventricular fibrillation
- Wolff-Parkinson-White syndrome
- Torsades de pointes

Bradycardia
- Sinus node disease
- Second-degree and third-degree atrioventricular block
- Prolonged QT syndrome
- Brugada syndrome
- Pacemaker malfunction
- Implanted cardioverter-defibrillator malfunction

Other Cardiovascular Disease

Aortic dissection
Myocardial infarction
Cardiomyopathy

Neurally Mediated (Neurocardiogenic)

Reflex syncope (vasovagal)
- Emotion
- Pain
- Instrumentation
- Valsalva—elevated intrathoracic pressure, weightlifting; tussive, sneeze

Situational
- Carotid sinus sensitivity (necktie, shaving syncope)
- Post-exercise
- Gastrointestinal—swallowing, vomiting, defecation
- Post-micturition

Orthostatic Mediated

Volume depletion
- Anemia—hemorrhage

Primary autonomic failure
Secondary autonomic failure
Medication-induced (see Box 11.4)

Focal Hypoperfusion of Central Nervous System Structures

Cerebrovascular disease
Hyperventilation
Subclavian steal
Subarachnoid hemorrhage
Basilar artery migraine
Cerebral syncope

Central Nervous System Dysfunction With Normal Cerebral Perfusion
Hypoglycemia
Hypoxemia—asphyxiation
Seizure
Narcolepsy
Psychogenic
- Anxiety disorder
- Conversion disorder
- Somatization disorder
- Panic disorder
- Breath-holding spells

Intoxication
- Medications
- Carbon monoxide
- Undetermined causes

unexplained syncope, the clinician should risk-stratify the patient using best clinical judgment regarding the constellation of findings from history, physical examination, and any ancillary testing, alone, or in combination with a risk-stratification tool, also known as a clinical risk score (see **Risk-stratification** in the following section). The disposition decision for patients with unexplained syncope has two to three general options: direct discharge from the ED, admission to the hospital, and in some settings, observation care. This decision should be based on the results of the clinical risk-stratification, as well as on the particular health and living circumstances, values, and preferences of the patient. When more than one reasonable management option exits, shared decision making should be employed with appropriate patients, that is, those willing and able to participate in the clinical decision-making process. See Figs. 11.1 and 11.2 for diagrams of diagnostic and management algorithms for syncope in the ED.

RISK-STRATIFICATION

Syncope risk-stratification has been an area of active research for over 20 years. Numerous risk-stratification tools have been published in an attempt to guide the management and disposition of patients with syncope. Examples of these include the San Francisco Syncope Rule, the OESIL Risk Score, the STePS Score, the Canadian Syncope Risk Score, and, more recently, the FAINT Score, among others. Although derivation studies have been quite promising, there is no clear evidence that these risk scores are superior to thoughtful clinical judgment with regard to predictive accuracy and optimization of resource utilization. While often displaying a high sensitivity for predicting adverse events, many of these risk scores have suffered from low specificity. Nonetheless, risk scores provide a useful, objective framework for estimating short- and medium-term risk, and can inform clinical decision making. See Box 11.7 for a list of clinical variables included in three risk scores designed for ED use and other commonly used short-term risk factors. At this time, they are best used in conjunction with clinical gestalt but cannot be recommended as a stand-alone tool. Lacking clear evidence of efficacy or superiority, these scores are best used as part of a consensus approach to syncope within a particular ED.

EMPIRIC MANAGEMENT

The ED management of syncope is driven largely by the presumed or confirmed diagnosis. Since syncope is a symptom, or chief complaint,

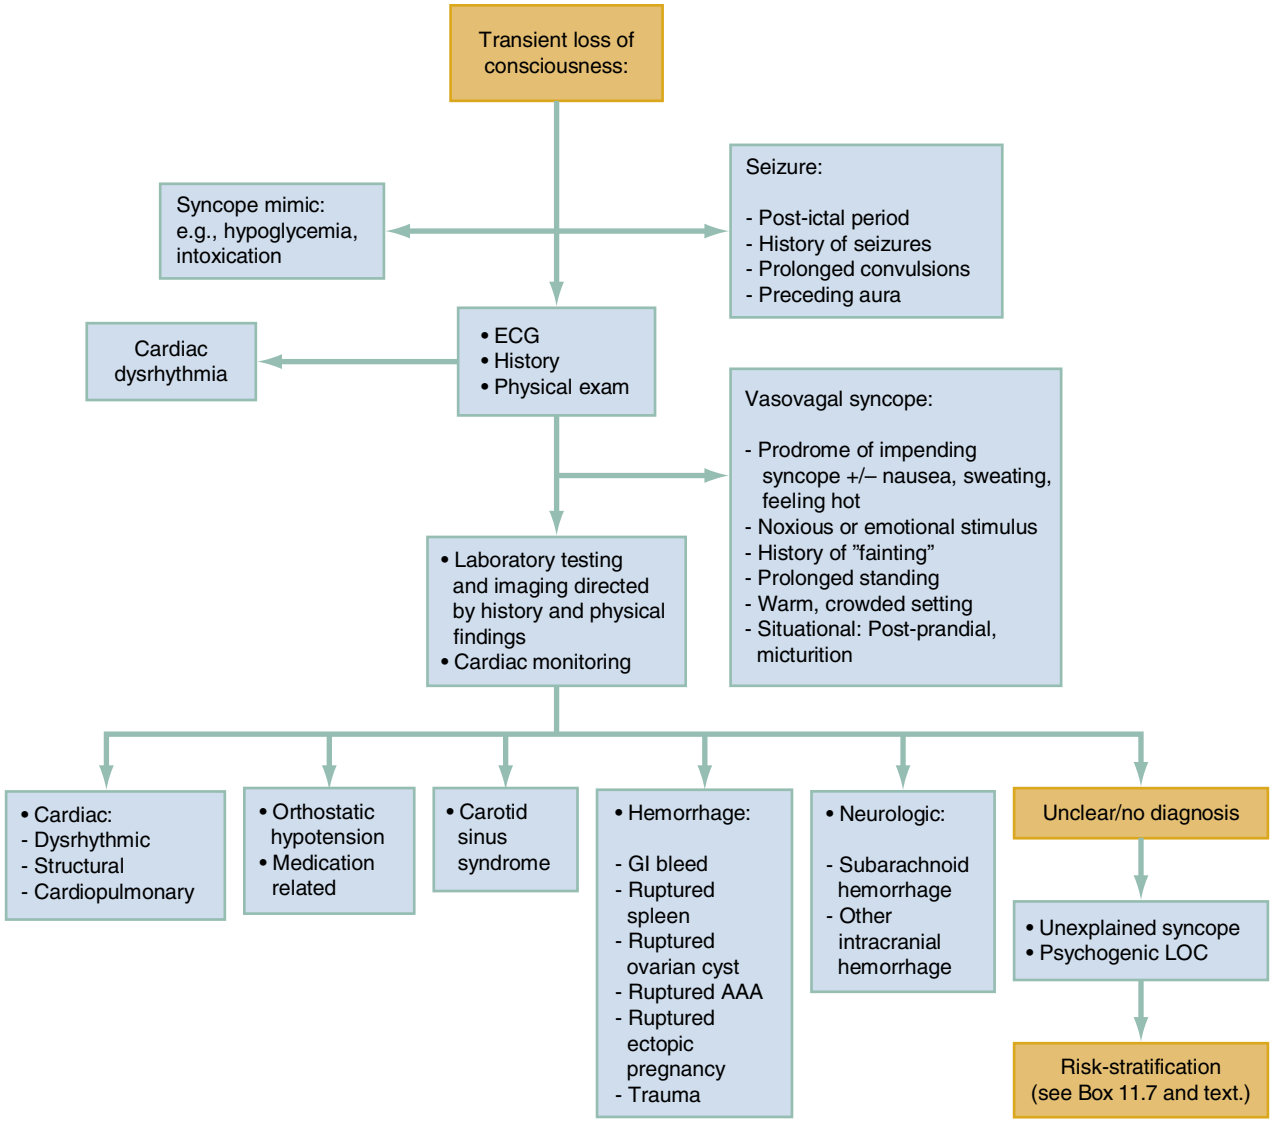

Fig. 11.1 Management Algorithm for Syncope in the Emergency Department. *AAA,* Abdominal aortic aneurysm; *LOC,* loss of consciousness.

it is not, per se, a treatable condition. Many syncope-related diagnoses require emergent treatment in the ED, for example, life-threatening dysrhythmias, gastrointestinal hemorrhage, ectopic pregnancy, MI, PE. For those patients in whom diagnostic uncertainty remains, disposition will be driven by the risk profile and circumstances of the patient, as described previously. In practice, factors that influence the decision to admit or discharge the patient include access to follow-up care, as well as the living situation, reliability, values, and preferences of the patient.

ED, Emergency department.

BOX 11.7 Clinical Variables From Syncope Clinical Risk Scores With Point Values

Canadian Syncope Risk Score

1. Predisposition to vasovagal syncope –1
2. History of heart disease +1
3. Any systolic pressure reading in the emergency department <90 or >180 mm Hg +2
4. Troponin level >99th percentile for normal population +2
5. Abnormal QRS axis (<–30 degrees or >110 degrees) +1
6. Prolonged QRS interval >130 ms +1
7. Prolonged corrected QT interval >.480 ms +2
8. Emergency department diagnosis of vasovagal syncope –2
9. Emergency department diagnosis of cardiac syncope +2

Score of –2 is very low risk, –1 or 0 is low risk, 1–3 is medium risk, and >3 is high risk

FAINT Score[a]

1. History of heart failure +1
2. History of cardiac arrhythmia +1
3. Initial abnormal 12-lead ECG result +1
4. Elevated N-terminal pro b-type natriuretic peptide (NT proBNP) >125 pg/mL +2
5. Elevated high-sensitivity troponin T >19 ng/L +1

San Francisco Syncope Risk Score[a]

1. History of congestive heart failure
2. Hematocrit <30%
3. Abnormal findings on 12-lead ECG or cardiac monitoring
4. History of shortness of breath
5. Systolic blood pressure <90 mm Hg at triage

Other Short-term Risk Factors

1. Older age
2. Male gender
3. Family history of early sudden death (under 50 years old)
4. Syncope without prodrome
5. Exertional syncope
6. Syncope while in supine position
7. Palpitations before syncope

[a] Absence of all of the clinical variables corresponds to "low-risk."

CHAPTER 11: QUESTIONS AND ANSWERS

1. Which of the following statements regarding the epidemiology of syncope is true?

a. Of athletes who die during exercise, the vast majority have had a prior episode of syncope.
b. People younger than 65 years account for 50% of all patients admitted for syncope from the emergency department.
c. Syncope in young adults is typically secondary to significant pathology.
d. Syncope is responsible for approximately 5% to 6% of all emergency department (ED) visits.
e. There is a slight female predominance among ED patients presenting with syncope.

Answer: e. Syncope accounts for approximately 1% to 2% of ED visits in the United States. There is a slight female predominance among ED patients with syncope. Approximately 32% of these patients are hospitalized, and people aged 65 years or older account for the majority of such hospitalizations. Benign causes of syncope predominate in adolescents and young adults. Approximately 30% of athletes who die during exercise have had a prior episode of syncope as a sentinel event.

2. Syncope resulting from serious pathology is usually caused by which of the following?

a. Transient ischemic attack (TIA)
b. Cardiac dysrhythmias
c. Pulmonary embolism
d. Atrial myxoma
e. Toxic-metabolic abnormalities

Answer: b. The principal serious causes of syncope are cardiac dysrhythmias. TIA is less frequently encountered but equally serious. Stroke generally does not cause isolated syncope. Toxic-metabolic abnormalities may induce syncope through alterations in blood pressure or cardiac rhythm. Structural cardiac lesions, such as atrial myxoma, and sudden interruption of right ventricular outflow by pulmonary embolism, can also cause sudden loss of consciousness but are less common.

3. Which of the following findings most strongly suggest that a patient presenting with syncope can be safely discharged from the emergency department (ED)?

a. Age under 85 years and a normal chemistry panel
b. A normal chest x-ray and CT scan of the head
c. Normal heart rate and temperature in the ED
d. Normal ECG findings and no past medical history
e. Absence of abdominal pain and absence of headache

Answer: d. A normal electrocardiogram in a patient without other significant risk factors (e.g., advanced age, preexisting heart disease) may be considered for outpatient disposition. The chemistry panel, chest x-rays, and CT head scan are commonly ordered but are of low diagnostic and prognostic utility. Abdominal pain, fever, and headache are important associated signs and symptoms to assess for, but their absence has little prognostic utility.

12

Depressed Consciousness and Coma

Charles Lei and Clay Smith

KEY CONCEPTS

- Coma is a state of depressed consciousness in which a patient is not aware, is not awake, and does not respond to vigorous stimulation. Consciousness consists of arousal (subcortical) and awareness (cortical).
- Damage to the dorsal brainstem, thalamus, axonal projections to the cortex, or extensive injury to bilateral cortices may result in depressed consciousness or coma.
- Toxicologic, metabolic, infectious, and other disorders causing diffuse brain injury cause 65% of coma cases; of these, toxins are the most common. Structural brain diseases account for most of the remaining cases.
- A patient with depressed consciousness is unlikely to provide a reliable history. Historical information should be elicited from other available sources, such as emergency medical services personnel, family members, the patient's belongings, or medical records.
- An abrupt onset of coma suggests a stroke, seizure, or cardiac event.
- The neurologic examination should include an evaluation of level of consciousness, cranial nerves, brainstem reflexes, and motor responses.
- Pinpoint pupils may represent a pontine infarct or intoxication from opioids, clonidine, or cholinergic substances.
- Nonconvulsive status epilepticus should be suspected in cases of coma of undetermined cause and is diagnosed by electroencephalography.
- Hypoglycemia and hypoxia are two easily identified and reversible causes of coma.
- An empiric trial of naloxone will lead to rapid reversal of opioid toxicity and other select medication overdoses.
- Targeted temperature management is recommended in comatose adult patients with return of spontaneous circulation after cardiac arrest from either a shockable or nonshockable rhythm, with a goal temperature range of 32°C to 36°C. In children who are comatose post arrest, it is reasonable to target a temperature range of 36°C to 37.5°C. Hyperthermia should be strictly avoided for all comatose postarrest patients.
- Most patients with coma will require intensive care monitoring. If the cause of coma is not treatable in the initial facility and the patient needs a higher level of specialty care (e.g., structural lesion requiring neurosurgery), then a coordinated transfer should be facilitated.

FOUNDATIONS

Coma is a state of depressed consciousness in which a patient is not aware, is not awake, and does not respond to vigorous stimulation. This stands in contrast to stuporous or lethargic patients, who also may have a decreased level of awareness or consciousness but can be aroused with external stimuli.

Epidemiology

Most cases of depressed consciousness or coma are the result of a metabolic derangement, usually a glucose disorder, drug overdose, or adverse drug effect, but other common causes include traumatic brain injury, systemic or central nervous system (CNS) infection, ischemic or hemorrhagic stroke, intracranial mass, and, less commonly, a psychiatric illness. Patients with depressed consciousness represent true emergencies because the potential causes are often life-threatening and must be rapidly diagnosed and reversed whenever possible. A review of relevant neuroanatomy and pathophysiology facilitates our understanding of how consciousness is affected in the setting of disease (Fig. 12.1).

Pathophysiology

To maintain normal consciousness, the brain requires a constant flow of sensory input and the ability to process this information. Visual, auditory, olfactory, gustatory, visceral, and somatosensory inputs are all synthesized and interpreted by the brain simultaneously. Disruption in this flow of information or inability to process it may lead to depressed consciousness.

Consciousness consists of two domains: arousal and awareness. Arousal ranges from fully awake, to arousable with verbal or tactile stimulation, to unarousable. Anatomically, arousal is maintained by the subcortical structures, including the brainstem nuclei, thalamus, basal forebrain, hypothalamus and, most notably, the ascending reticular activating system (ARAS). ARAS neurons are located predominately in the pons and midbrain, connect to the thalamus, and project to the cortex. Awareness consists of the content of consciousness, ranging from self-aware and coherent to confused, inattentive, or perhaps delusional. Awareness is generated by the bilateral cerebral cortices, which control the processing and understanding of sensory input. A patient's level of arousal may be low enough that the domain of awareness is difficult to assess.

Consequently, damage to the dorsal brainstem, thalamus, axonal projections to the cortex, or extensive injury to bilateral cortices may result in depressed consciousness or coma. The clinical presentation may vary considerably depending on the location of the insult.

DIAGNOSTIC APPROACH

Differential Considerations

Differential diagnoses of depressed consciousness and coma are broad (Table 12.1) and potentially involve dysfunction in any area of the brain, from the cortex to the brainstem. It may be the result of a global insult causing massive cortical neuronal dysfunction or a small injury to a critical area of the brainstem responsible for arousal. Toxicologic, metabolic, infectious, and other disorders causing diffuse brain injury or neuronal dysfunction cause 65% of coma cases; of these, toxins are the most common. Worldwide, the prevalence of unintentional drug overdose, particularly opioid overdose, is increasing.[1,2] Structural brain diseases account for most of the remaining cases. Common, largely reversible causes of depressed consciousness and coma, along with their clinical findings and emergency treatment, are listed in Table 12.1.

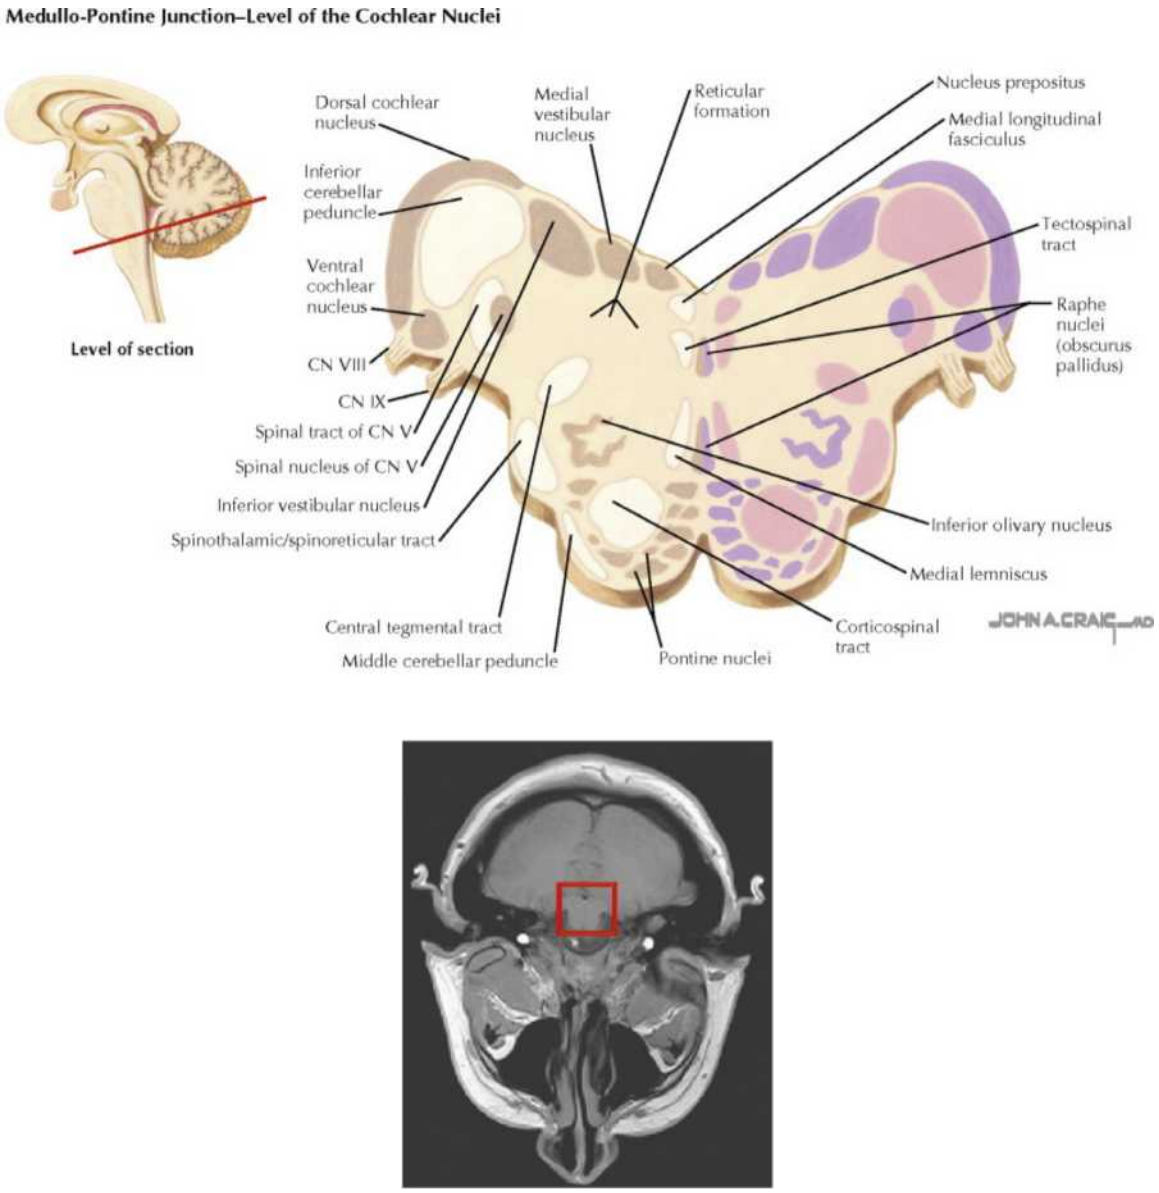

Fig. 12.1 Relevant anatomy showing the ascending reticular activating system and adjacent structures important for arousal. The *red box* denotes area of interest. *CN,* cranial nerve. (From www.netterimages.com. © 2018 Elsevier Inc. All rights reserved.)

Special consideration is needed for specific populations of patients. Older patients are often prescribed multiple medications and are at risk for accidental overdose, drug-drug interactions, and adverse drug reactions. Seemingly minor infections such as a urinary tract infection, upper respiratory infection, or viral gastroenteritis with dehydration may cause depressed consciousness or coma. In addition, immunocompromised patients are susceptible to opportunistic infections that are less common in the general patient population. Immunocompromise may result from acquired immunodeficiency syndrome (AIDS) or may be seen in patients receiving chemotherapy, immunosuppressive medications related to organ transplantation, or biologic agents (e.g., for rheumatologic illness or inflammatory bowel disease). Psychogenic causes of coma are uncommon, and caution is advised when making this definitive diagnosis.

In the evaluation of an undifferentiated comatose patient, keeping a broad initial differential diagnosis may prevent premature clinical fixation that could lead to diagnostic error. A careful history and clues from the physical examination will often shorten the list of possibilities, allowing a focused evaluation and rapid initiation of treatment.

Pivotal Findings

Symptoms

A patient with depressed consciousness is unlikely to provide a reliable history. Historical information elicited from alternate sources, such as emergency medical services (EMS) personnel, family members, or witnesses, usually guides the diagnostic evaluation. The time course of the patient's alteration in consciousness should be established. An abrupt onset of coma suggests a stroke, seizure, or cardiac event, whereas a more gradual onset of symptoms suggests an infectious or inflammatory process, metabolic disorder, or enlarging intracranial mass. Coma from poisoning may occur in minutes if the patient was exposed to a fast-acting agent or large dose of toxin. Conversely, substances with sustained or extended release can cause delayed toxicity resulting in depressed consciousness over the course of hours.

EMS personnel are trained to gather information at the scene and often provide valuable details about the circumstances surrounding the discovery of the patient, such as the presence of a suicide note

TABLE 12.1 Critical and Emergent Diagnoses of Coma

Diagnosis	Cause	Findings	Treatment (Adult Dosage)	Comments
Metabolic				
Critical diagnoses	Hypoglycemia	Diaphoresis, insulin pump	$D_{50}W$ 50 mL IV	
	Hyperglycemia (DKA, HHS)	Tachypnea, nausea, vomiting, abdominal pain, dehydration	Isotonic fluid; insulin	
	Adrenal crisis	Weakness, weight loss, hypotension, hyperpigmentation	D_5NS volume repletion; correct hypoglycemia; hydrocortisone 100 mg IV	Expect hyperkalemia as well
	Pituitary apoplexy	Sudden headache, visual impairment, multihormonal dysfunction	Treat electrolyte abnormalities; hydrocortisone 100 mg IV	May have pituitary adenoma; consult neurosurgery
	Sepsis	Fever, hypotension, poor end-organ perfusion	Isotonic fluid; appropriate antibiotics; source control	
Emergent diagnoses	Wernicke encephalopathy	CN III or CN VI palsy, nystagmus, sluggish pupillary response, anisocoria, gait instability, peripheral neuropathy	Thiamine 500 mg IV	Often seen in alcoholic or severely malnourished patients, seldom in hyperemesis gravidarum
	Hyponatremia	Progressive confusion, headache, anorexia, seizure	Free water restriction; hypertonic saline for seizures	Side effect of many medications
	Hyperammonemia	Lethargy, irritability, vomiting, seizure, poor feeding	Monitor protein intake; hemodialysis; levocarnitine for valproic acid toxicity	Seen in liver disease, inborn errors of metabolism, or as side effect of valproic acid or bariatric surgery
	Hypercalcemia	Lethargy, polyuria, AKI, constipation	Isotonic fluid; bisphosphonates IV; calcitonin	Causes nephrogenic DI; suspect malignancy
	Uremia	Nausea, vomiting, anorexia, fatigue, uremic fetor	Treat hyperkalemia; hemodialysis	Check ECG for hyperkalemia changes
	Hepatic encephalopathy	Fetor hepaticus, asterixis, ascites, stigmata of cirrhosis	Lactulose or rifaximin	Evaluate for sepsis, GI bleeding, SBP
	Thyrotoxic crisis	Fever, tachycardia, diaphoresis, diarrhea	Isotonic fluid; propranolol 1 mg IV, PO; propylthiouracil 600 mg PO starting dose (variable)	May also need to treat adrenal insufficiency
	Myxedema coma	Sluggishness, weight gain, edema, depression, hair loss, constipation	Levothyroxine or liothyronine; hydrocortisone 100 mg IV (variable)	May be precipitated by acute illness
	Heat stroke	Hyperpyrexia (>41.1°C), flushing, exertion in heat, dehydration	Isotonic fluid; evaporative cooling	Classic in older adults with comorbidities unable to seek cool environment
	High altitude cerebral edema	Rapid ascent, headache, confusion, psychosis	Rapid descent from altitude; hyperbaric oxygen; dexamethasone 10 mg IV	More common >3500 m
Toxic				
Critical diagnoses	Hypoglycemic agents	Older adult with worsening renal function, intentional overdose	Dextrose; octreotide if refractory hypoglycemia due to sulfonylurea toxicity	Sulfonylureas can be lethal with only one pill in children
	Opioids	Stupor, apnea, miosis, needle tracks	Naloxone IV, IN, or IM	Check skin for fentanyl patches
	Simple asphyxiants	Sudden lightheadedness, collapse, syncope	100% oxygen	Leaking CO_2 tank in enclosed space (e.g., walk-in freezer); also nitrogen, helium, argon, or methane gas
	Carbon monoxide	Combustion of fuel in enclosed space, headache, confusion, malaise, nausea	100% oxygen; hyperbaric oxygen per toxicology	Multiple people may be affected simultaneously; consider hyperbaric oxygen, especially during pregnancy
	Histotoxic hypoxia	Confusion, seizure, collapse, hydrogen sulfide smells like rotten eggs, cyanide (bitter almond smell) may result from combustion of plastics	100% oxygen; hydroxocobalamin 70 mg/kg (or 5 g) IV for cyanide	Consider cyanide in any house or car fire
	Methemoglobinemia	Use of medications, such as topical anesthetics or dapsone, cyanosis, pulse oximeter 85%	100% oxygen; methylene blue 1–2 mg/kg IV	Also may result from severe diarrhea in infants

Continued

TABLE 12.1 Critical and Emergent Diagnoses of Coma—cont'd

Diagnosis	Cause	Findings	Treatment (Adult Dosage)	Comments
Emergent diagnoses	Sedatives	Alcohol, benzodiazepines, and many others may be the culprit	Supportive; flumazenil for benzodiazepine toxicity	Avoid flumazenil in chronic benzodiazepine users, patients with proconvulsant drugs (cyclic antidepressants, isoniazid)
	Toxic alcohols	Nausea, vomiting, intoxication, vision changes, early osmolar gap then anion gap acidosis, renal failure	Fomepizole 15 mg/kg IV load; correct electrolyte abnormalities; isotonic fluid 500 mL/h	Consult nephrology and toxicology to consider hemodialysis for elevated levels and metabolic acidosis
	Inhalants	Often young, paint on hands or face, diplopia, slurred speech, cardiac dysrhythmia	Check ECG and monitor on telemetry; definitive airway if lip or tongue edema	Inhalants may be cold, may cause frostbite and edema to mucous membranes and hands
	Psychiatric medications	Hypotension, wide QRS, seizures	High-dose IV sodium bicarbonate for tricyclic antidepressant overdose	
	Anticonvulsants	Confusion, slurred speech, elevated drug levels	Supportive measures	Hyperammonemia may occur with valproic acid use
	Anticholinergics	Hyperpyrexia, pupillary dilation, urinary retention, visual hallucinations	Physostigmine; benzodiazepines may help in severe agitation	Consider physostigmine in severe anticholinergic toxicity; avoid if seizure, bradycardia, or abnormal QRS or QTc on ECG ; administer via slow IV push over 5 minutes
	Clonidine	Bradycardia, hypotension, somnolence	Isotonic fluids; vasopressors	Discuss naloxone with toxicology
	Beta blockers	Bradycardia, hypotension, hypoglycemia, seizure	Isotonic fluid; glucagon IV (5 mg); atropine IV (0.5 mg); vasopressors IV; high dose insulin infusion; transcutaneous or transvenous pacing	High doses of vasopressors may be needed. Discuss lipid rescue therapy and ECMO with toxicology and perfusionist, respectively
	Salicylates	Nausea, vomiting, tinnitus, delirium, hyperpnea, anion gap metabolic acidosis with mixed respiratory alkalosis	Isotonic fluids; urinary alkalinization with sodium bicarbonate; correct hypokalemia; consider hemodialysis	May come from oil of wintergreen or other non-aspirin source
	Neuroleptic malignant syndrome	Hyperpyrexia, muscular rigidity, delirium, autonomic instability, elevated CPK	Cooling, isotonic fluid; benzodiazepines, bromocriptine	Pharmacologic paralysis with nondepolarizing agent if severe
	Serotonin syndrome	Multiple serotonergic agents, hypertension, tachycardia, hyperreflexia, muscular rigidity, tremor, nausea, diarrhea, clonus	Isotonic fluid; check CPK; benzodiazepines; cooling, hydration, cyproheptadine	Pharmacologic paralysis with nondepolarizing agent if severe
Structural				
Critical diagnoses	Intracranial hemorrhage	Sudden onset headache, hypertension, neurologic deficits	CT without contrast; reversal of anticoagulation ; blood pressure control, antihypertensives and/or hyperosmolar agents	Early neurosurgical consultation for possible evacuation
	Cortical infarct	Sudden unilateral neurologic deficits	CT without contrast to evaluate for hemorrhage; neurology consultation; consider tPA and intraarterial clot retrieval; blood pressure control or antihypertensives	tPA contraindications must be excluded; tPA 0.9 mg/kg IV, not to exceed 90 mg total dose; administer 10% of total dose as initial IV bolus over 1 min and remainder infused over 60 min
	Cerebellar infarct	Sudden vertigo, nausea, ataxia, dysarthria	Consider tPA as above	Neurosurgery consultation if severe edema to consider decompressive craniectomy
	Basilar artery occlusion	Hemiparesis or quadriparesis, abnormal spontaneous movements, facial weakness, dysarthria, dysphagia	Consider tPA as above	May develop locked-in syndrome (loss of all voluntary movements except for eyes)

AKI, acute kidney injury; *CN*, cranial nerve; CO_2, carbon dioxide; *CPK*, creatine phosphokinase; *CT*, computed tomography; D_5NS, 5% dextrose in normal saline; D_5W, 5% dextrose in water; $D_{50}W$, 50% dextrose in water; *DI*, diabetes insipidus; *DKA*, diabetic ketoacidosis; *ECG*, electrocardiogram; *GI*, gastrointestinal; *HHS*, hyperosmolar hyperglycemic state; *IV*, intravenous; *PO*, per os (orally); *SBP*, spontaneous bacterial peritonitis; *tPA*, tissue plasminogen activator.

empty pill bottles, syringes, or medicinal (transdermal) patches. In addition, the possibility of trauma, seizure activity or the possibility of traumatic exposures. Family members or caregivers may have information regarding the patient's recent symptoms, which can offer important diagnostic clues. For example, a preceding, severe, sudden-onset headache suggests intracranial hemorrhage, cerebral venous sinus thrombosis, or cervical artery dissection; preceding fever may suggest meningitis or encephalitis; and a history of depression may suggest a drug overdose or adverse effects of psychotropic medications. The patient's medication history should be carefully reviewed for any recent changes to the medication regimen or dosages. A history of taking over-the-counter or alternative "herbal" medications should also be obtained.

The patient may be carrying additional pieces of information, such as a medical alert bracelet or medication list in the wallet. The patient's own mobile device may be used to retrieve supplemental data, review recent text messages, or contact next of kin.[3] If the patient can be reliably identified by a family member or photo identification card, the medical record may be accessed for additional medical history. In addition, the patient's pharmacy may be contacted to obtain an accurate prescription medication list.

Signs

After necessary stabilization measures have been instituted, the patient should be evaluated systematically, starting with an assessment of vital signs. Alterations in temperature are most commonly seen in infections, environmental exposures, metabolic disorders, and poisonings. Hypotension with depressed consciousness indicates shock with resultant cerebral hypoperfusion. Hypertension may be a sign of intoxication (e.g., sympathomimetic agents, amphetamines, cocaine, phencyclidine) or withdrawal (e.g., from alcohol, benzodiazepines, or opioids), cerebral or brainstem infarction, subarachnoid hemorrhage, posterior reversible encephalopathy syndrome (PRES), or elevated intracranial pressure (ICP). The combination of hypertension and bradycardia, known as the *Cushing reflex*, suggests severe ICP elevation. Bradycardia may also be the result of a myocardial conduction abnormality, cardiac ischemia, or overdose from medications such as beta blockers, calcium channel antagonists, cardiac glycosides, or clonidine. Many medical conditions cause tachycardia and depressed consciousness, including sepsis, medications with stimulant or anticholinergic effects, severe anemia, hypovolemia, thyrotoxicosis, and acute structural brain injury. Alterations in respiratory rate, pattern, or depth are usually caused by primary CNS abnormalities and toxic or metabolic disorders. *Kussmaul breathing* consists of deep labored respirations and may be seen in patients with severe metabolic acidosis, particularly diabetic ketoacidosis (DKA). *Cheyne-Stokes respiration* is a cyclic breathing pattern in which episodes of gradually increasing and then decreasing respirations are separated by brief apneic periods and is associated with stroke and heart failure.

After an assessment of the patient's vital signs, a complete physical examination should be performed. The head should be inspected for signs of trauma, such as a scalp laceration or hematoma. Periorbital ecchymosis ("raccoon eyes"), retroauricular ecchymosis *(Battle sign),* hemotympanum, and cerebrospinal fluid (CSF) otorrhea or rhinorrhea are signs of a basilar skull fracture. The hydration of the oral mucous membranes and quantity of salivary secretions provide information regarding the patient's volume status and may indicate a specific toxidrome (e.g., dry mucosal membranes from anticholinergic toxicity or excessive salivation from cholinergic crisis). Laceration or contusion of the tongue suggests a recent seizure.

The patient's cervical spine should be immobilized if there is suspicion for a neck injury. The presence of meningismus raises suspicion for meningoencephalitis or subarachnoid hemorrhage. Stridor indicates obstruction of the large airways and is usually caused by infection, anaphylaxis, angioedema, trauma, or foreign body aspiration. Goiter in a patient with depressed consciousness suggests underlying myxedema coma or thyroid storm.

The cardiovascular system should be evaluated for rate or rhythm disturbances, murmurs, and signs of volume depletion or overload. Abnormal lung sounds, retractions, and impairments in chest wall excursion indicate a pulmonary cause of depressed consciousness. Examination of the abdomen may reveal hepatomegaly or ascites, suggesting a hepatic cause of coma. Diminished bowel sounds and bladder distension suggest an anticholinergic toxidrome. A rectal examination should be performed to assess for gastrointestinal bleeding, retained foreign bodies, and neurologic sphincter tone.

The patient should be fully undressed to evaluate the skin for needle track marks, medicinal patches, rashes, and signs of trauma or infection. The presence of jaundice, palmar erythema, spider angiomata, or caput medusa in a patient with depressed consciousness should raise concern for hepatic encephalopathy. Petechiae or purpura can be seen in patients with meningococcemia, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, and vasculitis. Diaphoresis may be present in sympathomimetic poisoning, whereas excessively dry, flushed skin is associated with anticholinergic toxicity. Unusual odors emanating from the patient may provide additional diagnostic clues, such as ethanol, isopropanol, uremic fetor, fetor hepaticus, melenic stools, or the "fruity," acetone-like breath odor in some patients with DKA.

The main objectives of the neurologic examination are to determine the depth of coma, identify lateralizing deficits, and assess for brainstem dysfunction. The examination should proceed systematically and include an evaluation of the patient's level of consciousness, cranial nerves, brainstem reflexes, and motor responses. The patient's level of consciousness should be assessed with stimuli of increasing intensity. Auditory stimuli, such as a verbal cue or loud noise, may be used first. If the patient does not exhibit a response to auditory stimuli, noxious stimuli may be applied, such as a sternal rub, nail bed compression, trapezius squeeze, or pressure on the medial aspect of the supraorbital ridge or posterior aspect of the mandibular ramus. These maneuvers should be applied gently in pediatric and elderly patients.

Level of consciousness may also be evaluated using a coma scale. The two most widely used scales are the Glasgow Coma Scale (GCS; Table 12.2) and Full Outline of UnResponsiveness (FOUR) score (Table 12.3). Both grading systems can be performed rapidly and have high interrater reliability. Although originally developed as a prognostic indicator in patients with traumatic brain injury, the GCS is commonly applied to all patients presenting with depressed consciousness. The GCS has considerable limitations because it does not account for abnormalities in brainstem function and may not detect subtle changes in the neurologic examination. In addition, the score may widely vary in individual patients (e.g., a patient with an opioid overdose may initially present with a GCS of 3 but may rapidly improve to a score of 15 after administration of naloxone). The FOUR score has been validated in a variety of clinical settings, incorporates a more detailed assessment of brainstem reflexes and breathing patterns, and may have greater predictive value than the GCS in intubated patients and those with very low GCS scores.[4] The utility of both coma scales can be maximized by reporting the scores of each element in addition to the total score.

The cranial nerves should be tested, with particular attention to the eye exam. The size, reactivity, and symmetry of the pupils can provide important diagnostic clues. Pinpoint pupils that are minimally reactive or unreactive to light may be a result of damage to the pons, usually from hemorrhage or infarction. Pupillary dilation with loss of pupillary reactivity in a comatose patient should raise concern for an expanding intracranial mass with transtentorial herniation, resulting

TABLE 12.2 Glasgow Coma Scale

Parameter	Rating	Score
Eye Opening		
Open before stimulus	Spontaneous	4
Open after spoken or shouted request	To voice	3
Open after fingertip stimulus	To pain	2
No opening at any time, no interfering factor	No response	1
Closed by local factor	Not testable (NT)	NT
Best Verbal Response		
Correctly gives name, place, and date	Oriented	5
Not oriented but communicates coherently	Confused	4
Intelligible single words	Inappropriate words	3
Only moans or groans	Incomprehensible sounds	2
No audible response, no interfering factor	No response	1
Factor interfering with communication	NT	NT
Best Motor Response		
Obeys two-part request	Obeys commands	6
Moves hand across body or above clavicle to stimulus	Localizes pain	5
Bends arm at elbow rapidly, features not predominantly abnormal	Withdraws from pain	4
Bends arm at elbow, features clearly predominantly abnormal	Flexion to pain	3
Extends arm at elbow	Extension to pain	2
No movement in arms or legs, no interfering factor	No response	1
Paralyzed or other limiting factor	NT	NT

TABLE 12.3 Full Outline of UnResponsiveness Score

Response	Score
Eye Response	
Eyelids open or opened, tracking, or blinking to command	4
Eyelids open but not tracking	3
Eyelids closed but open to loud voice	2
Eyelids closed but open to pain	1
Eyelids remain closed with pain	0
Motor Response	
Thumbs-up, fist, or peace sign	4
Localizing to pain	3
Flexion response to pain	2
Extension response to pain	1
No response to pain or generalized myoclonus status	0
Brainstem Reflexes	
Pupil and corneal reflexes present	4
One pupil wide and fixed	3
Pupil or corneal reflexes absent	2
Pupil and corneal reflexes absent	1
Absent pupil, corneal, and cough reflex	0
Respiration	
Not intubated, regular breathing pattern	4
Not intubated, Cheyne-Stokes breathing pattern	3
Not intubated, irregular breathing	2
Breathes above ventilator rate	1
Breathes at ventilator rate or apnea	0

in compression of the oculomotor nerve or injury to the midbrain. Drugs and other toxins can also cause miosis (e.g., opioids, clonidine, organophosphates) or mydriasis (e.g., cocaine, amphetamines, anticholinergics, tricyclic antidepressants). Fixed, midsize pupils can be seen in severe midbrain injury and may be the first sign of brain death.

Eye position and movement should also be assessed. Forced deviation of the eyes, usually in the horizontal plane, may indicate an ipsilateral hemispheric or contralateral pontine lesion. Seizures can also cause horizontal eye deviation, typically away from the cerebral lobe generating the epileptiform activity. Horizontal disconjugate gaze can be seen in patients who are sedated, drowsy, or intoxicated and those with metabolic disorders. Disconjugate gaze in the vertical plane, also known as skew deviation, strongly suggests a cerebellar or brainstem lesion. Spontaneous conjugate "roving" eye movements indicate bihemispheric dysfunction with a relatively intact brainstem. Nystagmus in an unresponsive patient may be a sign of nonconvulsive status epilepticus (NCSE), brainstem dysfunction, drug overdose (e.g., anticonvulsants, lithium, ketamine, ethanol, phencyclidine), or envenomation (scorpion sting).

A funduscopic examination may yield additional diagnostic information. The presence of a subhyaloid hemorrhage should raise suspicion for aneurysmal subarachnoid hemorrhage. Papilledema and retinal hemorrhages are associated with increased ICP and malignant hypertension. Optic disc hyperemia is a finding associated with severe methanol poisoning.

Brainstem function is evaluated through the various brainstem reflexes, including the *oculocephalic reflex* (doll's eyes), oculovestibular reflex (cold caloric testing), corneal reflex, and gag reflex. Provided that there are no airway issues or suspicion for cervical spine injury, the oculocephalic reflex is tested by rotating the head from side to side in the horizontal plane. In a patient with a normally functioning brainstem, the eyes will move in a direction opposite the head movement and appear to maintain visual fixation on a single point in space. Brainstem dysfunction should be suspected if the eyes remain in midposition with respect to the bony orbits and move in unison with the head. Conscious patients can usually suppress the oculocephalic reflex.

The *oculovestibular reflex* is a more sensitive test for brainstem dysfunction and cannot be resisted voluntarily. After cerumen impaction and tympanic membrane perforation have been excluded, the patient's head is elevated to 30 degrees up from the horizontal and ice water is infused into the external auditory canal. In a comatose patient with an intact brainstem, the stimulus results in sustained conjugate deviation of the eyes toward the ear being irrigated. Absence of a response to the irrigation should raise suspicion for brainstem dysfunction. In response to cold water caloric testing, conscious patients experience not only tonic deviation of the eyes toward the stimulated ear but also nystagmus (with the fast phase away from the side of irrigation), vertigo, nausea, and vomiting. The presence of nystagmus is suggestive of wakefulness and psychogenic unresponsiveness.

The corneal reflex is tested by gently touching the edge of the cornea with a wisp of cotton or small drop of saline and observing for blinking of the eyes. Elderly and diabetic patients may have a diminished or absent corneal reflex at baseline. The gag reflex is elicited by gently stimulating the posterior pharynx and observing for brisk elevation of the soft palate and bilateral contraction of the pharyngeal muscles. Because the gag reflex is symmetrically reduced or absent in a subset of normal individuals, the test is most informative when the response is asymmetric.

Motor function is assessed by observing any spontaneous movements and testing the motor responses to verbal commands and noxious stimuli. Purposeful movements should be distinguished from reflex activity. Examples of purposeful movements include following commands and localizing painful stimuli. Reflexive responses include withdrawal from pain, decorticate posturing (adduction of the shoulders and flexion of the elbows, wrists, and fingers), and decerebrate posturing (shoulder adduction, elbow extension, and forearm pronation). Although usually associated with focal brain lesions, posturing reflexes can also be seen in systemic conditions affecting the CNS, such as toxic and metabolic disorders.

Muscle tone, assessed by passive manipulation of the extremities, is usually decreased in structural brain disease but not affected in most metabolic conditions. Generalized muscle rigidity occurs in patients with neuroleptic malignant syndrome and malignant hyperthermia. Myoclonus may be a sign of NCSE, hepatic or renal dysfunction, serotonin syndrome, or hypercarbic respiratory failure. Myoclonic jerks can be seen with hypocalcemia and potassium imbalance. Tremors are classically noted with Parkinson disease, lithium toxicity, and withdrawal from alcohol and benzodiazepines.

Ancillary Testing

Diagnostic laboratory evaluation of a patient with depressed consciousness should begin with point of care measurement of the serum glucose level to confirm or exclude hypoglycemia. A comprehensive metabolic panel should be analyzed to identify metabolic acidosis, renal or hepatic dysfunction, and any electrolyte derangements, such as hyponatremia or hypercalcemia. In a patient with metabolic acidosis, a widened anion gap suggests possible ketosis (e.g., from diabetes, heavy alcohol use, or starvation), lactic acidosis (e.g., from sepsis, hypoperfusion, metformin or cyanide toxicity), uremia, or poisoning (e.g., with methanol, ethylene glycol, or salicylates). Anion gap acidosis in the context of poisoning is discussed in Chapter 135.

A complete blood count may identify profound anemia or thrombocytopenia and reveal a potential cause of severe hypotension or intracranial hemorrhage. Although an elevated white blood cell count can be a marker of infection, it is nonspecific and rarely helpful in discerning the cause of depressed consciousness. However, an abnormally low white blood cell count suggests an immunocompromised state and should raise suspicion for infection or malignancy. An elevated prothrombin or partial thromboplastin time can be seen in blood dyscrasias, disseminated intravascular coagulation, liver disease, and anticoagulant use.

Urinalysis can provide valuable diagnostic information. A high urine specific gravity suggests dehydration. Glucosuria can be seen in DKA and hyperosmolar hyperglycemic state. Detection of white blood cells, leukocyte esterase, or nitrites in the urine indicates a urinary tract infection. The presence of calcium oxalate crystals is associated with ethylene glycol ingestion.

Serum salicylate and acetaminophen levels should be determined if toxicity is suspected, such as in a case of an unexplained anion gap acidosis or hepatic failure. Other toxicologic tests, such as the serum ethanol level and urine drug screen, are less likely to significantly affect the acute management of a patient with depressed consciousness.

Oxygenation and ventilation may be rapidly and noninvasively assessed using pulse oximetry and end-tidal carbon dioxide monitoring. Blood gas analysis can be used to confirm acid-base balance and more accurately quantify the degree of hypoxia or hypercarbia. Co-oximetry should be included if carbon monoxide poisoning or methemoglobinemia is suspected. Due to its poor sensitivity and specificity, the serum ammonia level has little utility in the evaluation of comatose patients. Ammonia concentrations can be elevated in a variety of nonhepatic conditions, such as valproic acid toxicity and inborn errors of metabolism and may be normal or elevated in patients with hepatic encephalopathy. Thyroid function studies can help to confirm myxedema coma or thyrotoxicosis. Blood and urine cultures should be obtained if there is concern for infection. CSF analysis should be performed if CNS pathology such as infection or hemorrhage is suspected. Neuroimaging should be considered prior to lumbar puncture to exclude an intracranial mass lesion.

Noncontrast computed tomography (CT) of the brain, because of its wide availability and rapid acquisition, is the imaging modality of choice for the initial evaluation of a patient with depressed consciousness. It should be obtained in patients with preceding head trauma, those with suspected structural brain disease, and those in whom the diagnosis is not identified by other diagnostic means. Noncontrast cranial CT may identify intracranial hemorrhage, hydrocephalus, cerebral edema, mass lesion, or may reveal signs of ischemic stroke or elevated ICP. Other more subtle CT findings include putaminal necrosis or hemorrhage with methanol toxicity and low attenuation in the globus pallidus region associated with carbon monoxide poisoning.

CT angiography (CTA) of the head and neck should be performed if brainstem dysfunction is suspected on neurologic examination. It can provide valuable information regarding the cerebral vasculature and aid in the diagnosis of an intracranial aneurysm, arteriovenous malformation, cerebral venous thrombosis, and basilar or vertebral artery stenosis, dissection, or occlusion.

Due to bone artifact, CT has limited utility in the visualization of the posterior fossa. In comparison, magnetic resonance imaging (MRI) of the brain is better for identifying structural lesions in this region. MRI also provides greater anatomic differentiation of cortical and brainstem structures and is superior to CT imaging for detecting early ischemic stroke and identifying infectious, inflammatory, and neoplastic processes. However, MRI is less practical than CT because of cost, accessibility, and the length of time needed to acquire each study, which limits the ability to monitor and access a critically ill patient.

Electroencephalography (EEG) should be performed to evaluate for NCSE, which can manifest de novo and present with coma or persist after cessation of convulsive seizures. An EEG is also indicated in seizure patients who have received sedative or paralytic medications to assess for ongoing seizure activity (see Chapter 14).

An electrocardiogram may diagnose cardiac ischemia, conduction block, or other dysrrhythmias. It may also provide supporting evidence for an electrolyte abnormality (e.g., potassium, calcium), drug ingestion (e.g., tricyclic antidepressant, digoxin), or structural brain injury.

DIAGNOSTIC ALGORITHM

Critical and emergent diagnoses that require immediate consideration, evaluation, and treatment are listed in Table 12.1. Information from the history, physical examination, and initial battery of tests guides the direction of imaging and additional diagnostic testing. Advanced neuroimaging is performed next but not before treating emergent causes, such as hypoglycemia or opioid toxicity. An algorithmic approach to

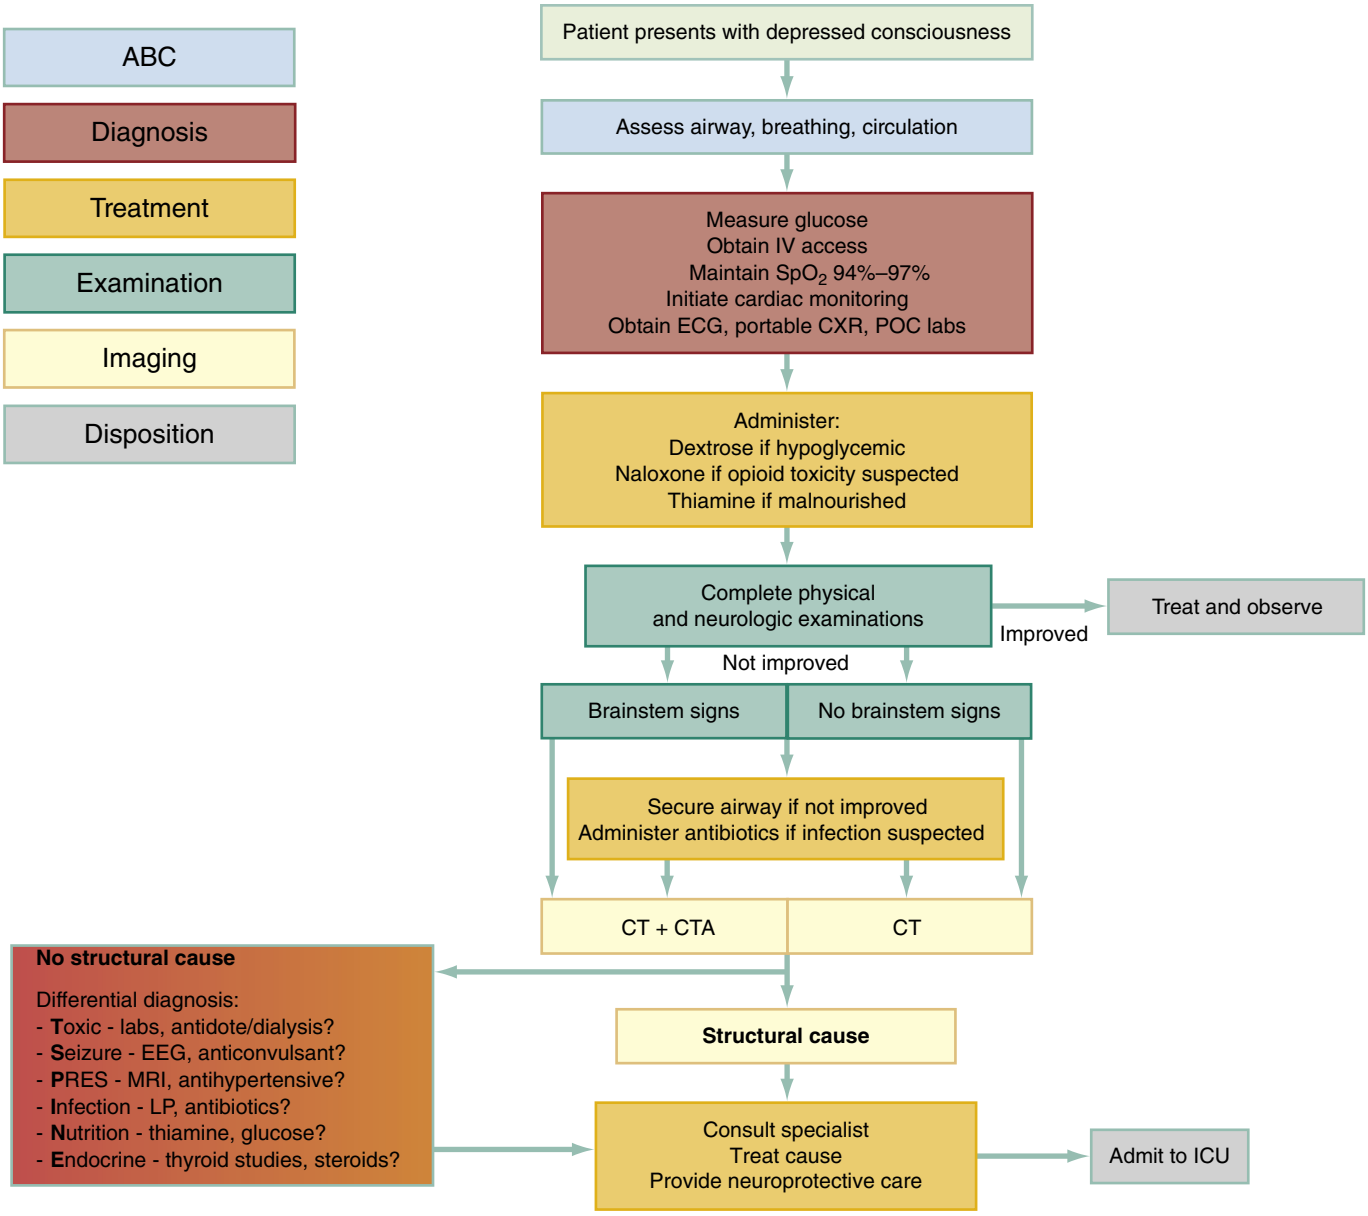

Fig. 12.2 Algorithm for Diagnostic and Management Approach to Depressed Consciousness and Coma. *ABC*, airway, breathing, circulation; *CT*, computed tomography; *CTA*, computed tomography angiography; *CXR*, chest x-ray; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *ICU*, intensive care unit; *IV*, intravenous; *LP*, lumbar puncture; *MRI*, magnetic resonance imaging; *POC*, point of care; *PRES*, posterior reversible encephalopathy syndrome; SpO_2, oxygen saturation.

the diagnosis and management of patients with depressed consciousness is presented in Fig. 12.2. This approach allows diagnostic assessment and therapeutic intervention to proceed in parallel.

EMPIRICAL MANAGEMENT

The management of comatose patients should begin immediately on arrival to the emergency department, before a definitive diagnosis is established. Management prioritizes oxygenation and perfusion while the diagnostic evaluation is initiated. Care should be taken to avoid hypoxia and hyperoxia because both are deleterious.[5] A goal oxygen saturation of 94% to 97% is acceptable and avoids both extremes. Intravenous (IV) access should be established and cardiac monitoring initiated. A rapid bedside glucose level should be measured and, if hypoglycemic, treated immediately with dextrose administration. Rapid treatment of hypoglycemia will lead to reversal of coma due to neuroglycopenia. An empirical trial of naloxone (0.4 to 2.0 mg) will rapidly reverse opioid toxicity, as well as several other medication overdoses (see Chapter 151). We recommend administering an initial naloxone dose of 0.4 mg IV and increasing up to 10 mg IV if necessary. For patients with difficult IV access, especially in the prehospital setting, intranasal naloxone is also highly effective.[6] Effective reversal with naloxone may obviate the need for endotracheal intubation in these patients. In cachectic malnourished patients, women with severe hyperemesis gravidarum, chronic alcoholics, or other patients with suspected thiamine deficiency, empirical administration of thiamine 500 mg IV is recommended.

If initial management efforts do not promptly result in improvement, the patient's ability to protect and maintain a patent airway should be reassessed. Failure to oxygenate, ventilate, or protect the airway is an

indication for endotracheal intubation. GCS scores inversely correlate with aspiration risk, but GCS alone does not accurately predict which patients will maintain protective airway reflexes. Patients with a GCS score higher than 8 cannot be considered safe or not at risk for aspiration. We recommend endotracheal intubation in most trauma patients with coma and a GCS score less than or equal to 8 and for any patient thought to be incapable of sustained airway self-maintenance and protection. However, not all patients with GCS of 8 or less require endotracheal intubation.[7,8] It is best to consider the history, examination, expected clinical course, and ability of future critical care providers caring for the patient to perform an airway intervention successfully, should it become necessary, when making the decision to intubate. For example, patients with altered consciousness due to ingestion of a depressant or sedative hypnotic substance may not require endotracheal intubation. The expected clinical course for most of these ingestions is to closely observe the patient in a monitored setting and allow time for metabolism. The majority of such patients recover without need for airway intervention.

Prior to intubation, a detailed neurologic examination should be performed, with particular attention to assessing brainstem function. Once the airway has been reassessed and secured as needed, we recommend treating patients with undifferentiated coma and clinical suspicion for meningitis (e.g., fever, other signs of infection, sepsis, rash) empirically with ceftriaxone 2000 mg IV prior to CT imaging. Additional antibiotics may be added based on suspected infection source, local antibiogram, and patient-specific risk factors. If encephalitis is suspected, empirical acyclovir dosed at 10 mg/kg IV in adults and 20 mg/kg IV in pediatrics is also recommended.

If the head CT or CTA is diagnostic, notify the appropriate consultant (neurosurgery or neurology) and arrange for definitive management. In all patients with brain injury of any type, especially those with signs of herniation, general principles of neuroprotective care are recommended (Box 12.1; see Chapter 33).

If the head CT or CTA is nondiagnostic, determine if there are any other emergent conditions that could be treated and potentially reversed. Differential diagnoses are listed in Fig. 12.2 and may be easily recalled using the mnemonic shown.

Special consideration should be given to patients who present comatose following resuscitation from cardiac arrest. In addition to following the principles of neuroprotective care, which include simple avoidance of hyperthermia, adult patients should undergo targeted temperature management (TTM), with a goal temperature between 32°C and 36°C.[5,9] This applies to all comatose patients who have return of spontaneous circulation (ROSC) after cardiac arrest, including those with shockable and nonshockable rhythms as the cause of arrest.[10,11] Efficacy of a lower temperature target of 33°C (vs. 36.8°C) was not as convincing in children for both out-of-hospital and in-hospital cardiac arrest.[12,13] However, TTM has been recommended as a reasonable option in the 2019 Pediatric Advanced Life Support update, with an initial target temperature of 32°C to 34°C followed by 36°C to 37.5°C, or to simply target a temperature range of 36°C to 37.5°C.[14] Prehospital cooling using an infusion of cold saline was shown to be ineffective and is not recommended.[15] The most important principles in both adults and children with ROSC after cardiac arrest who remain comatose are rapid initiation of mild cooling and strict avoidance of hyperthermia.

BOX 12.1 Principles of Neuroprotective Resuscitation

- Elevate head of bed to 30 degrees if there is no suspicion for thoracic spine injury.
- Avoid constricting ties or collars around neck.
- Avoid hypoxia and hyperoxia.
- Maintain end-tidal CO_2 at 35 cm H_2O.
- Avoid hypotension.
- Avoid hyperthermia.
- Prevent and treat seizure activity.

CO_2, Carbon dioxide; *H_2O*, water.

Once the initial diagnostic evaluation has been completed and initial management is underway, most patients will require definitive treatment in an intensive care unit. The disposition will depend on what is discovered during the evaluation. Patients found to have a structural abnormality on neuroimaging potentially requiring neurosurgical intervention should be rapidly transferred to a facility with neurosurgical capabilities, if not available at the initial medical facility.

Many patients with toxic or metabolic causes (e.g., opioid overdose, hypoglycemia) of depressed consciousness may be rapidly treated and stabilized in the emergency department and some may be safely discharged home after a period of observation. Patients with alcohol or recreational drug intoxication and no other discernible cause of depressed consciousness may be discharged when clinically sober. Most patients with depressed consciousness of unclear etiology will require admission to the hospital or observation unit even if the level of consciousness markedly improves with initial treatment.

CHAPTER 12: QUESTIONS AND ANSWERS

1. In infants, what is the most common cause of a depressed level of consciousness?

a. Accidental toxic ingestion
b. Inborn error of metabolism
c. Infection
d. Physical abuse

Answer: c. The most common causes of depressed consciousness vary with patient age. In infants, infectious causes are most common; however, trauma secondary to physical abuse and metabolic derangements from inborn errors of metabolism can also be seen. Accidental toxic ingestions are often seen in younger children but are very uncommon in infants. Young adults and adolescents are more likely to present with depressed consciousness after recreational drug use or trauma. Older adults are particularly vulnerable to infectious causes, medication effects, and alterations in their living environments.

2. What Glasgow Coma Scale (GCS) score would be given to an adult patient who opens the eyes to painful stimuli, speaks in an incomprehensible manner, and withdraws from pain?

a. 7
b. 8
c. 9
d. 10

Answer: b. Using the GCS, this adult patient would receive 2 points for eye opening to pain, 2 points for a verbal response consisting of incomprehensible sounds, and 4 points for withdrawing from painful stimuli.

3. What Glasgow Coma Scale (GCS) score would be given to a pediatric patient who opens the eyes and flexes the extremities to painful stimuli and who is irritable and continually cries?

a. 6
b. 7
c. 8
d. 9

Answer: d. Using the GCS, this pediatric patient would receive 2 points for eye opening to pain, 4 points for persistently being irritable, and 3 points for flexion in response to painful stimuli. The pediatric GCS takes into account that younger children might not yet be verbal.

4. Awareness of one's self and surroundings defines which of the following?

a. Cognition
b. Consciousness
c. Judgment
d. Orientation

Answer: b. Consciousness is defined as the awareness of one's self and surroundings; it is made up of both arousal and awareness. Cognition involves knowing and understanding, especially through the perception of what is experienced by the senses; judgment is the ability to process input data to generate more meaningful information; and orientation is the ability to determine the relative position of oneself in relation to one's person, place, time, and situation.

5. In the evaluation of a comatose patient, which of the following responses most clearly indicates brainstem dysfunction?

a. A drop of saline on the cornea of one eye causes both eyes to blink
b. Infusion of cold water into the right ear causes rightward deviation of the eyes
c. Stimulation of the posterior pharynx has no effect on the soft palate of pharyngeal muscles
d. When the head is rotated from side to side in the horizontal plane, the eyes remain in midposition and move in unison with the head.

Answer: d. Brainstem function is evaluated through the various brainstem reflexes. The oculocephalic reflex is tested by rotating the head from side to side in the horizontal plane. In patients with normal brainstem function, the eyes should move in a direction opposite of head movement and appear to maintain visual fixation on a single point in space. The corneal reflex is tested by touching the edge of the cornea with a wisp of cotton or drop of water and observing for blinking of the eyes. The oculovestibular reflex is tested by infusing cold water into the external auditory canal. In patients with an intact brainstem, the stimulus causes sustained conjugate deviation of the eyes toward the ear being irrigated. The gag reflex is tested by stimulating the posterior pharynx and observing for brisk elevation of the soft palate and contraction of the pharyngeal muscles. Because the gag reflex is symmetrically reduced or absent in a subset of normal individuals, the utility of this brainstem reflex is limited.

13

Confusion

Patrick J. Maher

KEY CONCEPTS

- Confusion and delirium are symptoms, not a diagnosis.
- Focal cortical dysfunction, such as from tumor or stroke, typically does not cause confusion.
- Any underlying clinical process that disrupts optimal central nervous system (CNS) functioning can result in confusion.
- Emergent causes of confusion that need immediate detection and treatment include hypoglycemia, hypoxemia, hypotension, sepsis, and toxic ingestions.
- Assessment of attention is fundamental for the assessment of patients with confusion as disturbances in attention are consistent with delirium versus psychiatric illness or dementia.
- Recommended tools for identifying patients with delirium in the emergency department are the Delirium Triage Screen (DTS) and brief Confusion Assessment Method (bCAM), if indicated.
- Delirium often goes unrecognized unless a structured assessment tool is used.
- Sedatives, including antipsychotics, are useful for managing undifferentiated agitation while the diagnostic evaluation is in progress.

FOUNDATIONS

The term *confusion* indicates an acute impairment in higher cerebral functions, such as memory, attention, or awareness. The disorder has multiple synonyms, some of which imply causative mechanisms, and always represents a symptom of another underlying disease process. Confusion ranges in severity from mild disturbances of short-term memory to a global inability to relate to the environment and process sensory input. Along this spectrum, the disorder overlaps with the term *delirium* (see Chapter 90), and the two terms are often used interchangeably. The degree of confusion may fluctuate over time, as may the patient's level of consciousness.

Delirium implicitly develops over a short period of time, typically hours or days, although it may persist for weeks. Although patients with preexisting dementia are at higher risk for developing delirium, the acute changes of delirium are distinct from and cannot be better explained diagnostically by a newly diagnosed or evolving dementia. The same pathophysiologic processes causing confusion and delirium may manifest with altered mentation and diminished alertness along the coma spectrum.

Confusion has many causes, and an orderly approach is helpful to discover the causative diagnosis. The assessment of mental status and cognitive impairment, with a focus on changes from baseline function, is an important part of the evaluation in older emergency department (ED) patients. Altered mental status may be a frequent finding even without a chief complaint of confusion. Collateral history from family or caregivers, a structured physical examination, and the use of a specific assessment tool may be needed to detect the presence of confusion.

Epidemiology

Emergency clinicians underestimate the incidence of confusion in patients. Because confusion is often accepted as an incidental or secondary component of another condition, it may be overshadowed by the primary condition being treated. When confusion exists as an isolated or unexplained finding, it is more likely to receive full and immediate consideration by the emergency clinician. Confusion occurs in a high percentage of hospitalized patients, with highest risk in frail, elderly, and critically ill populations.[1] An estimate of ED prevalence of delirium in elderly patients is 8% to 17%, and delirium in the ED often persists into the hospitalization.[2] Presence of delirium carries important negative prognostic implications for patients. In hospitalized patients, delirium is associated with higher mortality, worse functional and cognitive outcomes, and decreased rates of home discharge.

Pathophysiology

Conceptually, consciousness is divided into elements of alertness, or arousal, and elements constituting the content of consciousness. Although arousal may be abnormal, the characteristic disturbance in confusion is to the content portion of consciousness, resulting in abnormalities of attention and awareness. Any underlying clinical process that disrupts optimal central nervous system (CNS) functioning can result in confusion. Global CNS dysfunction usually results from substrate deficiencies (e.g., hypoglycemia, hypoxemia), neurotransmitter dysfunction, intoxication with or withdrawal from neuroactive drugs, or circulatory dysfunction. Individuals with a preexisting impairment are more sensitive to these factors and may become confused after even minor changes in their normal physiologic state.

DIAGNOSTIC APPROACH

Differential Considerations

Four major groups of disorders encompass most causes of confusion: (1) systemic diseases secondarily affecting the CNS; (2) primary intracranial disease; (3) exogenous toxins; and (4) drug withdrawal states (Box 13.1). Within these groups, certain causes, such as hypoxia and hypoglycemia, require immediate evaluation and treatment. A more general mnemonic for causes of altered mental status, many of which can present with acute confusion, is presented in (Table 13.1).

Schizophrenia and mood disorders, such as bipolar and major depressive disorder, do not generally cause acute confusion, but similarities in presentation can lead to diagnostic difficulty. Many inpatients evaluated for new depression are eventually diagnosed with acute delirium. Likewise, the diagnosis of a psychiatric disorder requires exclusion of organic causes. Attention in patients with primary psychiatric

BOX 13.1 Critical and Emergent Causes of Confusion[a]

- Critical
  - Hypoxia
  - Hypoventilation
  - Hypoglycemia
  - Delirium tremens
- Emergent
  - Primary intracranial disease
    - Seizure/nonconvulsive status epilepticus
    - Traumatic brain injury
    - Hypertensive encephalopathy
  - Systemic diseases secondarily affecting the central nervous system
    - Sepsis
    - Hepatic encephalopathy
    - Uremia/renal failure
    - Hyperthermia/hypothermia
    - Endocrinopathy
    - Nutritional deficiency
  - Exogenous toxins
    - Sedatives/hallucinogens
    - Ethanol/toxic alcohols
    - Narcotics
    - Antihistamines
  - Drug withdrawal
    - Alcohol
    - Drugs of abuse

[a]This list is not meant to serve as a comprehensive catalog of all causes of acute confusional state.

disorders is typically normal unless psychosis or agitation is severe. A careful evaluation is required to differentiate between psychiatric and medical origins of thought disturbances (Table 13.2).

CNS causes of confusion include stroke, seizure, and infection. Focal cortical dysfunction, such as from tumor or stroke, may present as confusion when receptive or expressive dysphasia is present. Occasionally, other neurologic abnormalities may mimic a confusional state when involving bilateral lobar structures. Subcortical or brainstem dysfunction usually results in a diminished level of alertness, rather than confusion. Frontal lobe dysfunction from stroke, trauma, or tumor may result in personality changes and the report of confusion by family or friends. Postictal state or nonconvulsive or petit mal status epilepticus may present with acute confusion. Atypical migraines or migraine variants may present with confusion alone. Meningitis and encephalitis cause alterations of consciousness, often with other signs of infection. Neuroimaging or other diagnostic studies may be required to narrow the differential in these cases.

Pivotal Findings

A patient with confusion is evaluated through a focused history, physical examination, and rapid bedside screening assessment tools. Response to specific therapies (e.g., dextrose, naloxone) may identify critical causes. Additional evaluation may include laboratory testing and diagnostic imaging, which are usually confirmatory of one of a number of suspected conditions. Examples of pivotal historical findings that provide the key to the diagnosis include new medications, infection symptoms, history of head trauma, history of seizures, history of migraines, and time course of symptom onset. Examples of pivotal physical findings include vital sign abnormalities, evidence of trauma, focal neurologic deficits, loss of attention, preservation of orientation, and presence of a toxic syndrome ("toxidrome").

TABLE 13.1 Mnemonic for Altered Mental Status

A	Alcohol or Drug Intoxication; Atypical migraine (confusional migraine)
E	Electrolytes, Environment (hyper/hypothermia), Endocrinopathy, Encephalopathy (Wernicke), Epilepsy
I	Infection (meningitis, encephalitis, sepsis)
O	Overdose, Oxygen (hypoxia, pulmonary embolism)
U	Uremia
T	Trauma, Tumor
I	Insulin (hypoglycemia, DKA, HHS)
P	Poisons, Psychosis
S	Stroke, Status epilepticus (petit mal)

DKA, Diabetic ketoacidosis; *HHS,* hyperosmolar hyperglycemic state.

Symptoms

Confusion is frequently reported by caregivers and family members, rather than by the patient. Families may articulate the complaint as confusion but also may describe incoherent speech, disorientation, hallucinations, visuospatial disturbances, or simply "not being right." Increased anxiety and ill-defined delusions of harmful intent may be present. An essential goal of the history is to determine the baseline level of neurologic function for the particular patient, and when the patient last exhibited their baseline thinking and behavior.

The initial task in evaluating the patient is to define the symptoms and severity of confusion. The specific behaviors that are of concern to the patient or caregivers should be delineated. Often, the family is the most valuable source for information; a physician or other caregiver with an established relationship with the patient also may be helpful. The duration of the confusion, recent changes in medications, and recent illnesses are important points in the clinical history. A history of previous episodes that have resolved spontaneous may be a clue to petit mal status or confusional migraine. Hallucinations may occur in delirium and are classically visual, unlike the auditory hallucinations associated with schizophrenia. A history of medication or substance abuse and any recent changes, especially cessation of benzodiazepines or ethanol, should be sought.

Signs

The general physical examination may suggest a cause of confusion or altered mental status, such as asterixis and jaundice in liver dysfunction, fever and dysuria in urinary tract infection, or injection marks from illicit drug use. New focal neurologic findings suggest a possible mass lesion or stroke, but these would manifest with confusion only if global cortical dysfunction were caused by surrounding cerebral edema or elevated intracranial pressure by severe mass effect. Aphasia, fluent or nonfluent, is a focal sign suggesting a lesion in the dominant cerebral hemisphere. In confusional states, speech may be abnormal and is often incoherent, and the rate of speech may be rapid or slowed. Identification of the elements of a "toxidrome," such as serotonin syndrome, may assist in the identification of a drug effect as the cause of confusion, prompting intervention or consultation. A careful inspection of the skin, including the sacrum and lower leg, may reveal a culprit skin infection.

In some patients, confusion may be subtle, and an informal assessment of mental status and cognitive abilities may fail to detect

TABLE 13.2 Findings to Help Differentiate Between Delirium and Primary Psychiatric Disturbance

Delirium	Psychiatric	Dementia
History		
Acute onset	Onset usually over weeks to months	Onset over months to years
Any age	Onset usually age, 12–40 years	Usually >65, unless early-onset
Mental Status Examination		
Fluctuating level of consciousness	Alert	Usually alert
Disoriented	Oriented	Often disoriented
Attention disturbances	Agitated, anxious	Memory impairment
Hallucinations—visual, tactile	Hallucinations - auditory	Usually absent, except in dementia with Lewy bodies
Cognitive changes	Delusions, illusions	Word-finding difficulties
Physical Examination		
Abnormal vital signs	Normal vital signs	Normal vital signs
Nystagmus	No nystagmus	Neurologic deficits present in vascular dementia
Focal neurologic signs	Purposeful movement	Can show parkinsonism
Signs of trauma	No signs of trauma	No signs of trauma

abnormalities. In contrast to the agitated confused patient, delirium with hypoactive features may be both more common and more easily missed by clinicians. Studies have shown that delirium in older adults often goes unrecognized unless a structured assessment is performed. Casual conversation and basic questions about orientation will not detect confusion or delirium in all patients. A screening test for delirium must go beyond questions of orientation and the apparent ability to carry on a normal conversation.

Simple, rapid tests for diagnosing delirium in the ED have been derived. The algorithm recommended in current guidelines includes screening with a highly sensitive test, such as the Delirium Triage Screen (DTS) performed by emergency personnel, followed by confirmation using a specific test such as the brief Confusion Assessment Method (bCAM) (Fig. 13.1).[3] The DTS assesses level of consciousness using the Richmond Agitation and Sedation Scale (RASS) and assesses attention by a simple question (backward spelling of five-letter word, such as "LUNCH" or "WORLD" with positive result for more than one error). The screening test can be performed in less than 20 seconds, and the bCAM can be performed in less than 2 minutes (Fig. 13.2). Although other tests, including the Quick Confusion Scale (QCS) and the Mini-Mental State Exam (MMSE), have been used to rule out a diagnosis of confusion and delirium in the ED, both of these exams take longer to perform than the combination of the DTS and bCAM, without appreciable gains in accuracy of diagnosis. In comparison with the DTS with RASS and test of attention, a modified RASS scale alone does not have similar sensitivity for delirium.[4]

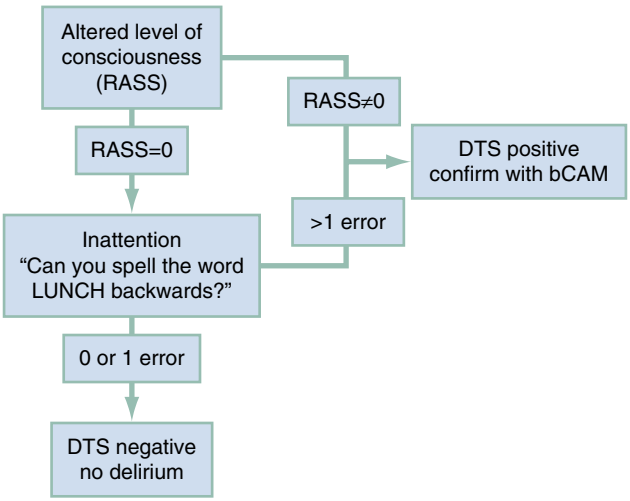

Fig. 13.1 Delirium Triage Screen *(DTS). bCAM,* Brief Confusion Assessment Method; *RASS,* Richmond Agitation and Sedation Scale.

Ancillary Testing

Synthesis of information from the history and physical examination guide the emergency clinician in the choice of laboratory tests most likely to yield valuable diagnostic information. Pulse oximetry may reveal hypoxia, or bedside glucose testing may reveal hypoglycemia or hyperglycemia. In the presence of fever, chest radiography and urinalysis often reveal the source of the infection causing the altered mentation. Serum chemistry tests for liver function may support a clinical diagnosis of hepatic encephalopathy, which does not require elevated serum ammonia level to be present. If there are clinical findings or a history suggestive of thyroid disease, thyroid-stimulating hormone (TSH) testing is indicated. Electrolyte testing can reveal either elevated or decreased sodium and calcium levels. Creatinine level and blood urea nitrogen levels may be elevated in renal failure and uremic encephalopathy.

Electrocardiography is indicated in older patients because myocardial infarction may manifest atypically as confusion. A complete blood count is unlikely to provide useful diagnostic clues unless profound anemia is suspected. White blood cell counts may be elevated, normal, or low, without specificity as to the presence or nature of a disorder. Blood gas testing may demonstrate acid-base disturbance or hypercarbia, although arterial, rather than venous, samples are rarely required unless pulse oximetry is not reliable.

If common and simple tests do not identify a cause, advanced diagnostic testing may be indicated. Selected drug and toxicologic testing may be ordered in this second tier of evaluation, although false-positive and false-negative results can occur. Caution should be applied before attributing mental status changes entirely to substance use in unclear cases. Blood and urine cultures are obtained in the febrile patient when hospital admission is anticipated and a clear infectious source is not evident. Paracentesis or thoracentesis may be appropriate if ascites or a new pleural effusion is present. Cranial computed tomography (CT)

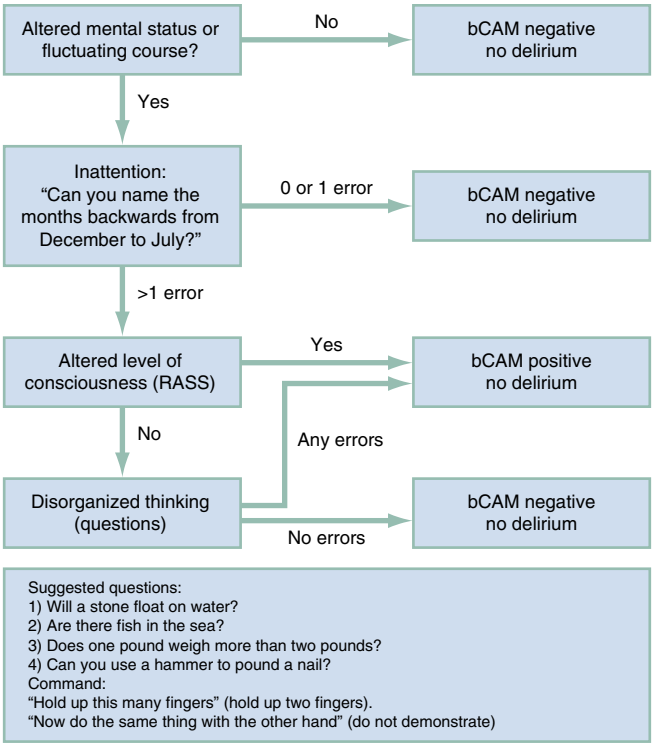

Fig. 13.2 Brief Confusion Assessment Method *(bCAM)*. *RASS,* Richmond Agitation and Sedation Scale.

scanning is often done to screen for CNS lesions in the absence of another identified source of the confusion and in patients with focal neurologic findings on examination. Lumbar puncture may allow discovery or exclusion of CNS infection if no other source has been identified. Cerebrospinal fluid examination may clarify a diagnosis of meningitis, encephalitis, or subarachnoid hemorrhage.

Additional evaluation with magnetic resonance imaging (MRI) or electroencephalography (EEG) can be considered, but the yield of these tests in unselected patients with delirium is unknown. In patients for whom stroke remains a possibility, MRI shows lesions with higher sensitivity than CT, whereas EEG effectively rules out ongoing seizures, but the results are nondiagnostic in many patients.

DIAGNOSTIC ALGORITHM

Certain critical and emergent diagnoses require prompt recognition to reduce morbidity or mortality (see Box 13.1). The diagnosis of confusion relies heavily on the history and physical examination, supplemented by indicated laboratory and imaging tests, for exclusion of common causes (Fig. 13.3).

Concurrent with the ongoing work-up of a patient with confusion, early steps of the management algorithm can be taken to ensure patient and provider safety, facilitate testing, and reverse critical causes (e.g., hypoxia, hypercarbia, hypoglycemia; Fig. 13.4). A complete set of vital signs, including temperature and oxyhemoglobin saturation, and a bedside blood glucose level should be determined promptly. Next, an assessment for delirium is performed using the DTS and bCAM if indicated. If the patient's bCAM score is negative, and if an underlying organic disorder can be ruled out as the cause of presentation, then a more comprehensive cognitive and mental status assessment can be performed, looking for evidence of an underlying dementia or psychiatric disorder.

The history and physical examination search for precipitating factors underlying the onset of the confusional state. Investigations continue until the patient is stabilized, a likely diagnosis is discovered, or consultation and admission are deemed necessary. Focal neurologic findings suggesting stroke, tumor, or some other mass lesion prompt immediate neuroimaging. If the examination is nonfocal, the presence of fever with other abnormal vital signs may lead to the discovery of an infectious cause of the confusion.

Postictal confusion is common in patients with seizures, usually improving within 20 to 30 minutes but lasting several hours in certain cases. If the patient remains unconscious or confused after a seizure, the possibility of ongoing or intermittent seizure activity should be entertained, and neurologic consultation and EEG should be considered. Nonconvulsive status epilepticus (NCSE) and convulsive subtle status epilepticus can present on a spectrum from confusion and abnormal behavior to deep coma, and these diagnoses carry significant morbidity if not diagnosed promptly.

Atypical migraine presentations, specifically confusional migraine, may or may not present with associated headache. If the cause of confusion remains unclear, or if the patient is unable to function safely in their current environment, admission is recommended for observation. Ideally, care is promptly coordinated with consultants and admitting physicians.

EMPIRICAL MANAGEMENT

Oral or intravenous (IV) glucose therapy is indicated if an abnormally low blood glucose level is discovered. In adults, one IV dose of dextrose (commonly 25 g as either a "D50" ampoule of 50 mL of 50% dextrose, or a prepared solution of 250 mL of 10% dextrose or similar product) is commonly administered, and the bedside glucose level is checked again. Thiamine, 100 mg IV, can be given at the time of dextrose administration if Wernicke encephalopathy is a concern. A "banana bag," which may include thiamine, folate, magnesium, and multivitamin for infusion within 1 L of normal saline, probably does not confer additional benefit over IV thiamine alone. Hypoxia and hypercarbia are addressed with noninvasive or invasive ventilation strategies tailored to the patient's presentation. If a "toxidrome" is present, treatment is directed toward the specific toxin.

Confused or agitated patients should be protected from harming themselves or others. Close observation may need to be supplemented by medications or physical restraint. Family members may offer valuable assistance in observing and comforting the patient. Environmental manipulations such as dim lighting or providing a quiet environment may be helpful. Confinement or physical restraint may be necessary at times but should be used with careful adherence to institutional guidelines. Use of physical restraints and bladder catheterization have been associated with prolonged duration of delirium.[5]

No medications are US Food and Drug Administration (FDA) approved for the treatment of delirium. Benzodiazepines can be used for acutely agitated patients requiring sedation for safety, but these agents can prolong delirium in hospitalized patients.

Antipsychotics have been studied extensively for chemical sedation of delirium in acutely ill patients, with conflicting data on efficacy.[6] Given a relatively rapid onset, availability of IV and intramuscular (IM) formulations, and some positive data from intensive care unit (ICU) populations, haloperidol may be the treatment of choice for acute confusion with agitation, at a dose of 1 to 5 mg, repeated up to every 15 minutes IV or every 30 minutes IM as needed to a maximum of 10 to 20 mg/day. Adverse events including QT prolongation, acute dystonic reactions, and tardive dyskinesia, with chronic use, may occur. Haloperidol administration is associated with an increased risk of death in patients with Parkinson's disease, which is why it is contraindicated in this patient population. Atypical antipsychotics, including quetiapine, dosed as 25 to 50 mg per os (PO) 1 to 4 times daily, and olanzapine, dosed 5 to 10 mg IM every 2 to 4 hours to a maximum of 30 mg/day based

on patient tolerability, have been studied for treatment of agitation as well, and may be effective in some cases.

Age-appropriate antibiotic treatment for coverage of causes of sepsis tailored to the patient's comorbidities may be considered in ill febrile patients while a definitive evaluation is in progress. If a CNS infection is suspected, age-guided empirical antibiotic treatment without delay for lumbar puncture is recommended.

In patients with history of epilepsy who have uncontrolled seizures or are suspected of being in nonconvulsive status epilepticus, empirical treatment with benzodiazepines may be considered, although this may cause increased somnolence. Other antiepileptics, such as levetiracetam IV, may be considered as well to rapidly achieve therapeutic plasma levels and prevent recurrence of seizures.

Prochlorperazine or other medications to treat migraine headache may be administered if confusional migraine is suspected.

CHAPTER 13: QUESTIONS AND ANSWERS

1. A 70-year-old man with a chief complaint of confusion is brought to the emergency department by his family. Which of the following initial assessments should be included?

a. Blood pressure
b. Pulse oximetry
c. Temperature
d. All of these

Answer: d. Confusion may result from shock states, hypoglycemia, and hypoxia. Evaluation for these conditions is a priority. Confusion is a symptom rather than a medical condition, and reversible causes should be investigated.

2. A variety of brief screening tools may aid in the detection of confusion. All of these tests focus on which cardinal finding of confusion?

a. Attention impairment
b. Decreased level of arousal
c. Disorientation
d. Long-term memory impairment

Answer: a. Inattention is the critical finding for diagnosis of confusion and delirium. All of the screening tools (brief Confusion Assessment Method [bCAM], Mini-Mental State Exam [MMSE], Quick Confusion Scale [QCS]) evaluate this abnormality, although other components of consciousness are tested in some models.

3. A 30-year-old patient is brought to the emergency department for evaluation of odd behavior. Which of the following characteristics might suggest a psychiatric cause for the behavior?

a. Auditory hallucinations
b. Disorientation
c. Fever
d. Visual hallucinations

Answer: a. Auditory hallucinations are common in psychiatric illness. If hallucinations are present in organic causes of delirium, they are usually visual, tactile, or olfactory. Orientation is generally preserved with primary psychiatric disorders unless psychosis or severe impairment is present.

4. Postictal confusion is common in patients with seizures, but if improvement in consciousness does not occur within 20 to 30 minutes after seizure cessation, which of the following conditions should be considered?

a. Electrolyte abnormalities
b. Hypoglycemia
c. Nonconvulsive or subtle status epilepticus
d. All of these

Answer: d. For a patient with a generalized convulsive seizure, termination of the seizure activity is usually **followed** by improvement of mental status within a short period of time. For the patient with persistently altered consciousness or prolonged confusion, consider causes of provoked seizures with prolonged altered mental status or persistence of subtle seizures.

14

Seizures

Carolina Barbosa Maciel and Marie-Carmelle Elie-Turenne

KEY CONCEPTS

- Lifetime seizure incidence reaches up to 10% in the US population and depends upon multiple factors including age, history of epilepsy, structural brain or neurodegenerative disease, genetic predisposition, acuity and severity of metabolic derangements.
- Seizures are the result of an imbalance in the excitation and inhibitory neuronal synapses in the cerebral cortex or limbic system.
- Epilepsy is a condition associated with a lower seizure threshold and an inherently higher risk of recurrent seizures in a lifetime.
- Acute symptomatic seizures occur at, or in close temporal relationship with, a distinct provoked event, and may occur with any toxic or metabolic, structural, ischemic, inflammatory, or infectious insult.
- The initial evaluation of seizure includes the identification of seizure characteristics, duration, and etiology of possible inciting events. Recognizing the occurrence of similar events in the past is key in determining triggers and distinguishing the management priorities between patients with epilepsy or with acute symptomatic seizures.
- The majority of seizures will cease spontaneously within 5 minutes; however, when physiologic seizure termination pathways are overwhelmed resulting in status epilepticus, characterized by the persistent and exponential refractory response to abortive seizure therapies. The magnitude of treatment refractoriness is time dependent; therefore a prompt stepwise escalation of therapies aiming at seizure termination is warranted.
- Prompt identification and, whenever possible, reversal of seizure triggers are priorities. In particular, assessing for and correcting hypoglycemia should occur as early as possible.
- Initial nonpharmacologic interventions include ensuring physical safety of patients with seizures to prevent traumatic injuries and aspiration. During convulsions, focusing on lateral decubitus positioning and suctioning of oral cavity are important to prevent aspiration; the use of intraoral devices may lead to trauma without additional benefit.
- Pharmacologic interventions center on the timely and dose-appropriate administration of parenteral benzodiazepines, which are first-line therapy (i.e., lorazepam intravenous [IV] up to 0.1 mg/kg in divided doses, or midazolam IV/intramuscular [IM]/intranasal [IN] 5 to 10 mg).
- In pregnant patients, eclampsia should be considered the underlying etiology of de novo seizures after 20 weeks of gestational age and up to 8 weeks postpartum. Clinical evaluation should focus on evaluating for associated symptoms (e.g., headache, visual abnormalities and confusion), as well as focal neurologic deficits. Neuroimaging should be considered if neurologic deficits persist, prolonged loss of consciousness or encephalopathy. IV magnesium 4 to 6 g is first-line therapy in the pregnant patient experiencing new-onset seizures.
- During the postictal state, key priorities in management include ensuring airway patency with optimal positioning in those with alteration of consciousness, evaluation for nonconvulsive seizures and acute brain injuries or inciting factors that warrant further definitive treatment.
- Nonconvulsive status epilepticus can only be diagnosed with electroencephalography (EEG) monitoring and should be considered in any patient with prolonged, unexplained altered mental status. Patients at higher risk include those with poorly controlled epilepsy, acute brain injury, sepsis, and intoxication.
- A patient with new-onset seizures with a normal neurologic examination who returns to baseline mental status and does not have comorbid disease does not require diagnostic testing beyond, serum glucose and sodium levels, a pregnancy test (in women), and a noncontrast head computed tomography (CT); a toxicologic screen is considered in select patients.

FOUNDATIONS

Epidemiology

Seizures represent distressful and physically traumatic events that have the potential for lifelong social consequences and challenges to quality of life. The risk for an unprovoked or acute symptomatic seizure is approximately 8% to 10%; however, only 3%, or 1 in 26 Americans, will ultimately be diagnosed with epilepsy at some point in their lifetime. Up to one in four seizures evaluated in the emergency department (ED) represent first-time seizures.[1]

The incidence and risk of seizures are influenced by many factors, including age; history and type of epilepsy, structural brain disease, neurodegenerative diseases; presence of renal or hepatic disease; metabolic derangements; and exposure to triggers. Patients presenting to the ED with seizures have a bimodal distribution in terms of age, with the highest incidence among infants and individuals older than 75 years old. This is explained by the high prevalence of febrile seizures in infants and structural brain damage in elders.

Up to 45% of adults presenting with a first unprovoked seizure will experience another within 2 years, most occurring in the first year.[2] The risk is higher with known brain lesions, neuroimaging or electroencephalography (EEG) abnormalities, or nocturnal seizures[2]; the latter are associated with epilepsy syndromes. Up to 50% of patients with epilepsy have recurrent seizures despite initiation of therapy. Human immunodeficiency virus (HIV)-positive patients have an increased risk of seizures, and two-thirds of those who present with new-onset seizures experience recurrence.[3]

Etiologies underlying seizure events are diverse; importantly, the etiology plays a role in the risk for seizure recurrence and the progression to status epilepticus. For a comprehensive list of etiologies of

seizures and status epilepticus according to type of insult and neurologic process refer to Chapter 88 (Box 88.1), and for pediatric considerations, refer to Chapter 169.

Pathophysiology

Seizures are the clinical manifestation of increased excitation or impaired inhibition of neurons that result in the abnormal firing and synchronization of neighboring neurons. This *recruitment* is complex and follows neural networks that may be deep and cross the midline of the brain. Marked alteration of consciousness ensues when seizures propagate diffusely to the bilateral cortex or diencephalon or to deeper structures involving the reticular activating system in the brainstem. Increased inhibition, effect of medications, and neuronal exhaustion mediate postictal states, which reflect transient neurologic deficits that may include alteration of consciousness, language, sensory, motor deficits (Todd paralysis), and/or abnormal emotional states. The duration of a postictal state ranges from minutes to a few hours, with the majority lasting less than 1 hour. Longer postictal states are associated with generalized convulsive seizures, duration of the seizure, and older age.[4]

Seizures are typically self-limited. A combination of mechanisms ultimately leads to their termination including reflex inhibition, neuronal exhaustion, or alteration of the local balance of neurotransmitters between the excitatory acetylcholine and glutamate with the inhibitory γ-aminobutyric acid (GABA). However, when these mechanisms fail, progression to status epilepticus ensues, leading to a cascade of changes within the brain: a decrease in $GABA_A$ receptor subunits as these migrate inside cells and a parallel increase in the excitatory *N*-methyl-D-aspartic acid (NMDA) receptors occur; these events are time sensitive and underscore the pathophysiology of treatment refractoriness and benzodiazepine resistance ($GABA_A$ mediated). The International League Against Epilepsy put forth operational time definitions of status epilepticus according to different seizure types that reflect: (1) likelihood of continued seizure activity due to failure of abortive mechanisms and (2) likelihood of secondary long-term sequelae (Table 14.1).[5] This time distinction originated from the notion that different seizure types may have different consequences and distinct pathophysiologic mechanisms. The understanding that seizure types may have different presentations and associated sequelae lays the foundation for individualized therapeutic algorithms according to the type of status epilepticus. For example, the clinical threshold for escalating antiseizure therapies should be lower in seizure patterns associated with high morbidity: much lower in convulsive generalized status epilepticus than in focal nonconvulsive status epilepticus.

TABLE 14.1 Classification of Status Epilepticus According to Time Domains.[5]

Type of Status Epilepticus	Duration of Time (Further Seizure Activity Likely)	Duration of Time (Long-term Sequelae Likely)
Tonic-clonic	5 min	30 min
Focal with impaired awareness	10 min	>60 min
Absence	10–15 min	Unknown

DIAGNOSTIC APPROACH

Pivotal Findings

History and physical findings assist in differentiating seizure from other acute medical conditions. They help identify triggers, which will heavily influence decisions on the need for secondary prophylaxis and guide the selection of antiseizure drug according to the specific seizure type.

Clinical manifestations of seizures vary widely depending upon the region of the brain affected; they may range from subtle cognitive and/or mental status changes to coma, apneic spells, sensory and motor manifestations, and dysautonomia. Seizures can be classified according to their semiology into types, duration, refractoriness to treatment, and etiology. The classification of seizure types has therapeutic implications and facilitate communication between providers.

A revised classification of seizure types by the International League Against Epilepsy provides an operational framework that relies on the clinical manifestations of seizures (Fig. 14.1).[6] The first classification branch underscores the importance of the seizure onset: focal which include those with secondary generalization (i.e., focal to bilateral tonic-clonic), generalized, or unknown; the latter is reserved for cases when the onset is not witnessed. The terms "complex seizures" or "focal dyscognitive seizures" traditionally used to reflect impairment of consciousness have been replaced by the term "focal seizures with impaired awareness." Note that patients may be immobile during a focal aware seizure, so long as they retain awareness of self and the environment. Further specification of motor onset or nonmotor onset centers on the descriptive assessment of the first prominent sign or symptom in the seizure. Automatisms usually include oral or finger stereotypic movements such as lip smacking, yawning, repetitive vocalizations, or picking at sheets or clothing; these automatisms can be complex and often arise from a frontal seizure focus. Seizures impairing distinct cognitive domains such as language (e.g., aphasia) or abnormal thoughts and perceptions (e.g., dèjá vu, hallucinations, illusions, or perceptual distortions)—often referred to as "auras"—are now termed "cognitive seizures." These cognitive seizures commonly arise from the orbital frontal region manifesting as olfactory hallucinations, or from the temporal lobe, which classically manifests as epigastric rising sensation, auditory hallucinations, and increased fear or impending doom.

The time criteria for status epilepticus are based on duration of seizures and depend on seizure type (see Table 14.1). Other classifications of status epilepticus, which include several different categorizations according to semiology, etiology, age, and EEG correlates, are reported in Chapter 88 (Table 88.1 and Box 88.2).

History Taking and Physical Exam

The ramifications of a seizure diagnosis have important direct consequences for patients, which include restriction of certain activities (e.g., driving, swimming unsupervised, and operation of heavy machinery) and therapeutic implications. The first diagnostic task in the ED is to determine whether the patient has actually experienced an epileptic event and if similar events have occurred in the past. Obtaining a detailed description of the sequence of events leading to the seizure-like activity and the semiology of the episode is paramount.

In general, ictal events have five properties:

1. *Abrupt onset.* Identify immediate preceding events and whether auras, which are focal seizures, were present (e.g., perception alterations: visual, smell, tactile, auditory, gastric heave, impending doom, anxiety, and irrational fear). Check for immediate triggers, such as sleep deprivation, missed medications, new medications, alcohol or substance use, infections, or other inciting events.
2. *Brief duration.* Seizures rarely last longer than 60 to 120 seconds (except in status epilepticus), although bystanders may overestimate their duration.
3. *Alteration of consciousness.* Generalized seizures are characterized by loss of consciousness, whereas focal seizures may be accompanied by an alteration in consciousness.

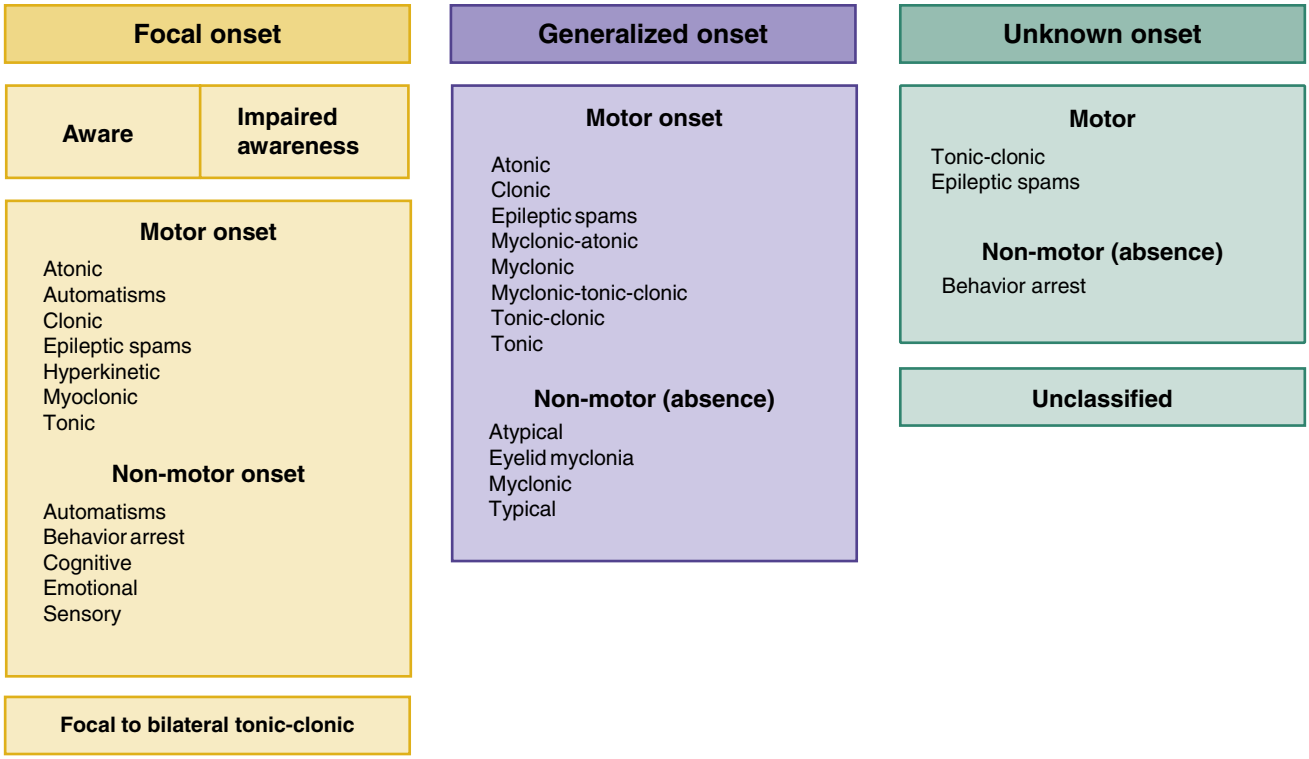

Fig. 14.1 Classification of Seizure Types (Extended Version).[6]

4. *Purposeless, stereotypic, and nonsuppressible.* Automatisms and undirected tonic-clonic movements are common in ictal events; if witnessed, a gentle attempt to suppress clonic activity (i.e., brief careful restraint of a convulsing limb in an attempt to extinguish movement) helps differentiate tremors and other nonepileptic convulsive events from seizures. Tonic-clonic movements are often rhythmic and if involving other body parts, synchronous. Dystonic posturing in tonic seizures is also common; they are usually asymmetric when bilateral and distinct from extensor or flexor posturing associated with neurologic emergencies.
5. *A postictal state of variable duration, which correlates with the duration of the preceding seizure.* The transient neurologic deficit may be sensory, motor, visual, cognitive, emotional, or related to consciousness. In general, the postictal state occurs with all seizure types, except absence. Postictal periods following seizures are typically transient (length-dependent according to seizure duration); the acute encephalopathic state may include lethargy, confusion, and impaired recollection of events.

Seizures may also be accompanied by transient cardinal systemic signs of sympathetic stimulation, such as tachycardia, hypertension, or tachypnea. Autonomic discharges and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting (with aspiration risk), lateral tongue biting, and airway compromise in the peri-ictal period. All of these signs are helpful discriminators in the differential evaluation of seizure-like episodes, although the presence or absence of these findings neither confirms nor excludes seizure occurrence. Evidence of physical injury should be thoroughly investigated because these may be occult in the altered patient.

Once a seizure is suspected, determining the underlying trigger is imperative. This should be followed by an inquiry regarding prior seizure history. New-onset seizures or a change in seizure patterns in those with known epilepsy may be the primary manifestation of serious underlying diseases and should prompt a thorough evaluation. If there is a documented history of seizures, ED evaluation may be limited to identifying precipitants and obtaining an antiseizure drug level, when applicable/available as the most common etiology is poor compliance or adjustment in regimen leading to subtherapeutic levels. The history should focus on clinical factors known to decrease the seizure threshold, such as recent illness or trauma, drug or alcohol use, sleep deprivation, potential adverse drug-drug interactions with antiseizure drugs, medication noncompliance, recent change in dosing regimens, or change in ictal pattern or characteristics. In women of reproductive age with epilepsy, catamenial exacerbation of seizures is extremely common. Furthermore, pregnancy can affect clearance of antiseizure drugs, leading to subtherapeutic levels. In pregnant women with and without a history of epilepsy, eclampsia must be considered.

After the seizure activity has ceased, resting vital signs are evaluated. Fever and underlying infection can cause seizures, although there may be a low-grade temperature elevation immediately after a generalized convulsive seizure. Tachypnea, tachycardia, fever, or an abnormal blood pressure that persists beyond the immediate postictal period may indicate toxic exposure, hypoxia, infection, or an acute central nervous system lesion. Pertinent physical findings may include nuchal rigidity, stigmata of substance abuse, lymphadenopathy suggestive of HIV disease or malignancy, dysmorphic features, or skin lesions. The examination should also focus on potential adverse sequelae of convulsive seizures, such as head trauma, oral and tongue injury, posterior shoulder dislocation, or back pain. (See Table 88.3.)

Finally, a complete neurologic examination is performed. A persistent focal deficit after a seizure (e.g., Todd paralysis) often indicates the focal origin of the event but also may suggest underlying structural injury, such as ischemic or hemorrhagic strokes. Approximately half of patients with convulsive generalized status epilepticus have subsequent nonconvulsive seizures when placed on continuous EEG monitoring, and more than 15% will be in nonconvulsive status epilepticus. The patient with persistent altered consciousness should be carefully examined for signs of ongoing subtle convulsive or nonconvulsive seizures, such as abnormal eye movements and facial myoclonus. The

higher-risk population for ongoing nonconvulsive status epilepticus include those with acute or remote brain injury (including prior violations of the intracranial cavity with craniotomies), toxic exposure, sepsis, or renal or liver failure.

ANCILLARY TESTING

Laboratory Testing

Women of reproductive age should be tested for pregnancy.

The serum glucose level should be determined in every seizing or postictal patient because hypoglycemia is a common metabolic cause of provoked seizures. Ictal activity of any semiology can occur at a plasma glucose level less than 45 mg/dL, although some patients may have a seizure at higher levels. Prolonged seizures can also *cause* hypoglycemia. Seizures that do not cease after correction of low blood glucose deserve further evaluation and treatment for alternative causes.

Patients with prolonged generalized convulsions (e.g., >2 minutes) should have creatine kinase and lactic acid tested to assess for rhabdomyolysis and acute metabolic acidosis, respectively; prolonged convulsions or tonic posturing without increased lactic acid are less likely to be epileptic in nature. Presence of a lactic acidosis that resolves on subsequent ED testing supports a seizure diagnosis. In epilepsy patients with unexplained increase in seizure frequency and a stable antiseizure regimen, infections such as common viral illness should be considered as precipitating events. Patients with a dramatic increase in the severity of seizures or those with an abnormal neurologic examination should undergo a more thorough laboratory assessment.

In patients with advanced age or comorbidities or who are ill in appearance, the diagnostic evaluation should be expanded to include a basic or comprehensive metabolic panel to assess metabolic derangements that may trigger seizures. Sodium, calcium, and magnesium are all associated with cell membrane stabilization; most commonly, hyponatremia and hypocalcemia are triggers of seizures. Because magnesium helps stabilize the neuronal cell membrane, hypomagnesemia is a common finding in adult and children presenting with seizures in several settings. Keep in mind that total body magnesium levels may not be reflected by serum levels. Hypomagnesemia must be considered and may warrant empiric treatment in cases of malnutrition or chronic alcoholism, for example. Patients with lower serum bicarbonate on basic metabolic panel may benefit from blood gas analysis and lactic acid testing. Anion gap metabolic acidosis is commonly secondary to lactic acidosis in convulsive seizures; acidosis is typically transient with lactic acid levels declining within the first hour after convulsions cease. Patients with prolonged nonepileptic convulsions often have normal lactic acid levels and white blood cell count. Persistent lactic acidosis or other anion gap acidosis suggests an underlying process, including sepsis, ketosis (alcoholic or diabetic), or poisoning (methanol, iron, isoniazid, ethylene glycol, salicylates, carbon monoxide, or cyanide). Liver enzyme (i.e., AST and ALT) abnormalities may indicate the presence of chronic disease or underlying hepatic-mediated metabolic derangements. Patients with known or suspected history of liver disease or those that take valproic acid should have ammonia tested given the heightened risk for hyperammonemia, which further increases the risk for seizures and will impact therapeutic decisions on antiseizure regimen. Routine testing of prolactin is not indicated given its relative lack of sensitivity and specificity for seizures.

Proposed cutoff laboratory values for acute symptomatic seizures and those values that can be interpreted as thresholds of metabolic derangements for lowering the seizure threshold can be found in Chapter 88 (Box 88.3).

Patients with or without history of epilepsy who are on antiseizure medications for any indication (i.e., seizure prophylaxis, mood stabilization, anxiety, and/or adjunctive psychiatric treatment) should have levels obtained, as available. The turnaround time for antiseizure drug level results varies widely; phenytoin, phenobarbital, valproic acid, and carbamazepine are the most commonly available levels with the fastest turnaround times and well-established therapeutic ranges. Lamotrigine, topiramate, and oxcarbazepine have therapeutic ranges established, but prolonged turnaround times reaching several days makes their assessment impractical in the emergent setting. Levetiracetam level has a broad therapeutic range with unclear ideal targets and variable turnaround times based on institution but may still prove instrumental in confirming compliance, particularly when patients have repeated visits to the ED with similar presentations who report not missing doses. Free levels of antiseizure drugs that are highly protein bound (e.g., valproic acid and phenytoin) are more accurate, and widely available online calculators provide a correction of total levels according to albumin.

Patients who are on medications that have epileptogenic potential (e.g., lithium) should have the levels of these drugs tested, whenever available. Directed toxicology screens with blood or urine samples should be performed if substance abuse (particularly cocaine, amphetamines, and other sympathomimetic agents) or overdose of aspirin or acetaminophen is suspected. However, many drugs of abuse (e.g., synthetic marijuana) and medications (e.g., baclofen, bupropion) that may be implicated in the etiology of seizures do not have a widely available testing method, and so, negative routine toxicology screens should be interpreted with caution. Furthermore, positive urine toxicologic screen for sympathomimetic agents are not confirmatory of the etiology of seizures in all cases because these substances can be detected in specimens for several days to weeks after the exposure. However, the screen may suggest a possible etiology and may help with future medical and psychiatric disposition.

Reactive leukocytosis of varying magnitude is very common after convulsive seizures; there are no thresholds of elevated white blood cell count that may definitively suggest a concomitant infectious process. Febrile patients should be evaluated for the source of the fever, including consideration of lumbar puncture and respiratory viral testing (i.e., influenza, respiratory syncytial virus). Lumbar puncture should also be considered in immunocompromised patients and in those presenting with acute headache concerning for subarachnoid hemorrhage, meningismus, or persistent altered mental status. Pleocytosis in cerebrospinal fluid may indicate infectious or autoimmune etiologies.

Imaging Studies

Neuroimaging is recommended by the American Academy of Neurology in adults presenting with new-onset seizures; it can be performed in the ED or at a follow-up in those who are back to a normal neurologic baseline and do not have headache. Most patients with a history of epilepsy, particularly in those who return to baseline, do not require neuroimaging. Box 14.1 summarizes characteristics of patients presenting with seizures that should prompt consideration for neuroimaging.

Headache is occasionally a postictal symptom. There are no specific characteristics pertaining to the quality of postictal headaches. Severe headache, thunderclap nature (reaching maximum severity from onset within seconds), associated neurologic deficits, altered mental status, meningismus, and/or fever should prompt additional evaluation with computed tomography (CT) of head. If there is clinical suspicion for meningoencephalitis or subarachnoid hemorrhage, after a nondiagnostic CT, lumbar puncture must be considered as part of the diagnostic management. Patients with a history of malignancy, immunosuppression, use of systemic anticoagulation, or history of prior intracranial hemorrhage; who are older than 40 years; or in whom trauma is suspected should have consideration for CT in the ED.

BOX 14.1 Characteristics Prompting Consideration of Neuroimaging in a Patient With Seizures

Age >40 years
Coma
Immunocompromised state
Clot disorder (hypercoagulability or hypocoagulability)
History of intracranial hemorrhage
History of malignancy
Severe, thunderclap headache
Status epilepticus, convulsive and nonconvulsive, of unclear etiology
Stigmata of neurocutaneous syndromes
Suspected trauma

CT perfusion, a contrast-enhanced modality with arterial phase and postsignal processing of imaging, can be particularly helpful in the evaluation of transient neurologic deficits consistent with Todd paralysis; in these cases, acute ischemic stroke is high in the differential and can be reliably detected by this modality.[7] However, there are no specific CT perfusion findings in seizure patients because their perfusion status is dependent on the temporal relationship of seizure and time of imaging acquisition. If magnetic resonance imaging (MRI) is readily available, it can be used instead of CT in most patients as long as the patient is stable to lay flat for a prolonged period: It has increased sensitivity for subtle structural lesions and adds to the diagnostic yield in patients with recurrent seizures and in those with focal abnormal EEG. When MRI is obtained in the work-up of seizures, the addition of gadolinium, T2 thin coronal views through hippocampus and limbic structures increases its diagnostic yield. Reversible cortical restricted diffusion is the typical signature of prolonged seizures on MRI (see Chapter 88, Fig. 88.1). For pediatric considerations, refer to Chapter 169); in brief, emergent neuroimaging in children presenting with seizures is indicated in the setting of an abnormal neurologic exam or medical or surgical comorbidities and in those younger than 3 years with focal or prolonged seizures.

Electroencephalography

EEG is useful to diagnose nonconvulsive status epilepticus, monitor seizure activity, guide third-line therapies after intubation and neuromuscular blockade, and help differentiate seizures from other nonepileptic presentations. ED-based EEG may assist with the prompt diagnosis of epilepsy in patients with new-onset seizures and decision making on the initiation of secondary seizure prophylaxis; however, studies demonstrating its cost-effectiveness are lacking.[1] New devices with limited montage or assembly that can be performed at the point of care in select cases may be of value and expedite EEG in the emergent setting but are not routinely recommended.

Cardiac Monitoring

Patients with a history of cardiac disease, with preceding or ongoing cardiac symptoms, and who continue to seize may benefit from cardiac monitoring. The same is true of patients suspected of overdose. An electrocardiogram (ECG) is also an early screen for drug toxicity. Tricyclic cardiotoxicity may manifest as a QRS complex lasting more than 0.1 second or a rightward shift of the terminal 40 ms of the frontal plane QRS complex (a prominent R wave in lead aV_R). The ECG can also identify a prolonged QT, a delta wave, Brugada pattern, or heart block, which might contribute further clues to the seizure etiology. Electrocardiographic changes are common in the peri-ictal period and range from sinus tachycardia to more concerning features such as ST segment depression and T wave inversion. Prolongation of intervals on ECG is common in the peri-ictal period, which may challenge differentiating seizures from a primary cardiac related etiology of syncope.[8]

BOX 14.2 Differential Diagnoses for Seizures

The following are diagnoses with presentations that can be difficult to differentiate from seizure activity.

Cardiac
Vasodepressive (vagal) syncope
Orthostatic syncope
Cardiogenic syncope

Neurologic
Stroke, transient ischemic attack (in particular, limb shaking TIA)
Complicated migraine
Movement disorders: chorea, dystonia, subcortical myoclonus, tremors
Parasomnias
Extensor or flexor posturing from herniation syndromes

Toxicologic
Intoxication, inebriation
Over sedation, over analgesia
Extrapyramidal symptoms

Metabolic
Hypoglycemia, hyperglycemia
Thyrotoxicosis
Delirium tremens

Infectious
Meningoencephalitis
Tetanus

Psychiatric
Nonepileptic spells
Conversion disorder
Panic attacks
Cataplexy

DIFFERENTIAL DIAGNOSES

The differential diagnoses to consider when evaluating for seizure are listed in Box 14.2. In all of these conditions, clarification of associated signs and symptoms (e.g., loss of sphincter control, postictal state, tongue biting, inability to suppress movements), exam (e.g., nystagmus, delayed pupillary response, hyperreflexia, abnormal plantar reflex), and the circumstances of the event (i.e., when and where the event occurred, the precipitating events, positioning, type of movements) are instrumental in discerning whether the event is epileptic or not in nature. In addition, several of these conditions may overlap with seizures because they are associated with seizure triggers, or even represent precipitating events themselves. Transient cerebral ischemia (focal or global) can be associated with nonepileptic convulsive symptoms such as convulsive syncope or limb-shaking transient ischemic attacks. A variety of movement disorders, including those that are transient and associated with toxins, can lead to tonic, myoclonic, or clonic symptoms that may be hard to differentiate from seizures. Migraine with an aura can be confused with nonconvulsive seizures given the positive visual phenomenon. However,

migraine has a gradual or protracted temporal evolution prior to developing a peak of symptoms over several minutes followed by gradual resolution; these are key distinctive features from occipital seizures, in which such evolution is much faster in the order of seconds to a few minutes. Furthermore, these patients will almost always have a history of migraine, often with similar presentation.

Nonepileptic spells, or pseudoseizures/psychogenic spells, are events that mimic seizures and status epilepticus, commonly reaching 5 minutes or longer.[9] Patients inadvertently medicated with high doses of benzodiazepine in an attempt to treat these seizure mimics must be monitored for respiratory failure and need for support of ventilation.[10] In fact, in the Established Status Epilepticus Treatment Trial (ESETT) trial that investigated second-line therapies for convulsive status epilepticus, more than 10% of enrolled patients were ultimately diagnosed with nonepileptic spells.[11] To complicate matters further, up to one-third of patients who have known epilepsy may also have nonepileptic spells. Features consistent with nonepileptic etiology of convulsions include prolonged duration of spells (at times reaching well over 20 minutes), a higher prevalence of "stop-and-go" pattern of convulsions, forward pelvic thrusting, horizontal head shaking and bilateral asynchronous convulsions while maintaining eyes closed, disproportionally shorter postictal period to duration of spells, avoidance of noxious stimuli, and preserved recollection of events. On laboratory testing, patients with psychogenic nonepileptic spells often lack reactive leukocytosis and lactic acidosis, which are nearly universal in those with prolonged generalized convulsive seizures or status epilepticus.

DIAGNOSTIC ALGORITHM

In patients suspected of having had a seizure, the first step is to determine whether the history from the patient or bystander(s) supports the diagnosis. Critical causes of seizures with specialized treatments include eclampsia, toxic ingestion (e.g., isoniazid, lithium, tricyclic antidepressants), hypoglycemia, hyponatremia, and increased intracranial pressure. Box 14.3 presents the critical and emergent diagnoses that must be considered.

Fig. 14.2 presents a practical framework for the approach of patients with seizures. Regardless of prior history of seizures, directed questions should be made to characterize event. In those with history of epilepsy, information should be gathered on the seizure disorder and typical events. Information regarding the onset, presence of aura, type of seizure, and duration of ictal and postictal periods is key to determining whether the seizure is similar to previous seizures. If the seizure appears typical for the patient, the emergency clinician should identify the antiseizure drug regimen and inquire about potential triggers that can lower the seizure threshold, such as sleep deprivation, infections, and new or modified medications. If the patient is taking an antiseizure drug for which a serum level can be measured (e.g., phenytoin, carbamazepine, valproic acid) and found to be subtherapeutic, then additional medication can be given via the intravenous (IV) or oral (PO) route as a bridge. The patient can then be discharged once recovered to their previous neurologic baseline, with outpatient evaluation by a neurologist or primary care physician.

In the absence of prior seizure history, the diagnostic approach is directed to assess for potential precipitants, such as toxic ingestions, and history or physical exam findings of a process that warrants further evaluation and specific treatment, such as immunosuppression, pregnancy, or head trauma.

Patients who arrive at the ED with ongoing seizure activity or who experience recurrent seizures without returning to baseline are in status epilepticus and require antiseizure therapy and cardiac monitoring. There should be a low threshold for obtaining a bedside EEG, especially if the postictal period is prolonged or automatisms are noted.

BOX 14.3 Critical and Emergent Diagnoses to Consider in a Patient With Seizures

Critical Diagnoses

Status epilepticus, convulsive and nonconvulsive, regardless of cause

Seizures with specialized treatments

- Eclampsia
- Toxic ingestion (e.g., isoniazid, lithium, tricyclic antidepressants)
- Hypoglycemia
- Hyponatremia, hypocalcemia
- Increased intracranial pressure

Emergent Diagnoses

Infection

Acute brain injury: ischemic or hemorrhagic strokes, traumatic brain injury, cerebral venous thrombosis

Serious mimics of seizure activity (e.g., cardiogenic syncope)

EMPIRIC MANAGEMENT

The initial priorities in the management of the actively seizing patient include the prompt recognition and treatment of hypoxia, hypotension, and hypoglycemia and the initiation of pharmacologic treatment when indicated (Fig. 14.3); there is overlap between prehospital and ED settings in these interventions.

The patient should be placed in a monitored setting, and airway should be assessed and secured if respiratory failure ensues and cannot be supported by cessation of seizure and bag-mask ventilation. The patient should be protected from injury related to uncontrollable convulsions and, if possible, placed in a lateral decubitus position to reduce aspiration risk. Intermittent suctioning of oral secretions must be performed with caution. Nasopharyngeal airway devices may help with transient obstruction that may occur in the peri-ictal period, but oropharyngeal devices should be avoided because they may induce gagging and vomiting and may damage the teeth or tongue. Oxygen may be administered to supplement immediate oxygenation and in preparation for possible rapid sequence intubation.

The majority of seizures will cease spontaneously, and thus abortive treatments are recommended for seizures lasting greater than 5 minutes or when airway or hemodynamic compromise is noted. In the prehospital and emergent setting, it may be difficult to ascertain the exact duration of seizure events; patients who are still seizing by the time of evaluation should be suspected to be in status epilepticus, and the management priority should be the rapid administration of a benzodiazepine. Well-designed trials have shown the efficacy and safety of early administration of benzodiazepines during prehospital care. Studies, specifically in children, have demonstrated that delays in first-line benzodiazepine treatment have been associated with increased mortality, longer seizure duration, and hemodynamic compromise.[12] Intramuscular (IM) midazolam can be quickly administered; there is evidence that it is superior to IV lorazepam in adults and noninferior in children. Based on ease of administration and comparable outcome to IV lorazepam, we recommend IM midazolam 0.2 mg/kg as the first-line intervention in field management of status epilepticus and IV lorazepam 0.1 mg/kg whenever access is established. We do not recommend the use of rectal diazepam in managing status epilepticus because absorption is erratic and not as dependable as other routes. Intranasal formulations of both midazolam and diazepam have recently been approved by the US Food and Drug Administration (FDA); however, available data are insufficient to make

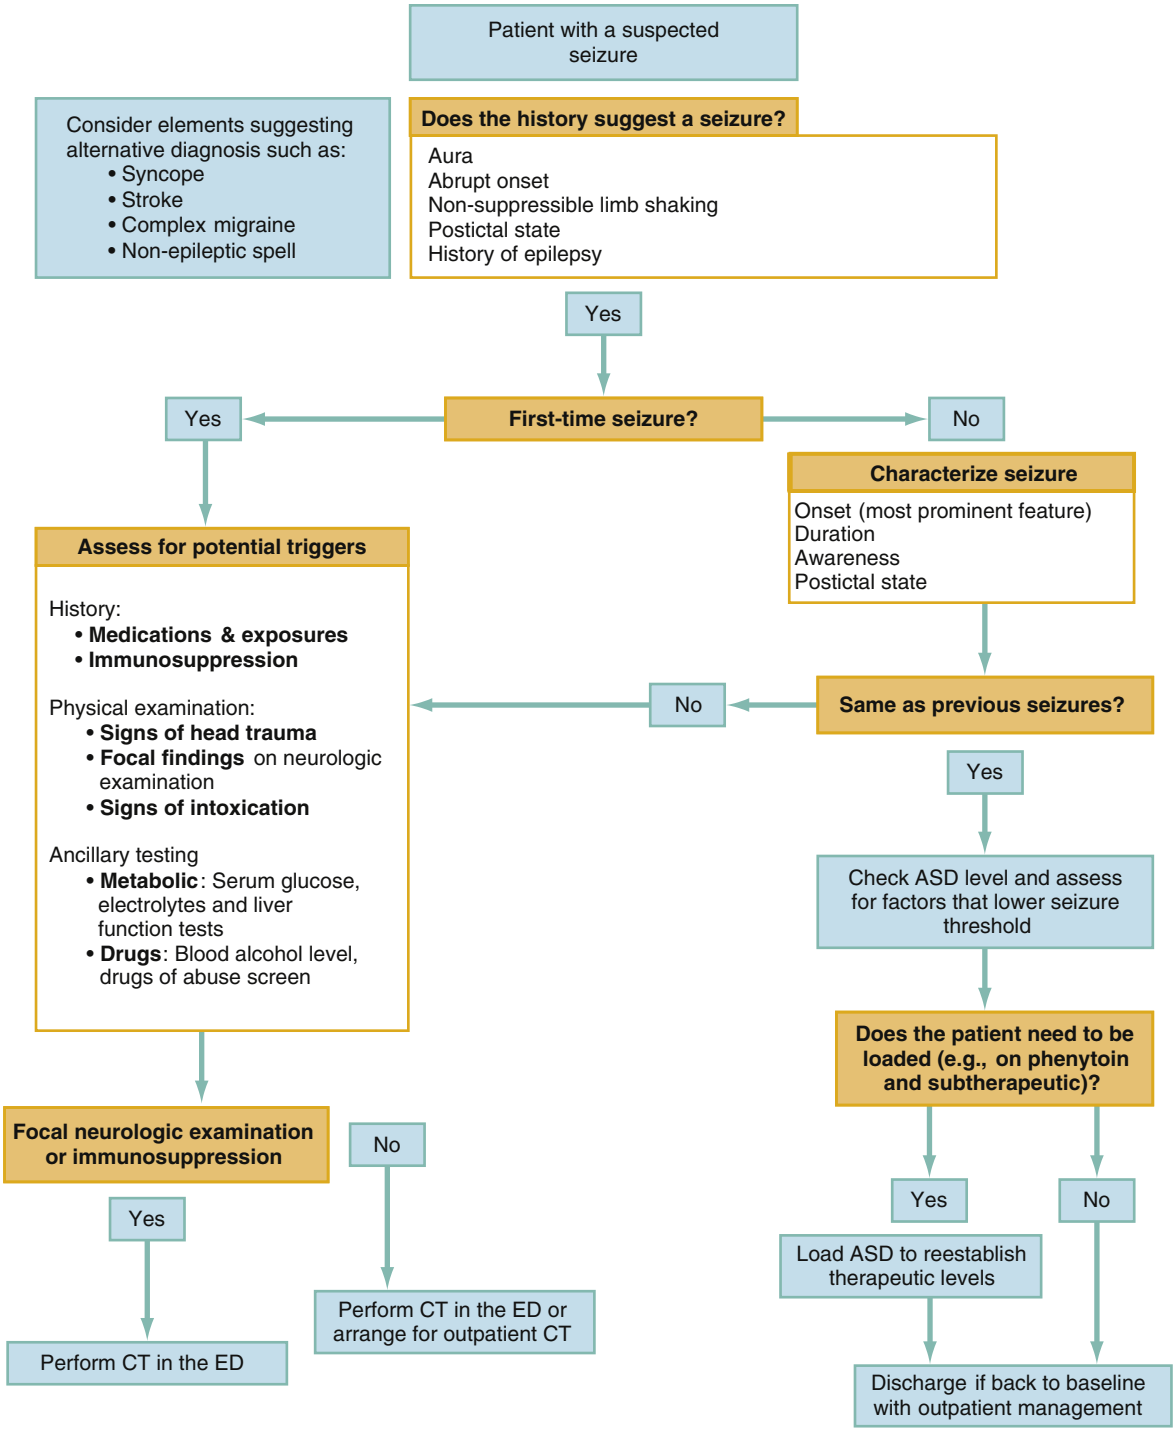

Fig. 14.2 Initial Approach to Patients With Suspected Seizure. *ASD*, Antiseizure drug; *CT*, computed tomography; *ED*, emergency department.

recommendations regarding their use in the ED. We recommend to repeat dosing of first-line therapy (i.e., midazolam or lorazepam) prior to moving on to second-line therapies.[13,14]

Among second-line therapies for convulsive status epilepticus, the best studied so far include valproic acid, phenytoin, and levetiracetam; when appropriately dosed, they have similar efficacy.[11] Table 14.2 provides details on dosing and pharmacologic considerations on the most commonly used medications according to the tier of intervention (medications are listed in alphabetic order; agent selection of second- and third-line therapy should be individualized). If seizures persist, endotracheal intubation and the consideration of third-line therapies are indicated. In patients at risk for hemodynamic compromise, the maintenance of cerebrovascular perfusion is paramount; and so the administration of fluid resuscitation and vasoactive support should be considered in the setting of administering parenteral antiepileptic medications that may compound the risk of hypotension in the setting of rapid sequence intubation (i.e., propofol, pentobarbital, ketamine, midazolam).

Refractory seizures require careful reassessment to ascertain underlying or occult processes, such as acute brain injury, drug overdose, and

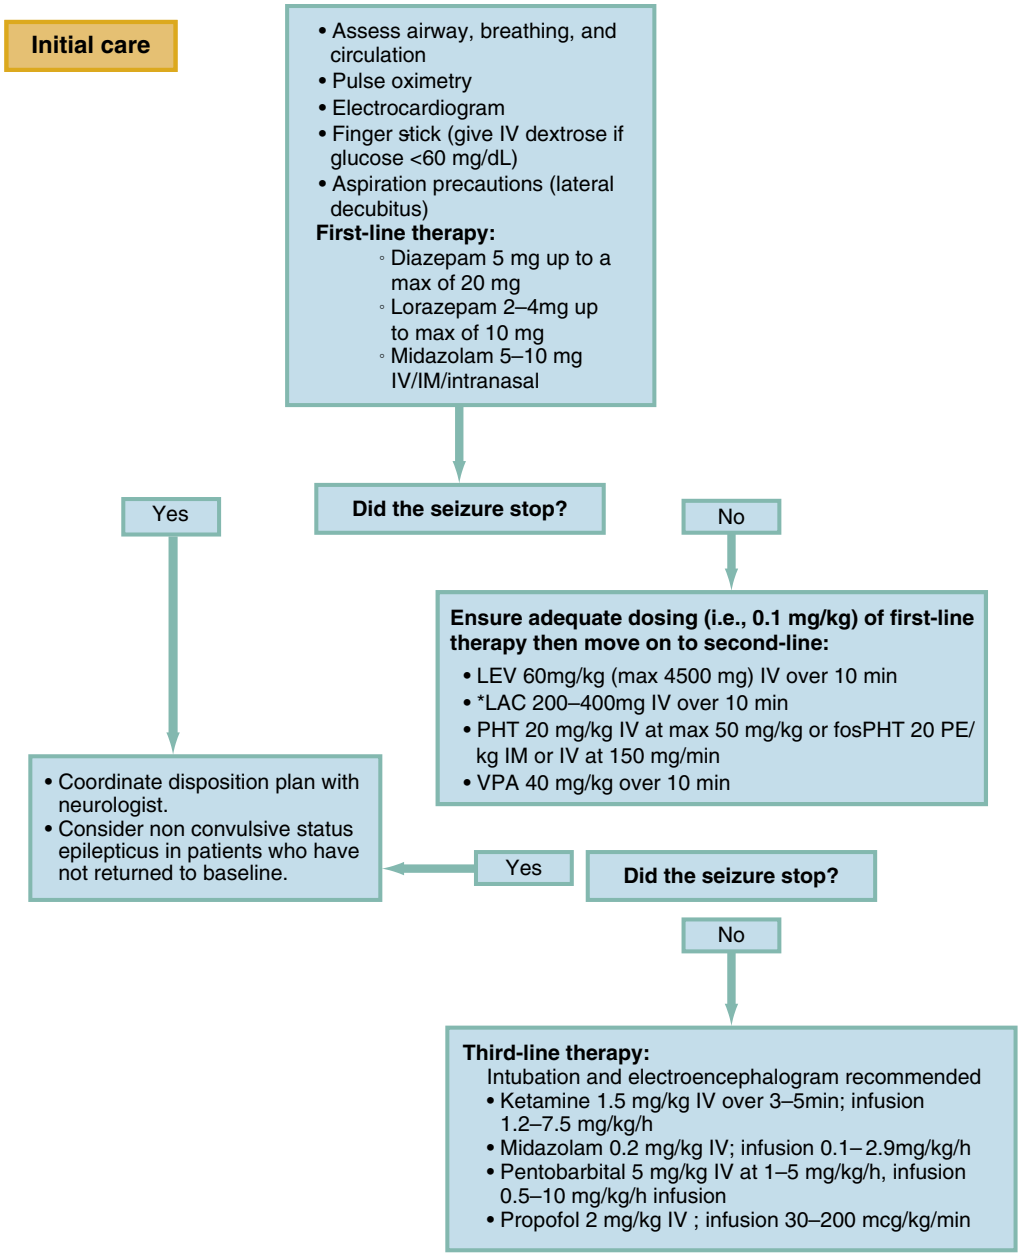

Fig. 14.3 Empiric Management of Patients With Seizures and Status Epilepticus.[14] Medications were listed in alphabetic order; agent selection of second- and third-line therapy should be individualized). *Limited high-quality data comparing efficacy of lacosamide with levetiracetam, phenytoin, fosphenytoin, and valproic acid in status epilepticus. *IM*, Intramuscular; *IV*, intravenous; *fosPHT*, fosphenytoin; *LAC*, lacosamide; *LEV*, levetiracetam; *PHT*, phenytoin; *PE*, phenytoin sodium equivalents; *VPA*, valproic acid.

metabolic abnormalities. Specific seizure syndromes should also be considered in patients at risk. For example, isoniazid overdose can cause prolonged seizures refractory to benzodiazepines and requires pyridoxine to terminate the seizures. In seizing female patients of childbearing age, eclampsia may be the cause, and IV magnesium is the treatment of choice. Eclamptic seizures refractory to magnesium may respond to benzodiazepines or barbiturates, with or without second-line therapy. Children and psychiatric patients at risk for water intoxication may be hyponatremic and require hypertonic saline therapy. See Chapter 88 (Table 88.4 for specific management strategies of these conditions and Table 88.5 for suggested loading doses to resume therapy in epilepsy patients).

Recurrence of seizures following first-time unprovoked seizures is highest in the first 2 years.[2] The consideration of secondary seizure prophylaxis—in collaboration with consulting neurologist—should include a risk stratification for recurrence (higher risk in those with prior brain insult, with abnormal EEG, brain imaging abnormality, and those with nocturnal seizures) and potential antiseizure drug related adverse effects.[2] Immediate antiseizure regimen initiation is associated with reduced recurrence risk in the initial 2 years and may positively influence quality of life,[15] but it is unlikely to change prognosis in the long term.[2]

Disposition

The disposition of a patient presenting to the ED with a seizure or history of a recent seizure must be individualized according to the underlying illness, likelihood of recurrence, indications for maintenance

TABLE 14.2 Commonly Used Parenteral Antiseizure Agents, Dosing, and Pharmacologic Considerations for Status Epilepticus

Medication	Adult Dose	Comments
First Line		
Diazepam	0.15–0.2 mg/kg IV over 1–2 min max 10 mg per dose, 10– 20 mg PR	Repeat doses every 5 min to a maximum of 30 mg; monitor respiratory status. Rapid redistribution. IV formulation contains propylene glycol. Preferred benzodiazepine for rectal route when IM midazolam and IV lorazepam are not available
Lorazepam	0.1 mg/kg IV over 1–2 min (maximum 4 mg per dose)	Repeat doses every 5 min to a maximum of 12 mg (adults); monitor respiratory status. Rapid redistribution. IV formulation contains propylene glycol. Preferred IV benzodiazepine; do NOT administer IM.
Midazolam	0.2 mg/kg IV over 1–2 min, IM, IN (max of 10 mg per dose)	Repeat doses may be administered every 5 min; monitor respiratory status. Half-life ~7 h. Rapid redistribution. Active metabolites. Preferred IM benzodiazepine.
Second Line		
Levetiracetam	1000–4500 mg over 10–15 mins (40-60 mg/kg for status epilepticus; maximum of 4500 mg)	Renally cleared.
Fosphenytoin	10–20 mg PE/kg IV (max 150 mg PE/min), IM	May give an additional 5 PE/kg 10 min after loading dose. May cause hypotension and dysrhythmia but less profound than phenytoin. May be administered IM if no IV access. Compatible in saline, dextrose and lactated Ringers.
Lacosamide	200–400 mg IV over 10 min	May give an additional 5 mg/kg over 5 min (max 250 mg IV). May cause arrhythmias (prolonged PR and QTc intervals, or tachyarrhythmias). Renally cleared.
Phenobarbital	15–20 mg/kg at 50–100 mg/min	May give additional 5–10 mg /kg. Monitor respiratory status. Strong cytochrome P450 (CYP) inducer. IV formulation contains propylene glycol.
Phenytoin	15–20 mg/kg IV infusion maximum at 50 mg/min (25 mg/min in patients with cardiac history)	May give an additional 5–10 mg/kg 10 min after the load, up to 30 mg/kg total. May cause hypotension and dysrhythmia. Potent CYP inducer. May cause rash, fever. IV formulation contain propylene glycol. Only compatible in saline. Severe tissue injury risk with extravasation.
Valproic acid	20–40 mg/kg IV over 5–10 min; max 3000 mg.	May give additional 20 mg/kg (max 2000 mg) over 5 min. Potent CYP inhibitor. May cause hyperammonemia, hepatotoxicity, and platelet dysfunction.
Third Line—Require Intubation, Mechanical Ventilation, and Hemodynamic Support		
Ketamine	Loading: 1.5 mg/kg IV over 3–5 min May repeat 0.5 mg/kg every 3–5 mins as needed Maintenance: starting dose 0.1-4 mg/kg/hr, max 15 mg/kg/hr	NMDA antagonist, which provides an alternative treatment to GABAergic mediated anesthetics. May cause hypotension when shock index ≥0.9. Higher infusion rates associated with large volumes due to dilution.
Midazolam	Loading: 0.2 mg/kg IV, followed by 0.2 mg/kg every 3–5 min (max 2 mg/kg) May repeat 0.2–0.4 mg/kg (max 40 mg bolus) max 2 mg/kg Maintenance: 0.05–2 mg/kg/h	May cause hypotension with higher doses.
Pentobarbital	Loading: 5–15 mg/kg at 50 mg/min, may administer an additional 5–10 mg/kg if needed, max 25 mg/kg Maintenance: 0.5–5 mg/kg/h	Half-life 22 h (up to 50 h as it is dose dependent). May cause hypotension, ileus, myocardial suppression, immunosuppression, and thrombocytopenia. Contains propylene glycol.
Propofol infusion	Loading: 1–2 mg/kg, may repeat 0.5–2 mg/kg every 3–5 mins up to max of 10 mg/kg total Maintenance: normal range 20–80 mcg/kg/min, max 200 mcg/kg/min	Half-life 0.6 h (extended with prolonged infusions). May cause hypotension, respiratory depression, hypertriglyceridemia, pancreatitis, propofol infusion syndrome

Medications are in alphabetic order. The selection of the second- and third-line agents should hinge upon consideration of potential side effects, interactions with other medications, severity of seizures, and their response to other types of medications and comorbidities.
GABA, γ-Aminobutyric acid; *IN*, intranasal; *IM*, intramuscular; *IV*, intravenous; *NMDA*, *N*-methyl-D-aspartic acid; *PE*, phenytoin sodium equivalents.

pharmacologic therapy, psychosocial considerations, and state reporting regulations.

Patients may be discharged home with early referral to a neurologist if they have a normal neurologic examination, no significant medical comorbidities, and no known structural brain disease, did not require more than one dose of a benzodiazepine in the ED, and are thought to have sufficient resources to comply reliably with follow-up instructions. When the diagnosis is uncertain, history of neurologic disease or other comorbidities exist or close follow-up is unlikely, neurologic consultation, longer observation, or admission for observation should be considered.

Patients discharged home from the ED should receive state-specific guidance regarding driver's license privileges, warning about potentially dangerous activities (e.g., swimming, climbing ladders and heights, operating machinery), and information for prompt follow-up with a neurologist.

CHAPTER 14: QUESTIONS AND ANSWERS

1. A 63-year-old woman with end-stage renal disease on hemodialysis, diabetes, and hypertension is brought to the emergency department after losing consciousness during hemodialysis. The episode occurred towards the end of the hemodialysis section approximately 45 minutes ago and was associated with foaming at the mouth, cyanosis, and bilateral tonic-clonic movements of upper extremities lasting nearly 3 minutes. On examination, T 36.6°C, HR 89 bpm, SBP 195 mm Hg, RR 11, pulse oximetry 94%, Glasgow Coma Score (GCS) is 10 with subtle nystagmus, and no meningismus. Computed tomography of the head (CTH) demonstrated hypodensities in bilateral parieto-occipital regions.

What is the leading diagnosis and required work up?

- **a.** Nonconvulsive status epilepticus from hypertensive emergency; electroencephalography (EEG)
- **b.** Cortical blindness from bilateral posterior cerebral artery stroke; computed tomography angiogram
- **c.** Coma from meningoencephalitis; lumbar puncture
- **d.** Coma from uremia; blood urea nitrogen (BUN)

Answer: a. The description of the episode of loss of consciousness with associated cyanosis, and tonic-clonic convulsions is highly suspicious for a generalized tonic-clonic seizure. The patient has not returned to baseline mentation as demonstrated by GCS of 10 and is displaying subtle signs of potentially ongoing seizures (nystagmus); thus the most likely diagnosis is nonconvulsive status epilepticus, which can be diagnosed only with an electroencephalogram. The elevated blood pressure along with hypodensities in the posterior cortical region on CTH are highly suggestive of posterior reversible encephalopathy syndrome, a form of hypertensive emergency. The patient has acute encephalopathy and the stem of the question does not display findings suggestive of cortical blindness (preserved pupillary light reflex with complete binocular vision loss). Lack of prodrome of headache and confusion, fever, and meningismus make meningoencephalitis less likely. The episode happened towards the end of hemodialysis section, so profound uremia is unlikely.

2. You suspected posterior reversible encephalopathy syndrome (PRES) and order a STAT electroencephalography (EEG) while lowering the blood pressure in a stepwise approach. While the patient is waiting to be admitted to the neurology intensive care unit and connected to EEG, the bedside registered nurse reports new left gaze deviation, fine eyelid twitching, and more prominent nystagmus that was refractory to 1 mg of lorazepam. Your index of suspicion for nonconvulsive status epilepticus is high and you decide to treat empirically. The patient weighs 52 kg.

What is the first-line therapy for status epilepticus treatment?

- **a.** Fosphenytoin 1000 mg intravenous (IV)
- **b.** Lorazepam 5 mg IV
- **c.** Levetiracetam 3000 mg IV
- **d.** Lacosamide 300 mg IV

Answer: b. The first-line therapy for seizures and status epilepticus is benzodiazepines. In the hospital setting, lorazepam IV is most commonly used. Although all the other choices are reasonable second-line antiseizure drugs, the patient has received only 1 mg of lorazepam at this point, and a total of 5mg of lorazepam (0.1 mg/kg) is considered appropriate first-line therapy.

3. According to the best evidence available from randomized controlled trials, which second-line antiseizure regimen is recommended for benzodiazepine-resistant convulsive status epilepticus?

- **a.** Fosphenytoin 20 mg phenytoin equivalent (PE)/kg
- **b.** Valproic acid 40 mg/kg
- **c.** Levetiracetam 60 mg/kg
- **d.** All of the above

Answer: d. According to the Established Status Epilepticus Treatment Trial (ESETT) fosphenytoin 20 mg PE/kg (max 1500 mg), valproic acid 40 mg/kg (max 3000 mg), and levetiracetam 60 mg kg (max 4500 mg) were equally effective in terminating convulsive status epilepticus in nearly half of randomized patients (fosphenytoin 45%, valproic acid 46%, levetiracetam 47%). The ESETT trial has provided the best

evidence to date on the second-line treatment of convulsive status epilepticus.

4. A 37-year-old woman with remote history of head trauma from a motor vehicle collision presents to the emergency department with ongoing bilateral convulsions. The patient's significant other witnessed the onset of convulsions 45 minutes ago following an argument. She received a total of 10 mg of intramuscular (IM) midazolam while being transported by the emergency medical services. On examination, T 36.3°C, HR 120 bpm, SBP 115 mm Hg, RR 22, pulse oximetry 100% on a nonrebreather mask; she has her eyes closed and resists passive eye opening of the examiner, does not respond otherwise to the examiner and has ongoing asynchronous, nonstereotypic, and suppressible convulsions of both upper extremities with associated pelvic thrust.

   What are the most important nonpharmacologic initial interventions in patients with suspected generalized convulsive status epilepticus?

   a. Placing an oropharyngeal airway device, lateral decubitus positioning, establishing an intravenous (IV) line
   b. Checking glucose fingerstick, establishing an IV line, lateral decubitus positioning
   c. Suctioning oral cavity, placing oropharyngeal airway device, lateral decubitus positioning patient
   d. Checking glucose fingerstick, placing nasopharyngeal airway device, supine positioning

Answer: b. Initial nonpharmacologic interventions include ensuring physical safety of patients with seizures to prevent traumatic injuries and aspiration. During convulsions, focusing on lateral decubitus positioning and suctioning of oral cavity are important to prevent aspiration; the use of intraoral devices may lead to trauma without additional benefit. Nasopharyngeal airway devices may help with transient obstruction that may occur in the peri-ictal period, but oropharyngeal devices should be avoided as they may induce gagging and vomiting and may damage the teeth or tongue. The serum glucose level should be determined in every seizing or postictal patient as hypoglycemia is a common metabolic cause of provoked seizures. Although some first-line seizure abortive medications can be given IM, intraosseous (IO), per rectum (PR), intranasal (IN), establishing an IV line is a helpful initial step to facilitate timely pharmacologic interventions.

5. An additional 6 mg of lorazepam IV (0.1 mg/kg) slows down the movements but does not abort them completely. What is the most common differential diagnosis for generalized convulsive status epilepticus?

   a. Nonepileptic spells
   b. Neuroleptic malignant syndrome
   c. Complex migraine
   d. Cardiogenic syncope

Answer: a. Although all the answers reflect conditions that can be considered seizure mimics, nonepileptic spells, or pseudoseizures, represent the most common differential diagnosis for generalized convulsive status epilepticus with an incidence of approximately 10% of subjects enrolled in clinical trials. Nonepileptic spells tend to last greater than 5 minutes, thus meeting criteria for convulsive status epilepticus by duration of events, and be resistant to high doses of benzodiazepines. Neuroleptic malignant syndrome is also associated with prolonged spells of abnormal movement, but the type of involuntary movement (typically tonic extension of all extremities, opisthotonos and rigors) and associated hyperthermia, tachycardia, and diaphoresis can distinguish these disorders. Complex migraine typically manifests as lateralizing dysesthesia in association with severe throbbing headache with phono/photophobia, and not with prolonged convulsions. Convulsions associated with cardiogenic syncope usually occur in the setting of hypoperfusion and are brief, unlike this case.

6. Which additional features may assist in the diagnosis of nonepileptic spells?

   a. Disproportionally short postictal confusional state
   b. Normal lactic acid and creatine kinase
   c. Lack of reactive leukocytosis
   d. All of the above

Answer: d. Although the only reliable way to diagnose nonepileptic spells is by characterizing the lack of an underlying seizure rhythm on electroencephalography (EEG) during spells, clinicians should be attentive to clues in the presentation and work-up that suggest a pseudoseizure diagnosis. Prolonged tonic-clonic convulsions (i.e., generalized convulsive status epilepticus) is invariably associated with some degree of rhabdomyolysis and elevation of lactic acid. The complete blood count often displays reactive leukocytosis. Postictal-related confusion or acute encephalopathy is one of the hallmarks of generalized tonic-clonic seizures and carries a direct relationship with the duration of seizures. Short periods of confusion following prolonged bilateral convulsions is suggestive of a nonepileptic spell diagnosis.

7. A 23-year-old woman currently 34 weeks' pregnant with her first baby presents to the emergency department with headache and fatigue. On exam, T 36.2°C, HR 89 bpm, SBP 145 mm Hg, RR 27, pulse oximetry 96%; she is fully oriented, complains of subjective blurry vision and has 2+ pitting edema of lower extremities. You suspect preeclampsia and initiate the work-up.

   What is the typical period for the development of preeclampsia and eclampsia?

   a. 16–37 weeks of gestational age
   b. 20 weeks of gestational age until 8 weeks postpartum
   c. 20 weeks of gestational age until delivery
   d. None of the above

Answer: b. In pregnant patients, the risk of eclampsia is highest from 20 weeks of gestational age up to 8 weeks postpartum. Clinical evaluation should focus on evaluating for associated symptoms (e.g., headache, visual abnormalities and confusion), as well as focal neurologic deficits.

8. What are the red flags that prompt neuroimaging in patients presenting with eclamptic seizures?

   a. No red flags needed, all patients should get a noncontrast computed tomography of the head with abdominal shielding
   b. If persistent neurologic deficits, including prolonged loss of consciousness or encephalopathy
   c. If more than two seizures are observed within 24 hours
   d. If seizures are refractory to benzodiazepines

Answer**: b.** Neuroimaging should be considered if neurologic deficits persist, prolonged loss of consciousness, or encephalopathy. Intravenous magnesium 4 to 6 g is first-line therapy in the pregnant patient experiencing new-onset seizures. Benzodiazepines and nonteratogenic antiseizure medications are reasonable alternatives in magnesium-refractory cases.

9. A 61-year-old previously healthy man presents to the emergency department with a first seizure. The episode consisted of left arm and face clonic movements with secondary generalization and postictal lethargy and left hemiparesis lasting 10 minutes. On examination, T 37.1°C, HR 79 bpm, SBP 105 mm Hg, RR 17, pulse oximetry 96%, GCS is 15 with no focal deficits. Given the focality of seizure onset and the patient age, you obtained a noncontrast computed tomography of the head, which was unremarkable. Which of the following factors should be considered when counseling patients on recurrent seizure risk after a first-time seizure?

a. Presence of focal abnormalities on electroencephalography (EEG)
b. Presence of focal abnormalities on neuroimaging
c. Identification of seizure triggers
d. All of the above

Answer: c. Up to 45% of adults presenting with a first unprovoked seizure will experience another within 2 years, most occurring in the first year 2. The risk is higher with known brain lesions, neuroimaging or EEG abnormalities, or nocturnal seizures 2; the latter are associated with epilepsy syndromes.

10. A 71-year-old man with advanced dementia from multiple prior strokes, atrial fibrillation on warfarin, localization related epilepsy on levetiracetam presents to the emergency department with a breakthrough seizure. The episode consisted of speech arrest and clonic movements of right face and arm. There was no postictal state identified. On examination, T 36.1°C, HR 109 bpm, SBP 115 mm Hg, RR 15, pulse oximetry 97%, GCS is 15 with no focal deficits. Which of the following factors should be considered when deciding on the need for neuroimaging after a breakthrough seizure?
a. No red flags needed, all patients should get a noncontrast CTH
b. Young age, specifically in the pediatric population
c. Use of vitamin K antagonist
d. Lack of identifiable triggers

Answer: c. Neuroimaging should be considered if neurologic deficits persist, prolonged loss of consciousness or coma, advanced age, immunocompromised state, coagulopathy (including anticoagulant drugs) or hypercoagulability, history of malignancy, preceding severe thunderclap headache, status epilepticus, in patients with stigmata of neurocutaneous syndromes, and suspected trauma.

11. What is the most common metabolic cause of seizure activity?
a. Hypercalcemia
b. Hyperglycemia
c. Hypermagnesemia
d. Hypocalcemia
e. Hypoglycemia

Answer: e. Seizure activity secondary to metabolic derangements is most commonly caused by hypoglycemia. The only treatment required in this situation may be intravenous (IV) glucose. Prolonged seizure activity may also cause hypoglycemia so that the cause-and-effect relationship may sometimes be reversed, and further therapy may be required.

12. A 15-year-old girl is brought to the emergency department for evaluation of a recent seizure. While awaiting laboratory results, she begins to have further seizure activity. Which of the following is the optimal first-line agent to terminate her seizure activity?
a. Fosphenytoin
b. Lorazepam
c. Phenobarbital
d. Phenytoin
e. Valproic acid

Answer: b. Benzodiazepines are the optimal first-line agents for stopping seizure activity in patients of all ages. Available agents include lorazepam, diazepam, and midazolam. Phenytoin is recommended as second-line therapy for adults with persistent seizure activity. The prodrug, fosphenytoin, can be administered more quickly, can be given intramuscularly, and has less of a tendency to cause hypotension. Second-line therapy for children is phenobarbital. Third-line therapy is pentobarbital, propofol, or a benzodiazepine infusion. Valproic acid should be considered for patients who are on chronic valproic therapy and whose levels are subtherapeutic.

13. A 24-year-old man is brought to the emergency department by emergency medical services (EMS). The patient's mother reports that she found her son seizing on the floor of her living room approximately 30 minutes before arrival at the hospital. Two months ago, the patient returned from Mexico, where he had been incarcerated for 6 months. The mother reports that during the past 2 months she has seen her son consistently take his seizure medicine and several other pills for a "bad lung infection" he got in Mexico. She cannot remember the names of any of the medications. Several doses of intravenous (IV) lorazepam have been administered, with no effect on the patient's seizure activity. Which of the following medications would be the most effective in aborting his seizure activity?
a. Diazepam
b. Magnesium sulfate
c. Phenytoin
d. Pyridoxine
e. Valproic acid

Answer: d. Several historical clues in this scenario point to tuberculosis being the "bad lung infection" in this patient. In patients with seizures that are refractory to benzodiazepines, isoniazid (a common medication for tuberculosis) overdose is a possibility and should be considered. Pyridoxine is the only fully effective pharmacologic treatment for toxic isoniazid seizures, although benzodiazepines have been shown to suppress seizure activity in some cases.

14. A mother arrives with her 10-year-old daughter (41 kg) who has been seizing for at least 10 minutes. The patient has a history of epilepsy, and a home dose of rectal diazepam has been ineffective. The mother states that the child has been in her usual state of good health until the seizure began, and there has been no history of trauma. Which of the following is the most appropriate initial action?
a. Administer 10 mg midazolam intramuscularly.
b. Consult neurology to obtain a bedside electroencephalogram.
c. Endotracheal intubation with vecuronium and etomidate.
d. Establish vascular access and administer 2 mg of lorazepam.
e. Obtain an immediate computed tomography scan of the head.

Answer: a. Early, aggressive benzodiazepine administration is associated with decreased morbidity and mortality in status epilepticus. Intramuscular midazolam is superior to intravenous lorazepam; in addition, the dose of lorazepam is inadequate. Endotracheal intubation may ultimately be required but is a secondary priority; use of a long-acting neuromuscular blockade agent, such as vecuronium, should be avoided. Cranial computed tomography may or may not be needed in this patient, depending on the response to benzodiazepine therapy. Bedside electroencephalograms are most useful in diagnosing nonconvulsive status epilepticus.

15. Paramedics present with a 24-year-old woman with a history of epilepsy after a seizure. She is somnolent but easily arousable and oriented to self and year. Her vital signs are normal, there are no signs of trauma, and an empty expired bottle of phenytoin is found in her purse. Her prehospital finger stick blood glucose level is 163 mg/dL. Which of the following treatment options is most correct?
a. Administer 20 mg/kg fosphenytoin intramuscularly and observe the patient until she returns to baseline.
b. Establish vascular access, and administer 4 mg lorazepam intravenously (IV).
c. Establish vascular access, obtain a phenytoin level, and administer 1 to 2 mg lorazepam IV if the patient begins to seize.
d. Place the patient in a monitored setting, establish vascular access, and withhold diagnostic tests and treatments unless patient's condition changes.

Answer: c. Medication noncompliance is a frequent cause of seizures in adults with epilepsy. It is recommended to check phenytoin levels before administering additional drug. Because the patient is not in status epilepticus, a low dose of benzodiazepines can be considered for patients who begin to seize while undergoing a period of observation.

16. Which of the following is not part of the routine emergency department evaluation and treatment of a 21-year-old healthy woman with a first seizure?

a. Discharge, with early outpatient neurology follow-up
b. Evaluation of serum electrolyte levels
c. Initiation of antiepileptic drug therapy
d. Performance of cranial computed tomography

Answer: c. Adults presenting with a first seizure should undergo cranial computed tomography and evaluation of serum electrolyte and glucose levels because abnormalities would likely influence disposition while identifying potentially life-threatening conditions. For otherwise healthy adults with normal findings after evaluation, early outpatient follow-up can be considered. In some cases, initiation of antiepileptic drugs can be considered after a first seizure; however, this should be done in consultation with the neurologist responsible for outpatient follow-up.

15

Dizziness and Vertigo

Andrew K. Chang

KEY CONCEPTS

- Neurologic complaints, such as imbalance, dysarthria, or numbness in patients with dizziness/vertigo raise the likelihood of transient ischemic attack (TIA) or stroke as the cause.
- Benign paroxysmal positional vertigo (BPPV) requires head movement to elicit symptoms. Consequently, the Hallpike test should *not* be performed if the patient is actively symptomatic during history taking (and the patient's head has not been recently moved) because such a history is inconsistent with BPPV.
- When performing the Hallpike test, the head should be turned to the side 45 degrees prior to laying the patient back into the head-hanging position.
- A positive Hallpike test should elicit upbeating (fast phase towards eyebrows) nystagmus.
- The Epley maneuver is used to treat posterior semicircular canal BPPV, which is the most common subtype of BPPV.
- Central causes of nystagmus are more likely when the pattern of nystagmus is purely vertical, downbeating (fast phase beating toward the nose), nonfatigable, direction changing with gaze, or spontaneous pure torsional.
- The presence of auditory symptoms (e.g., hearing loss, tinnitus) suggests a peripheral cause of the vertigo.
- Acute vestibular syndrome is diagnosed when dizziness develops acutely; is constant; is accompanied by nausea or vomiting, unsteady gait, nystagmus, and intolerance to head motion; and persists for longer than a day.
- Neck injury resulting in a vertebral artery dissection causes posterior circulation ischemia presenting with vertigo.
- Nystagmus is the cardinal sign of inner ear disease and the principal objective evidence of vestibular dysfunction.
- *HINTS* (Head Impulse test, Nystagmus, Test of Skew) is a bedside oculomotor examination test that helps to differentiate central from peripheral vertigo in symptomatic patients with a first ever onset of constant vertigo from acute vestibular syndrome.
- Meclizine (Antivert) has a time of onset of approximately 1 hour.
- Benzodiazepines are not recommended for the treatment of vestibular neuritis or labyrinthitis in patients who are discharged home, because they can interfere with the process of vestibular rehabilitation.

FOUNDATIONS

Epidemiology

Dizziness is an extremely common yet complex neurologic symptom that reflects a disturbance of normal balance perception and spatial orientation. Patients use the term *dizziness* to describe a variety of experiences, including sensations of motion, weakness, lightheadedness, unsteadiness, emotional upset, and depression. Dizziness has historically been categorized in a symptom-based approach into one of four categories though the validity of this categorization has recently been called into question.[1] The historical categories include vertigo, which is an illusion of motion and typically described as the room spinning; near syncope, which is a sensation of feeling faint or lightheaded; disequilibrium, which is a sense of unsteadiness when walking; and nonspecific dizziness, which is generally thought to be related to a polysensory disorder with an anxiety component.

Acute vestibular syndrome (AVS) is used to describe a clinical condition in which dizziness develops acutely, is constant, persists longer than a day, and is accompanied by nausea or vomiting, unsteady gait, nystagmus, and intolerance to head motion.[2] The major differential diagnosis in acute vestibular syndrome is vestibular neuritis versus posterior circulation stroke.[3] Some recommend subdividing this into acute vestibular syndrome with nystagmus and acute vestibular syndrome without nystagmus because the diagnostic approach differs between them.[3]

Approximately 4% of ED visits are from dizziness, and strokes are the underlying cause in approximately 5% of those visits.[4] Although common causes of dizziness (e.g., benign paroxysmal positional vertigo [BPPV] and vestibular neuritis) can often be readily diagnosed via history and specific diagnostic tests, a precise diagnosis is not always possible even after imaging and neurology consultation. Thus the challenge for the emergency clinician is to identify the patient with a dangerous underlying disorder from the many others who have benign causes.

Pathophysiology

The maintenance of equilibrium and awareness of the body in relationship to its surroundings depend on the interaction of the visual, proprioceptive, and vestibular systems. Input from these three systems is connected to the cerebellum by way of the vestibular nuclei in the brainstem. Any disease that causes a mismatch of information from any two of these three systems may give rise to symptoms of vertigo.

The vestibular apparatus helps maintain head position and stabilize head movement. It is housed in the inner ear, or labyrinth, which lies embedded in the petrous portion of the temporal bone. The vestibular apparatus consists of three semicircular canals and two otolithic structures (the utricle and the saccule). The semicircular canals and the utricle are connected to each other and contain endolymph. The semicircular canals provide information about movement and angular momentum, whereas the utricle (via otoliths, which are calcium carbonate particles attached to hair cells) provides information about head tilt and vertical linear acceleration.

The semicircular canals are paired (left and right ears) structures that normally respond to motion in a symmetrical manner. With

inner ear disease, the resting discharge or the discharge stimulated by motion can be altered in one ear. This alteration produces asymmetric responses and results in the perception of vertigo. For example, freely moving otoliths that are inappropriately located within the semicircular canals, as in BPPV, can produce positional vertigo even when the head is currently still if the head had been recently moved. This is because the recent head movement causes the otoliths to move under the influence of gravity and inappropriately signal the brain.

Impulses leave the vestibular apparatus by the vestibular part of the acoustic nerve (cranial nerve [CN] VIII), enter the brainstem just below the pons and anterior to the cerebellum, and proceed to the four vestibular nuclei of the brainstem and to the cerebellum. From there, impulses travel along two pathways that contribute to the clinical manifestations of vertigo: (1) the medial longitudinal fasciculus (MLF) and (2) the vestibulospinal tract, which connect to the motor neurons that supply the muscles of the extremities. In individuals with healthy vestibular systems, these connections allow the eyes to compensate for body movement in different directions and to maintain a visual axis that is stable with respect to the environment. However, patients with a defective vestibular apparatus may experience false steps or other body movements, which is different from true ataxia, because they attempt to correct for an imagined change in position. Connections between the vestibular nuclei and the autonomic system account for the perspiration, nausea, and vomiting that commonly accompany an attack of vertigo. Connections between the vestibular nuclei and the cerebellum account for the modulating influence of this organ on motor activity.

Nystagmus occurs when the synchronized vestibular information becomes unbalanced. Typically, it results from unilateral vestibular disease, which causes asymmetric stimulation of the medial and lateral rectus muscles of the eye. This unopposed activity causes a slow movement of the eyes toward the side of the stimulus, regardless of the direction of deviation of the eyes. The cerebral cortex then corrects for these eye movements and rapidly brings the eyes back to the midline, only to have the process repeated. By convention, the direction of nystagmus is denoted by the direction of the fast "cortical" component.

Vertebrobasilar insufficiency (VBI) describes a temporary set of symptoms due to ischemia in the posterior circulation of the brain, which supplies the medulla, pons, midbrain, and cerebellum. Major arteries of the posterior circulation include the posterior inferior cerebellar artery (PICA), which is a branch of the vertebral artery, and the anterior inferior cerebellar artery (AICA), which is a branch of the basilar artery.

Table 15.1 lists the pathophysiology for selected causes of peripheral vertigo.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis for peripheral and central vertigo is summarized in Box 15.1. More detailed information is given on selected causes in Table 15.2. Peripheral disorders are generally benign, whereas central disorders usually have serious consequences. Table 15.3 summarizes the different characteristics of peripheral and central vertigo.

The symptom-based approach to categorizing dizziness into four categories (vertigo, near syncope, disequilibrium, and nonspecific dizziness) has been criticized as being imprecise,[5] and new categorization systems have been recently proposed. One system uses three general categories: (1) acute severe dizziness (e.g., vestibular neuritis, stroke), (2) recurrent attacks of dizziness (e.g., Ménière disease, TIA), and (3) recurrent positional dizziness (e.g., BPPV, cerebellar tumor, multiple sclerosis). Another system uses a "timing and triggers" approach, resulting in three categories: (1) acute vestibular syndrome (e.g., vestibular neuritis, cerebellar stroke), (2) spontaneous episodic vestibular syndrome (e.g., Ménière disease, VBI), and (3) triggered episodic vestibular syndrome (e.g., BPPV).[5] Neither of these approaches has been prospectively validated or systematically studied as a diagnostic paradigm, but they may provide a superior way to differentiate among the many causes of dizziness and vertigo.

Pivotal Findings

Symptoms

Vertigo is described as the environment spinning; however, any sensation of disorientation (subjective or objective) in space or sensation of motion can qualify as vertigo. Vertigo is generally associated with some degree of nausea, vomiting, pallor, and perspiration. Peripheral vertigo is not associated with a change in mentation or syncope. A sensation of imbalance often accompanies vertigo but dissipates when the attack is over. This can distinguish more serious causes of true instability, disequilibrium, or ataxia, findings of which indicate a higher likelihood of a central process.

The time of onset and the duration of vertigo are important clues to the cause. For example, episodic vertigo produced primarily by a change in head position and lasting less than a minute suggests BPPV. It is important to tease out how long each *individual* episode of vertigo lasts because patients with BPPV often think their vertigo is constant because any time they move their head they get another episode of vertigo. Acute vestibular syndrome has an arbitrary cutoff of continuous vertigo for at least 1 day, in part to help differentiate acute vestibular syndrome from attacks of Ménière disease or prolonged migrainous vertigo.

The presence of auditory symptoms suggests a peripheral cause of the vertigo, usually on the side of end-organ disturbance. Acoustic neuroma, which can rarely cause vertigo, is usually associated with progressive unilateral hearing loss, typically of several months' duration. Hearing loss, vertigo, and tinnitus form the characteristic triad of Ménière disease. Labyrinthitis is differentiated from vestibular neuritis in that the former is associated with hearing loss due to inflammation of both the vestibular and cochlear components of the eighth CN.

Head injury can cause vertigo occasionally from intracerebral injury and more commonly from labyrinth concussion, as well as from displacement of otoliths resulting in BPPV. Neck injury can cause vertigo from vertebral artery dissection, resulting in posterior circulation ischemia.

TABLE 15.1 Pathophysiology of Selected Causes of Peripheral Vertigo.

Diagnosis	Pathophysiology
Benign paroxysmal positional vertigo (BPPV)	Otoliths inappropriately displaced from utricle into semicircular canals (posterior > horizontal > anterior)
Vestibular neuritis and labyrinthitis	Inflammation (possibly viral) of the vestibular nerve
Ménière disease	Endolymphatic hydrops (excessive endolymph in the inner ear)
Perilymph fistula	Abnormal opening between the middle and inner ear

BOX 15.1 Causes of Vertigo

Peripheral Causes

Benign paroxysmal positional vertigo (BPPV)
Vestibular neuritis (or neuronitis)/labyrinthitis
Ménière disease
Foreign body in ear canal
Acute otitis media
Perilymphatic fistula
Trauma (labyrinth concussion)
Motion sickness
Acoustic neuroma

Central Causes

Vertebral basilar artery insufficiency
Cerebellar hemorrhage or infarction
Tumor
Migrainous vertigo
Multiple sclerosis
Posttraumatic injury (temporal bone fracture, postconcussive syndrome)
Infection (encephalitis, meningitis, brain abscess)
Temporal lobe epilepsy
Subclavian steal syndrome

Associated neurologic symptoms such as imbalance, dysarthria, or numbness are concerning for posterior circulation TIA and stroke. Although the vast majority of patients with isolated dizziness/vertigo do not have TIA or stroke, dizziness and vertigo can be the only initial symptoms of cerebellar and other posterior circulation hemorrhage, TIAs, and infarction. In these cases, diagnostic testing is directed by history and physical examination risk assessment. Older age, male sex, hypertension, coronary heart disease, diabetes, prior stroke, and atrial fibrillation put patients at higher risk for TIA and stroke. Many medications (e.g., aminoglycosides, anticonvulsants, alcohols, quinine, quinidine, and minocycline) have direct vestibulotoxicity and can also be the cause of the patient's symptoms.

Physical Examination

Vital signs. The vital signs, including orthostatic changes, may be the key to identifying a cardiovascular etiology or drug effect as the cause of dizziness. When subclavian steal syndrome is suspected, which also can cause VBI, the pulse and blood pressure should be checked in both extremities. A difference in blood pressure of greater than 40 mm Hg from one arm to the other is concerning for subclavian steal syndrome, and the patient will likely have arm fatigue or other symptoms on the affected side.

TABLE 15.2 Selected Causes of Peripheral and Central Vertigo.

Cause	History	Associated Symptoms	Physical
Peripheral			
1. Benign paroxysmal positional vertigo (BPPV)	Short-lived (typically <30 s), positional, fatigable episodes; more often in older adults.	Nausea, vomiting	Certain positions can precipitate vertigo. Positive result on Hallpike test (posterior semicircular canal) or supine roll test (horizontal canal).
2. Vestibular neuritis/labyrinthitis	Vertigo may develop suddenly or evolve over several hours, usually increasing in intensity for hours, then gradually subsiding over several days but can last weeks. Can be worsened with positional change. Sometimes history of viral infection precedes initial attack. Highest incidence is found in third and fifth decades.	Nausea, vomiting	Spontaneous nystagmus beating away from the side of the lesion may be present in the first few hours. Positive head impulse test. Hearing is normal in vestibular neuritis; hearing loss for labyrinthitis.
3. Ménière disease	Recurrent episodes of severe rotational vertigo usually lasting hours. Onset usually abrupt. Attacks may occur in clusters. Long symptom-free remissions.	Nausea, vomiting, tinnitus, hearing loss (hearing loss required for formal diagnosis)	Positional nystagmus is not present; hearing loss
Central			
1. Vascular disorders			
A. Vertebrobasilar insufficiency (VBI)	Should be considered in any patient of advanced age with isolated new-onset vertigo without an obvious cause. More likely with history of atherosclerosis. Can occur with neck trauma. May be preceded by an episode usually lasting minutes.	Often headache; usually neurologic symptoms including dysarthria, ataxia, weakness, numbness, double vision; tinnitus and hearing loss uncommon but possible	Neurologic deficits usually present, but initially neurologic examination can be normal.

TABLE 15.2 Selected Causes of Peripheral and Central Vertigo—cont'd

Cause	History	Associated Symptoms	Physical
B. Cerebellar hemorrhage	Sudden onset of severe symptoms.	Headache, vomiting, ataxia	Signs of toxicity. Dysmetria, true ataxia. Ipsilateral sixth cranial nerve palsy may be present.
C. Occlusion of posterior inferior cerebellar artery (Wallenberg syndrome)	Vertigo associated with significant neurologic complaints.	Nausea, vomiting, loss of pain and temperature sensation, ataxia, hoarseness	Loss of pain and temperature sensation on the side of the face ipsilateral to the lesion and on the opposite side of the body, paralysis of the palate, pharynx, and larynx. Horner syndrome (ipsilateral ptosis, miosis, and decreased facial sweating).
2. Head trauma	Symptoms begin with or shortly after head trauma. Positional symptoms most common type after trauma. Self-limited symptoms that can persist weeks to months.	Usually mild nausea	Occasionally, basilar skull fracture.
3. Migrainous vertigo	Vertigo attacks can occur during the headache (in one study of 33 patients, 24% always had headache with vertigo and 67% had headache sometimes with vertigo) but often occur during the headache-free interval. Most patients have a family history of migraine. Syndrome usually begins in adolescence.	Imbalance, head motion intolerance, photophobia, phonophobia, oscillopsia	No residual neurologic or otologic signs are present after attack.
4. Multiple sclerosis	Vertigo presenting symptom in 7%–10% and appears in the course of the disease in a third. Onset may be severe. Disease onset usually between ages of 20 and 40. Often history of other attacks with varying neurologic signs or symptoms.	Nausea and vomiting, which may be severe	May have horizontal, rotary, or vertical nystagmus. Nystagmus may persist after the vertiginous symptoms have subsided. Internuclear ophthalmoplegia (INO) highly suggestive for multiple sclerosis. INO is diagnosed when, on eye movement, the adducting eye shows little to no movement while the abducting eye moves normally.

TABLE 15.3 Characteristics of Peripheral and Central Vertigo.

Characteristic	Peripheral	Central
Onset	Sudden	Gradual or sudden
Intensity	Severe initially, often decreasing over time	Mild in most but can be severe in stroke and multiple sclerosis
Duration	Intermittent episodes lasting seconds to less than a minute for BPPV; continuous and lasting hours to days for vestibular neuritis	Usually weeks, months (continuous) but can be seconds or minutes with vascular causes, such as with posterior circulation TIA
Direction of nystagmus	Usually torsional and upbeat (fast phase beating toward forehead) in classic posterior canal BPPV; horizontal in horizontal canal BPPV; horizontal-torsional in vestibular neuritis/labyrinthitis	Purely vertical, spontaneous and purely torsional, direction-changing on lateral gaze, downbeating (fast phase beats toward nose)
Effect of head position	Induces vertigo (BPPV); worsens vertigo (vestibular neuritis)	Usually little change but can worsen with head position change
Associated neurologic findings	None	Usually present
Associated auditory findings	May be present, including tinnitus (Ménière disease) and hearing loss (labyrinthitis)	Rarely

BPPV, Benign paroxysmal positional vertigo; *TIA,* transient ischemic attack.

Head and neck. Carotid or vertebral artery bruits suggest atherosclerosis and risk for TIA or stroke. The vertebral artery can be auscultated in the supraclavicular region.

Fluid in the middle ear as a result of a middle ear infection may cause mild vertigo, as can occlusion of the eustachian tubes associated with an upper respiratory tract infection or descent barotrauma. A perforated or scarred eardrum may indicate a perilymphatic fistula, especially if the history includes previous trauma.

Examination of the eyes is critical in assessing a patient with vertigo. Pupillary abnormalities may indicate third CN or descending sympathetic tract involvement. Papilledema suggests increased intracranial pressure. Relatively subtle extraocular movement abnormalities can be the only clue to a cerebellar hemorrhage. A sixth CN palsy ipsilateral to the hemorrhage may result from early brainstem compression by the expanding hematoma. Internuclear ophthalmoplegia, which indicates brainstem pathology, is recognized when the eyes are in a normal position on straight-ahead gaze, but on eye movement the adducting eye (CN III) is weak or shows no movement while the abducting eye (CN VI) moves normally (although often displaying a coarse nystagmus). This finding indicates an interruption of the MLF on the side that demonstrates third CN weakness and is virtually pathognomonic of multiple sclerosis.

Abnormal nystagmus is the cardinal sign of inner ear disease and the principal objective evidence of abnormal vestibular function. Positional nystagmus, induced by changing the position of the head, strongly suggests an organic vestibular disorder, typically BPPV. Noting the characteristics of the nystagmus can help to differentiate benign peripheral causes from serious central causes (see Table 15.3). Central causes of nystagmus are more likely when the pattern of nystagmus is purely vertical, downbeating (fast phase beating toward the nose), nonfatigable, direction changing with gaze, or spontaneous pure torsional. Severity of nystagmus is directly related to the degree of acute vestibular hypofunction that occurs. Spontaneous nystagmus usually occurs in severe cases. In mild cases, vestibular asymmetry is less prominent, so spontaneous nystagmus may be subtle or present only for the first few hours. After that it may be only detectable when the patient looks away from the damaged ear or if the examiner performs a head impulse test.

Neurologic examination. The presence of CN deficits suggests a space-occupying lesion in the brainstem or cerebellopontine angle, such as an acoustic neuroma, which can rarely manifest with vertigo.

Cerebellar function is tested several ways: Dysmetria is the inability to arrest a muscular movement at the desired point and should be assessed with finger-to-finger or finger-to-nose pointing. Dysdiadochokinesia (an inability to perform coordinated muscular movement smoothly) is assessed with rapid alternating movements.

Gait assesses ataxia, which, when of recent and relatively sudden onset, suggests cerebellar hemorrhage or infarction in the distribution of the PICA or the superior cerebellar artery. Ataxia that is slowly progressive suggests chronic cerebellar disorders. True ataxia may be difficult to discern from the unsteadiness that occurs when a patient with vertigo attempts to walk, although other findings (e.g., nystagmus and dysmetria) can help narrow the differential diagnosis. This examination is performed when the patient is both sitting and standing, because truncal ataxia, which is seen in midline cerebellar lesions, may become obvious only when the patient has to sit, stand, or walk unaided. Any marked abnormality (e.g., consistent falling or a grossly abnormal gait) should suggest a central lesion, especially in a patient whose vertiginous symptoms have subsided. Patients with an acute peripheral vestibular lesion typically can stand, although they will likely veer toward the side of the lesion. Patients with central vertigo often cannot stand without support. The main features of a cerebellar gait are a wide base, unsteadiness, irregularity of steps, tremor of the trunk, and lurching from side to side. The unsteadiness is most prominent on arising quickly from a sitting position, turning quickly, or stopping suddenly while walking. Patients with gait ataxia also cannot perform heel-to-toe walking.

Positional testing. Positional testing confirms the diagnosis of BPPV. The Hallpike test, also known as the *Dix-Hallpike test* or the *Nylen-Barany test,* confirms the diagnosis of posterior canal BPPV, which is the most common variant of BPPV.[6] This test should be reserved for those patients suspected of triggered vertigo from head position change, and caution should be exercised in performing it in patients with acute vestibular syndrome (acute and constant dizziness, nausea or vomiting, unsteady gait, nystagmus, and intolerance to head motion lasting more than a day) whose main differential diagnosis include vestibular neuritis and posterior circulation stroke. Some evidence indicates that provocative testing may lead to a nonspecific worsening of symptoms in these patients, which could be misinterpreted as diagnostic of a peripheral disorder before stroke has been adequately excluded. Thus, if a patient is actively experiencing vertigo during history taking and there has been no immediate prior head movement, then the Hallpike test should not be performed because this history is inconsistent with BPPV, which requires head movement to elicit symptoms.

The Hallpike test is performed with the patient sitting up. The examiner turns the patient's head 45 degrees to one side and then moves the patient from the upright seated position to a supine position with the head overhanging the edge of the gurney (Fig. 15.1). The patient is queried for the occurrence of vertigo, and the eyes are observed for nystagmus after a latency period of a few seconds. In a patient with classic posterior canal BPPV, the nystagmus usually lasts 5 to 30 seconds and is combined upbeating (the fast phase beats toward the forehead) and ipsilateral torsional (the top pole beating toward the downward ear). The patient is then brought back up to the seated position, and the test is repeated with the head turned 45 degrees to the other side. Findings are summarized in Box 15.2.

In general, if the patient has posterior canal BPPV, only one side should be positive during the Hallpike test, although it is theoretically possible to have otoliths inappropriately located in both right and left posterior semicircular canals. Assuming unilateral involvement, the downward ear indicates the involved side, which is the side to start with when treating with the curative bedside Epley maneuver. If the

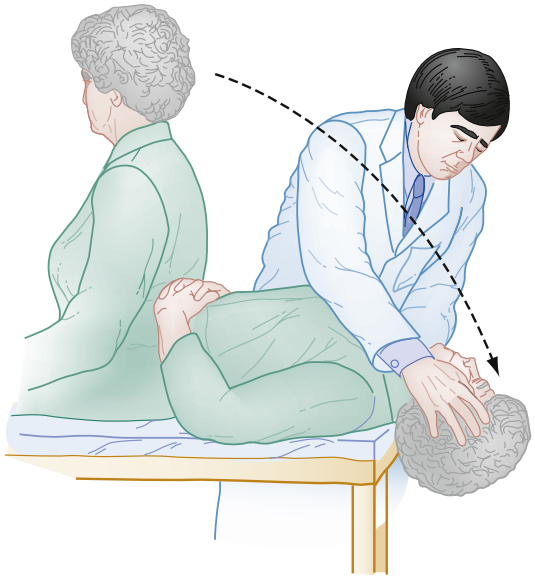

Fig. 15.1 Testing for Positional Vertigo and Nystagmus.

BOX 15.2 Classic Findings During Hallpike Test in Posterior Canal Benign Paroxysmal Positional Vertigo

- Latency (delay in nystagmus and vertigo once in head-hanging position) of approximately 3–10 s, although delay can take up to 30 s on rare occasions
- Reproduction of vertigo symptoms in head-hanging position
- Upbeat (fast phase toward forehead) and torsional nystagmus (usually toward the downward ear)
- Vertigo and nystagmus escalate in head-hanging position, then slowly resolve over 5–30 s
- Nystagmus and vertigo may reverse direction when patient returns to sitting position
- Nystagmus and vertigo decrease with repeated testing (fatigability)

patient pre-identifies the side that causes the symptoms, we test the opposite side first, and this should result in a negative Hallpike test. We then test the other side and, if positive, continue on to complete the Epley maneuver. (The first step of the Epley maneuver is the first part of the Hallpike test, which involves turning the head 45 degrees to the involved side and then laying the patient with the head hanging over the edge of the gurney.)

If the Hallpike test is negative or seems to be positive bilaterally, one can use the supine roll test to evaluate for the horizontal canal variant of BPPV. The patient starts in the supine position, although the head does not need to overhang the edge of the gurney as it would during the Hallpike test. The head is then turned 90 degrees to each side. With a positive test, the patient will have reproduction of symptoms and horizontal nystagmus with the head turned in either direction. The side that is involved is the side with the more intense symptoms and more dramatic nystagmus. Note that the nystagmus will change direction, but this is due to a change in head position and not from a change in gaze direction and so is not concerning for a central cause of vertigo. A video of a case involving failed attempts at the barbecue roll to treat horizontal BPPV, followed by conversion to posterior canal BPPV after a Gufoni maneuver[7] (with resultant cure using the Epley maneuver), can be found at www.youtube.com/watch?v=iOJOArGmepM.

The head impulse, or head-thrust test, is used to diagnose vestibular neuritis and labyrinthitis. The physician stands face to face with the patient and places both hands on the sides of the patient's head. The patient stares at the examiner's nose while the examiner rapidly turns the patient's head approximately 10 degrees to one side. Normally the patient's eyes should keep focusing on the examiner's nose. However, if there is a problem with the vestibular nerve, the eyes will temporarily move along with the head. A corrective saccade will then occur, in which the eyes jerk back toward the midline. If a saccade is seen, this denotes a positive head-thrust test result and indicates vestibular nerve dysfunction. In general, eliciting a positive head impulse test indicates a benign peripheral cause of vertigo, such as vestibular neuritis: The head must be turned rapidly to avoid concluding a false-negative which suggests a central cause.

Head Impulse Test, Nystagmus, Test of Skew. HINTS (*H*ead *I*mpulse test, *N*ystagmus, *T*est of *S*kew) is a bedside oculomotor examination test that has been proposed as a way to differentiate central from peripheral vertigo in patients with acute vestibular syndrome.[2]

The first part of HINTS is the head impulse test, and, as described earlier, a corrective saccade indicates a positive test and is more reassuring for vestibular neuritis, which is a benign cause of vertigo. The second part (nystagmus) refers to a direction change of nystagmus on eccentric gaze. Normally the fast phase is always directed to the same side regardless of gaze. But with direction changing nystagmus, when the patient looks to the left, the fast component beats to the left; and when the patient looks to the right, the fast component beats to the right. This direction-changing nystagmus may indicate a stroke in a patient with acute vestibular syndrome. The third part (test of skew) refers to vertical ocular misalignment during alternate cover testing, and its presence is suggestive of brainstem strokes.

Although the HINTS examination was initially thought to be possibly helpful to identify the smaller numbers of patients who are suffering from stroke or other central causes of vertigo, a recent systematic review and meta-analysis concluded that the HINTS examination, when used in isolation by emergency physicians, has not been shown to be sufficiently accurate to rule out stroke in those presenting with acute vestibular syndrome.[8] This is in large part because using HINTS requires experience and practice, and it should be used only in patients with a first ever episode of constant vertigo from acute vestibular syndrome, because this was the inclusion criteria in the majority of clinical studies involving the HINTS examination. For example, applying the head impulse test in a patient who is dizzy from BPPV would result in a negative test and may cause the emergency physician to incorrectly conclude that the patient's dizziness could be from a central cause of vertigo and lead to additional unnecessary testing. In general, performing both the Hallpike test and the HINTS examination on the same patient should not be routine. Instead, BPPV and acute vestibular syndrome should be distinguished from each other by history and by the presence of spontaneous nystagmus. Thus, if the patient does not have constant vertigo, then the patient does not have an acute vestibular syndrome and the HINTS examination should not be used. Overall the lack of evidence supporting the use of the HINTS examination by emergency clinicians is not evidence that it should not be performed by emergency physicians but rather that emergency clinicians should have a low threshold for referral and/or magnetic resonance imaging (MRI) in those presenting with AVS and one or more stroke risk factors.[8]

Ancillary Testing

Most routine laboratory testing is not helpful in the evaluation of a vertiginous patient except for a finger-stick blood glucose test. Blood counts and blood chemistries are helpful if the dizziness is thought to be due to anemia or dehydration. An electrocardiogram can evaluate for myocardial ischemia or dysrhythmia as a potential cause.

Radiologic imaging. Acute vertigo by itself does not warrant urgent computed tomography (CT) or MRI in all patients, particularly patients in whom a clear picture of peripheral vertigo emerges, such as with BPPV. Risk factor assessment can be helpful in deciding which patients warrant imaging: older age, male sex, hypertension, prior stroke, coronary artery disease, diabetes, and atrial fibrillation put patients at higher risk for more serious causes of dizziness and vertigo.

If cerebellar hemorrhage, cerebellar infarction, or other central lesions are suspected, emergent CT or MRI of the brain is indicated. MRI, when available, has become the diagnostic modality of choice for posterior fossa (cerebellum, medulla, and pons) lesions, as well as for rare causes of vertigo, including acoustic neuroma and multiple sclerosis.

DIAGNOSTIC ALGORITHM

Fig. 15.2 shows a diagnostic algorithm for dizziness and vertigo. Critical diagnoses include posterior circulation strokes. Emergent diagnoses include VBI, which should be considered in any patient of advanced age or at high risk of cerebrovascular disease who presents with isolated, new-onset vertigo without an obvious cause. Because of the possibility of progression of new-onset VBI in the first 24 to 72 hours,

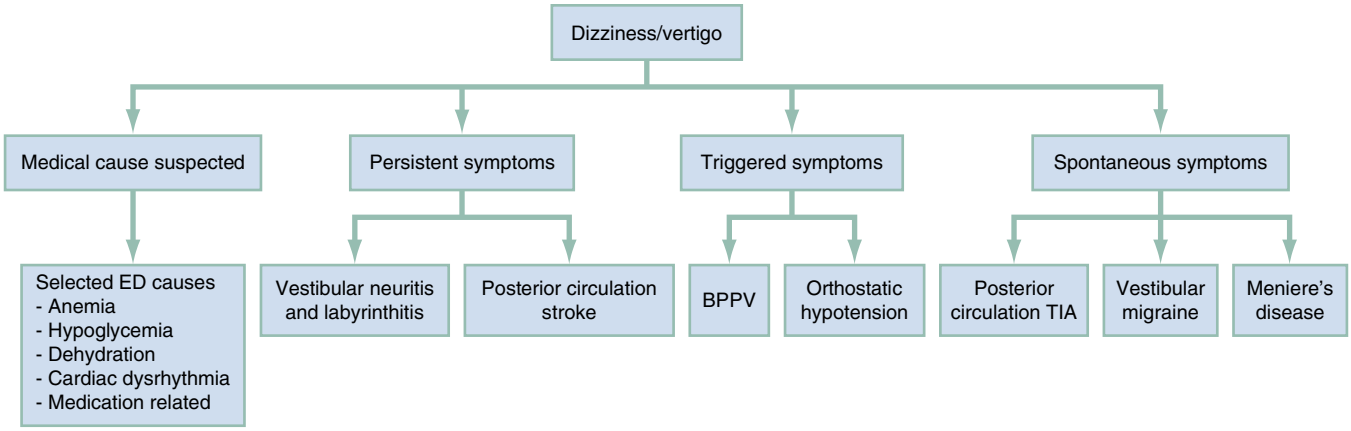

Fig. 15.2 Diagnostic Algorithm for Dizziness and Vertigo. *BPPV,* Benign paroxysmal positional vertigo; *TIA,* transient ischemic attack.

TABLE 15.4 Differentiating Benign Paroxysmal Positional Vertigo From Vestibular Neuritis/Labyrinthitis.

	Benign Paroxysmal Positional Vertigo	Vestibular Neuritis/Labyrinthitis
Age	More common in older adults	More common in younger patients
Hearing loss	None	None in vestibular neuritis; hearing loss in labyrinthitis
Frequency of symptoms	Episodic (occurs with certain movements of the head)	Constant
Hallpike test	Positive usually on one side only with upbeat and torsional nystagmus and reproduction of vertigo symptoms	Symptoms may be worsened in head-hanging position (*Note:* It is advised not to administer Hallpike test in a patient with a clinical history consistent with vestibular neuritis or labyrinthitis.)
Head impulse test	Negative (*Note:* It is advised not to administer head impulse test in a patient with a clinical history consistent with BPPV.)	Positive (corrective saccade seen)
Epley maneuver	Highly effective	Ineffective
Recurrence	Frequent	Rare (2%–11%)

BPPV, Benign paroxysmal positional vertigo.

hospital or observation unit admission and consideration of early magnetic resonance angiography (MRA) are reasonable, even in a stable patient. Changing or rapidly progressive symptoms suggest impending posterior circulation occlusion. If CT or MRI excludes hemorrhage as the source of the patient's rapidly progressive symptoms, an immediate neurologic consultation, further imaging (such as, angiography), and possible anticoagulation are indicated.

Most cases of vertigo are of peripheral origin and are not usually life-threatening. BPPV and vestibular neuritis are likely the most common peripheral causes of vertigo encountered in the ED. However, they are diagnosed and treated very differently. Table 15.4 helps to differentiate between these two diagnoses.

EMPIRICAL MANAGEMENT

Fig. 15.3 shows a general management algorithm in approaching patients with dizziness and vertigo. The Epley maneuver, which is the main canalith-repositioning maneuver used to treat posterior semicircular canal BPPV, involves four to five sequential rotations of the head, holding each position for approximately 30 seconds or until the nystagmus and vertigo resolves, as demonstrated in Fig. 15.4. Failure of the Epley maneuver is usually due to one of two problems: First, the head is lifted too high during the third step of the Epley maneuver, in which the patient rolls onto his or her side and looks toward the ground. Second, the Epley maneuver is often inappropriately applied to a patient who does not have BBPV but rather some other cause, such as vestibular neuritis (see Table 15.4).

The "barbecue roll" is a simple maneuver that can be used to treat the horizontal canal variant of BPPV, which is diagnosed by the supine roll test. The patient lies flat on the gurney with the head turned 90 degrees to the involved side. The head is then rotated in 45-degree intervals away from the involved side (each turn is held approximately 30 seconds or until nystagmus and vertigo resolve). Eventually the patient needs to turn over into the prone position. The maneuver is completed once the head has returned to the original starting position. The Gufoni maneuver is an alternative treatment for the horizontal canal variant (see http://careguides-videos.med.umich.edu/media/Gufoni+Left+Horizontal-Geotropic/1_3sii1rw8/20345631).

A practice guideline that was recently updated maintains that clinicians should not routinely treat BPPV with vestibular suppressant medications.[6] However, this guideline is from a specialty society whose patients often have chronic and likely milder forms of BPPV than patients who develop acute BPPV and come to the ED. For ED patients who are actively vomiting or cannot tolerate canalith-repositioning maneuvers and for those with other causes of acute vertigo (e.g., vestibular neuritis), it is reasonable to administer vestibular suppressants.

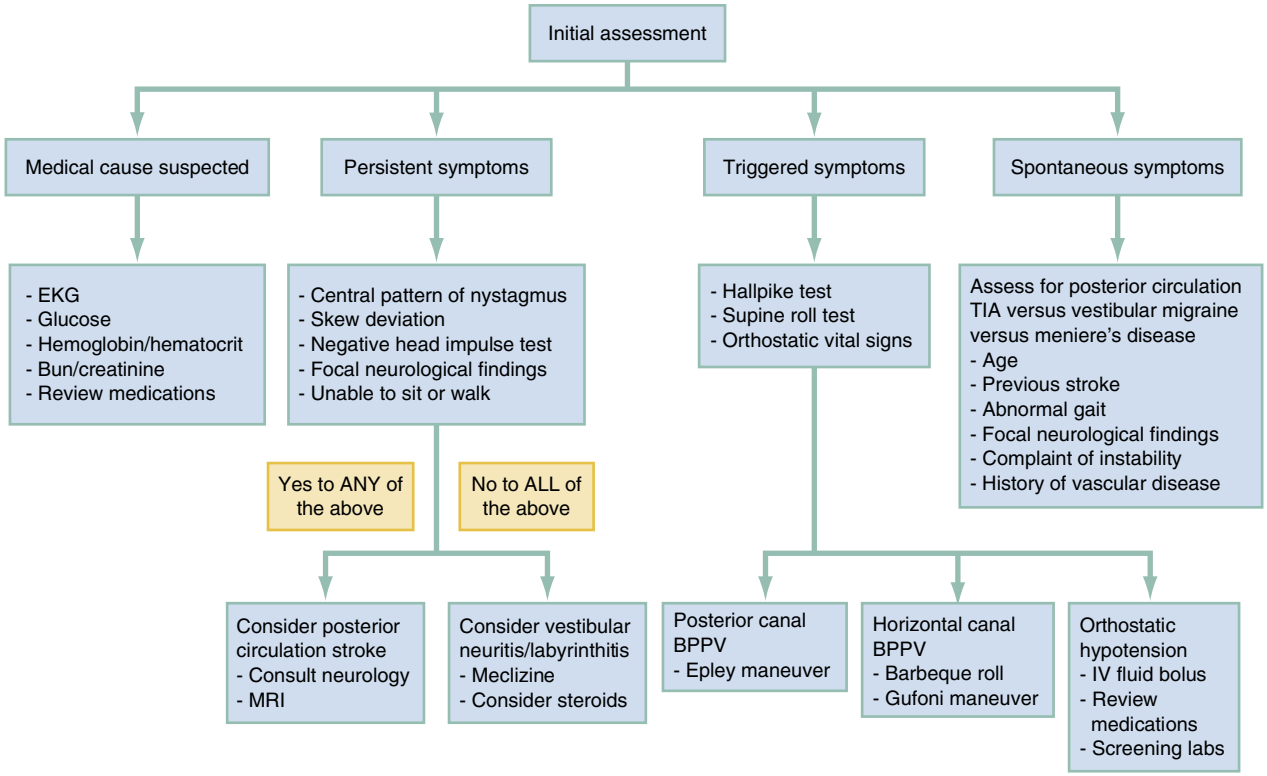

Fig. 15.3 Management Algorithm for Dizziness and Vertigo. *BPPV,* Benign paroxysmal positional vertigo; *ECG,* electrocardiogram; *IV,* intravenous; *MRI,* magnetic resonance imaging; *TIA,* transient ischemic attack.

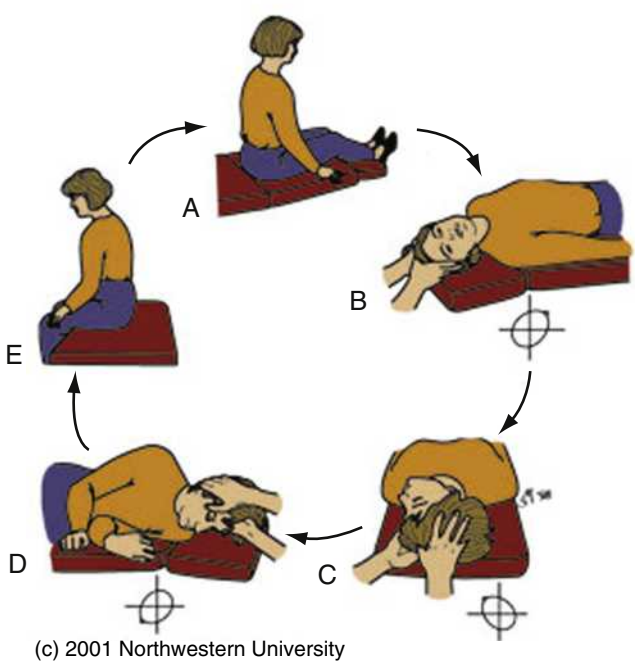

Fig. 15.4 (A to E) The Epley maneuver for benign paroxysmal peripheral vertigo, also known as the *particle-repositioning* or *canalith-repositioning procedure.* (Image used with permission of Timothy C. Hain, Professor of Neurology, Feinberg School of Medicine, Northwestern University, www.dizziness-and-balance.com/disorders/bppv/bppv.html.)

Most vestibular suppressants are antiemetic medications (Table 15.5), which not only suppress nausea and vomiting but also decrease the sensation of vertigo. Although promethazine (Phenergan) is likely the most effective parenteral vestibular suppressant, the US Food and Drug Administration (FDA) has given intravenous use of promethazine a boxed warning, and the use of the IM or oral routes are preferred. Trials using various agents including dimenhydrinate, lorazepam, and droperidol have given mixed results. We recommend intravenous ondansetron 4 mg as the first line intravenous medication for symptomatic vertigo, and a recent randomized clinical trial comparing intramuscular promethazine to intravenous ondansetron in patients with acute peripheral vertigo showed excellent improvement in both groups with fewer side effects in the ondansetron group.[9] Patients with intractable vertigo and vomiting who are unresponsive to antiemetics can be given an intravenous benzodiazepine, such as 1 to 2 mg of intravenous lorazepam. However, it is generally not recommended to discharge patients with oral benzodiazepines, especially in patients with vestibular neuritis and labyrinthitis, because these patients undergo a process of vestibular habituation, in which the vestibular system learns to adapt to the mismatch of information it is receiving, and benzodiazepines can interfere with this process.

Meclizine (Antivert) 12.5–50 mg every 4 to 6 hours can be given in the ED, although its time of onset is approximately 1 hour. Because it can exacerbate symptoms in patients with nonvertiginous types of dizziness, it should be reserved for patients with BPPV who have failed the Epley maneuver or for patients who have an alternative diagnosis of peripheral vertigo, such as vestibular neuritis. Transdermal scopolamine has shown disappointing results for treatment of peripheral vertigo but may be considered a third line option.

Vestibular neuritis results from inflammation of the eighth CN. Patients typically have severe vertigo for 1 to 2 days with gradual resolution over weeks to months. Nystagmus may be spontaneous during the first several hours of symptoms, and patients will have a positive head impulse test. Although vestibular neuritis is thought to be of viral origin[10] in a similar way to Bell palsy, antivirals, such as valacyclovir, are

TABLE 15.5 Medications for Acute Vertigo.

Drug	Usual Starting Dosage	Antiemetic Action
Promethazine (Phenergan)	12.5–25 mg IM, PO, PR (FDA boxed warning recommends IM over IV given risks of extravasation)	Moderate
Ondansetron (Zofran)	4 mg IV, SL/PO, IM	Prominent
Dimenhydrinate (Dramamine)	50–100 mg IM, IV, PO	Moderate
Prochlorperazine (Compazine)	5–10 mg IV, IM, PO, PR	Prominent
Droperidol (Inapsine)	0.625–2.5 mg IM	Prominent
Metoclopramide (Reglan)	5–10 mg IV, IM, PO	Prominent
Lorazepam (Ativan)	1–2 mg IV, IM, PO	Mild
Diazepam (Valium)	1 mg IV, IM, PO	Mild
Meclizine (Antivert)	12.5–50 mg PO	Mild
Scopolamine (Transderm-Scop)	0.2 mg transdermal patch	Moderate

IM, Intramuscular; *IV,* intravenous; *PO, per os* (by mouth); *PR,* per rectum; *SL,* sublingual.

not helpful in the treatment of vestibular neuritis. Corticosteroid use remains controversial, with four out of five studies in a recent review showing short-term benefits.[11] Until certainty is reached, we recommend steroid treatment with prednisone (or methylprednisolone) with a gradual taper over 2 to 3 weeks starting at 60 mg and decreasing to 10 mg before discontinuing the medication. However, shared decision making with the patient is an acceptable alternative.

Some cases of Ménière disease have been treated successfully with vasodilation and diuretic therapy. Diets low in sodium and caffeine and cessation of smoking also have been helpful. However, the diagnosis of Ménière disease requires documentation of hearing loss, so this is not a diagnosis that can be typically made during an ED visit, and the patient should be referred to otolaryngologist for further evaluation including audiology.

DISPOSITION

Documented or suspected VBI or cerebellar hemorrhage or infarction require diagnostic evaluation, treatment, and, usually, hospitalization. In patients older than age 55 with vascular risk factors, admission for observation and imaging of cerebral vasculature should be considered if the diagnosis is not certain. Most younger patients with peripheral causes of vertigo can be discharged from the ED after symptoms have been controlled. Some patients with peripheral vertigo may have such severe symptoms (e.g., intractable vomiting, inability to walk) despite medications that they require hospital admission for intravenous hydration, vestibular suppressants, and antiemetics. Reassessment of neurologic examination findings and assessment of response to therapy are encouraged to help ensure that symptoms are not of central origin. Discharged patients should receive primary care, neurology, or otolaryngology follow-up, particularly if symptoms are not significantly improved within 72 hours or are worsening despite symptomatic treatment.

CHAPTER 15: QUESTIONS & ANSWERS

1. A patient presents to the emergency department with dizziness and is diagnosed with horizontal canal benign paroxysmal positional vertigo (BPPV). What maneuver can be used to treat the patient?
   - **a.** Barbecue roll
   - **b.** Epley maneuver
   - **c.** Hallpike test
   - **d.** Head impulse test

Answer: a. The supine roll test, in which the patient lies flat on the gurney and the head is turned to each side, is used to diagnose horizontal canal BPPV, whereas the barbecue roll maneuver is used to treat the horizontal variant of BPPV. The Epley maneuver is used to treat posterior canal BPPV. The Hallpike test is used to diagnose posterior canal BPPV. The head impulse test is used to diagnose vestibular neuritis and labyrinthitis.

2. A 70-year-old woman presents with a first ever episode of severe vertigo. Which of the following examination findings should prompt the physician to order imaging tests and/or consultation with a neurologist?
   - **a.** Direction changing nystagmus on change in head position
   - **b.** Direction changing nystagmus on change in lateral gaze
   - **c.** Positive head impulse test
   - **d.** Torsional upbeat nystagmus during Hallpike test

Answer: b. Direction changing nystagmus on change in gaze is concerning for a central cause of vertigo and makes up part of the HINTS test. Direction changing nystagmus with changes in head position is expected in a patient with horizontal canal benign paroxysmal positional vertigo (BPPV) and is a benign finding. A positive head impulse test is expected in vestibular neuritis, while torsional upbeat nystagmus is expected in posterior canal BPPV.

3. Internuclear ophthalmoplegia most often suggests a diagnosis of which of the following conditions?
   - **a.** Horizontal canal benign paroxysmal positional vertigo (BPPV)
   - **b.** Labyrinthitis
   - **c.** Multiple sclerosis
   - **d.** Vestibular neuritis

Answer: c. Internuclear ophthalmoplegia is diagnosed when, on eye movement, the adducting eye shows little to no movement while the abducting eye moves normally. In a patient presenting with vertigo, this finding is virtually pathognomonic for multiple sclerosis.

4. Which of the following is a central cause of vertigo?
   - **a.** Labyrinthitis
   - **b.** Ménière disease
   - **c.** Vertebrobasilar insufficiency
   - **d.** Vestibular neuritis

Answer: c. All the other causes are peripheral.

5. Continuous vertigo of what duration is used to define acute vestibular syndrome?
   - **a.** 1 hour
   - **b.** 8 hours
   - **c.** 24 hours
   - **d.** 1 week

Answer**: c.** Acute vestibular syndrome has an arbitrary cutoff of continuous vertigo for at least 1 day in part to help differentiate acute vestibular syndrome from attacks of Ménière disease or prolonged migrainous vertigo.

16

Headache

Laura E. Walker

KEY CONCEPTS

- Patients with a known headache disorder who present with a change in the character of the headache should be evaluated for potential serious causes.
- The physical examination in the headache patient focuses primarily on mental status, funduscopic exam, meningeal signs, and neurologic examination, particularly cranial nerves (CNVs) II, III, IV, and VI, as well as specific cerebral territories.
- Mild to moderate primary and nonspecific headaches are treated with nonsteroidal analgesic drugs (NSAIDs). Severe headaches can be managed parenterally with dopamine antagonists (metoclopramide or prochlorperazine), migraine-specific agents (triptans), or NSAIDS (Ketorolac). Opioid pain medications are not indicated for the treatment of primary headaches.
- Most patients with headache do not require neuroimaging. When obtained, neuroimaging is tailored to the specific elements of concern in the differential diagnosis.
- The differential diagnosis of sudden severe headache includes subarachnoid hemorrhage (SAH) or other intracranial hemorrhage (ICH), cerebral venous thrombosis, and cervical artery dissection (Box 16.1).
- In patients suspected for SAH, a stepwise application of Ottawa SAH Rule, computed tomography (CT) imaging, followed by lumbar puncture (LP) and/or CT angiography (CTA) is appropriate.
- Antibiotics should be administered prior to performing a LP when bacterial meningitis is suspected.

FOUNDATIONS

Background and Importance

Headache is consistently among the top reasons for visits to the emergency department (ED). The vast majority of patients who have a primary complaint of headache do not have a serious medical cause for the problem. Most common primary headache etiologies are benign, such as tension headache and migraine. A minority of headaches are caused by underlying medical or surgical conditions that warrant prompt diagnosis and treatment. The low incidence of serious disease can create a "needle in the haystack" phenomenon, and headache is disproportionately represented in emergency medicine malpractice claims despite widespread overuse of imaging for benign headache conditions. Although representing only a small proportion of patients presenting with acute headache to the ED, the most important and commonly encountered life-threatening cause of severe sudden head pain is SAH.[1] Unfortunately, this is a diagnosis that is also missed on first presentation more than 25% of the time.[2] The other significant, potentially life-threatening causes of headache occur even less frequently. As is the case for SAH, these other serious disorders (i.e., meningitis, carbon monoxide poisoning, temporal arteritis, acute angle-closure glaucoma, ICH, cerebral venous sinus thrombosis, and increased intracranial pressure from space-occupying lesions or idiopathic intracranial hypertension [IIH]) can often be linked with specific historical elements and physical findings that facilitate their diagnosis.

Pathophysiology

The brain parenchyma is insensitive to pain. The pain-sensitive areas of the head include the meninges, the arteries and veins supplying the brain, and the various tissues lining the cavities within the skull. The ability of the patient to specifically localize head pain is often poor. Much of the pain associated with headache, particularly with vascular headache and migraines, is mediated through the fifth CNV. Such pain may proceed back to the nucleus and is then referred through various branches of CNV to areas not directly involved. Inflammation in a specific structure (e.g., periapical abscess, sinusitis, or trigeminal neuralgia) is much easier to localize than the relatively diffuse pain that may be generated by tension or traction headaches. Pain in the head and neck regions may easily overlap and should therefore be thought of as a single unit when complaints of headache are considered.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis of headache is complex due to the large number of potential disease entities and the diffuse nature of many types of pain in the head and neck region (Table 16.1). In evaluating the patient with a primary complaint of headache, the top priority is to exclude the causes with significant morbidity and mortality: SAH, ICH, meningitis, encephalitis, temporal arteritis, preeclampsia, central venous sinus thrombosis, and mass lesions. Carbon monoxide is an exogenous toxin, the effects of which may be reversible by removing the patient from the source and administering oxygen. Carbon monoxide poisoning is a rare example of a headache in which relatively simple interventions may quickly improve a critical situation; however, returning the patient to the poisoned environment without a diagnosis could be lethal (see Chapter 148).

Pivotal Findings

Symptoms

Physical findings may be minimal or nonspecific, even in serious causes of headache, so the clinical history is extremely important (Table 16.2).

1. Determine the *pattern and the onset* of the pain. Patients may remember having had frequent and recurrent headaches similar to their current headache; a marked variation in the headache pattern can signal a new or serious problem. A rapid and severe onset of pain ("thunderclap") has been associated with serious causes of headache. Thunderclap headache alone cannot indicate if there is a serious underlying cause of headache, such as SAH, but is used in

BOX 16.1 Emergent Causes of Headache and Associated Risk Factors

1. Carbon monoxide poisoning
   a. Breathing in enclosed or confined spaces with engine exhaust or ventilation of heating equipment
   b. Multiple household members with the same symptoms
   c. Wintertime and working around machinery or equipment producing carbon monoxide (e.g., furnaces, heaters)
2. Meningitis, encephalitis, abscess
   a. History of sinus or ear infection or recent surgical procedure
   b. Immunocompromised state
   c. General debilitation with decreased immunologic system function
   d. Acute febrile illness—any type
   e. Extremes of age
   f. Impacted living conditions (e.g., military barracks, college dormitories)
   g. Lack of primary immunization
3. Temporal arteritis
   a. Age >50
   b. Females more often than males (4:1)
   c. History of other collagen vascular diseases (e.g., systemic lupus)
   d. Previous chronic meningitis
   e. Previous chronic illness, such as tuberculosis, parasitic or fungal infection
4. Glaucoma—acute angle closure
   a. Not associated with any usual or customary headache patterns
   b. History of previous glaucoma
   c. Age >30
   d. History of pain increasing in a dark environment
5. Increased intracranial pressure
   a. History of previous benign intracranial hypertension
   b. Presence of cerebrospinal fluid (CSF) shunt
   c. History of congenital brain or skull abnormalities
   d. Female gender
   e. Obesity
6. Cerebral venous sinus thrombosis
   a. Female gender
   b. Pregnancy, peripartum, hormone replacement therapy or oral contraceptive use
   c. Prothrombotic conditions
7. Reversible cerebral vasoconstriction syndrome
   a. Episodic sudden severe pain, with or without focal neurological findings or seizure
   b. Recurrent episodes over a period up to several weeks
   c. Exposure to adrenergic or serotonergic drugs
   d. Postpartum state
8. Intracranial hemorrhage (ICH)
   a. Subarachnoid hemorrhage (SAH)
      i. Sudden and severe pain; "worst headache of life"
      ii. Acute severe pain after sexual intercourse or exertion
      iii. History of SAH or cerebral aneurysm
      iv. History of polycystic kidney disease
      v. Family history of SAH
      vi. Hypertension—severe
      vii. Previous vascular lesions in other areas of the body
      viii. Young and middle-aged
   b. Subdural hematoma
      i. History of alcohol dependency with or without trauma
      ii. Current use of anticoagulation
   c. Epidural hematoma
      i. Traumatic injury
      ii. Lucid mentation followed by acute altered mentation or somnolence
      iii. Anisocoria

TABLE 16.1 Headache Etiologies and Associated Spectrum of Severity of Disease by System

Organ System	Critical	Emergent	Nonemergent
CNS, neurologic, vessels	SAH	Shunt failure	Migraine, various types
	Carotid dissection	Traction headaches	Vascular headache, various types
	Venous sinus thrombosis	Tumor or mass	Trigeminal neuralgia
		Subdural hematoma	Post-traumatic (concussion)
		Reversible cerebral vasoconstriction syndrome	Post LP headache
Toxic/metabolic, environmental	Carbon monoxide poisoning	Mountain sickness	
Collagen vascular disease	Temporal arteritis		
Ocular/ENT		Glaucoma	Sinusitis
			Dental problems
			TMJ disease
Musculoskeletal			Tension headache
			Cervical strain
Allergy			Cluster or histamine headaches
Infectious disease	Bacterial meningitis	Brain abscess	Febrile headaches, non-neurologic source
	Encephalitis		
Pulmonary or oxygen		Anoxic headache	
Cardiovascular		Hypertensive crisis	Hypertension (rare)
Unspecified		Preeclampsia	Effort-dependent or coital headaches
		IIH	Medication overuse/rebound

CNS, Central nervous system; *ENT,* ear, nose, and throat; *IIH,* idiopathic intracranial hypertension; *LP,* lumbar puncture; *SAH,* subarachnoid hemorrhage; *TMJ,* temporomandibular joint.

TABLE 16.2 Signs and Symptoms of Various Headache Etiologies

Symptom	Finding	Possible Diagnosis
Sudden onset of pain	"Thunderclap" with any decreased mentation, any positive focal finding, meningismus or intractable pain	SAH, cervical artery dissection, cerebral venous thrombosis, acute angle closure glaucoma
Sudden onset of pain	Recurrent thunderclap episodes, may be associated with stroke-like symptoms	Reversible cerebral vasoconstriction syndrome
"Worst headache of my life"	Associated with sudden onset	SAH, cervical artery dissection, cerebral venous thrombosis
Near syncope or syncope	Associated with sudden onset	SAH, cervical artery dissection, cerebral venous thrombosis
Increased with jaw movement	Clicking or snapping; pain with jaw movement	TMJ disease
Facial pain	Fulminant pain of the forehead and area of maxillary sinus; nasal congestion	Sinus pressure or dental infection
Jaw, forehead and/or temporal area pain	Tender temporal arteries	Temporal arteritis
Periorbital or retro-orbital pain	Sudden onset with tearing	Temporal arteritis or acute angle closure glaucoma

SAH, Subarachnoid hemorrhage; *TMJ,* temporomandibular joint.

conjunction with other signs and symptoms.[3] Similarly, slow onset of headache cannot be solely relied on to rule out a potentially life-threatening cause, and the nature of the onset usually is not possible to ascertain if the headache came on during sleep.

Almost all studies dealing with subarachnoid bleeding report that patients move from the pain-free state to severe pain within seconds to minutes. The thunderclap headache is common in acute presentations of SAH but is not highly specific. If the patient with moderate or severe headache can indicate the precise activity in which he or she was engaging at the time of the onset of the headache, the suddenness of onset warrants consideration of SAH. Careful questioning about the onset of headache may lead to the correct diagnosis of SAH, even if the pain is improving at the time of evaluation.

2. The patient's *activity at the onset of the pain* may be helpful. Headaches that come on during exertion raise concern for vascular events. Additionally, although the syndrome of postcoital headache is well known, coitus is also recognized as an activity associated with SAH, so a pattern of previous postcoital headache is key, as is understanding whether the current headache fits that pattern. Postcoital headaches require the same evaluation on initial presentation as any other exertion-related head pain.
3. If there is a *history of head trauma*, the differential diagnosis shifts markedly toward epidural and subdural hematoma, traumatic SAH or intraparenchymal hemorrhage, skull fracture and closed head injuries, such as concussion and diffuse axonal injury.
4. The *intensity of head pain* is difficult to quantify objectively. Almost all patients who come to the ED consider their headaches to be severe. Use of a pain scale with appropriate explanation may help differentiate patients initially but has more value in monitoring their response to therapy. Rapid resolution of pain in the ED, either from time or therapy, should not be relied on to rule out serious causes of headache.
5. The *character of the pain* (e.g., throbbing, pressure), although sometimes helpful, may not be adequate to differentiate one type of headache from another.
6. The *location of pain* at onset (and as the pain progresses) is helpful when the patient can identify a specific area. It is certainly useful to direct the examination to evaluate for externally visible contributing factors, such as an infectious process or trauma. Unilateral pain is more suggestive of migraine or localized inflammatory process in the skull (e.g., sinus) or soft tissue. Muscle tension headache often starts at the base of the skull and can extend over the entire head, following the occipital-frontal aponeurosis. Temporal arteritis, temporomandibular joint (TMJ) disease, dental infections, and sinus infections frequently have a highly localized area of discomfort. Meningitis, encephalitis, SAH, and even severe migraine, although intense in nature, are usually more diffuse in their localization.
7. *Exacerbating or alleviating factors* may be important. Patients whose headaches rapidly improve when they are removed from their environment or recur each time they are exposed to a particular environment (e.g., basement workshop) may have carbon monoxide poisoning. Most other severe causes of head pain are not rapidly relieved or improved when patients get to the ED. Intracranial infections, dental infections, and other regional causes of head pain tend not to be improved or alleviated before therapy is given.
8. *Associated symptoms and risk factors* may relate to the severity of headache but rarely point to the specific causes (see Box 16.1). Nausea and vomiting are nonspecific symptoms seen in both primary and secondary headaches, but they are rare in simple muscle tension headache. Migraine headaches, increased intracranial pressure, temporal arteritis, and glaucoma can all manifest with severe nausea and vomiting, as can some systemic viral infections with headache. Such factors may point toward the intensity of the discomfort but are not specific in establishing the diagnosis. Immunocompromised patients are at risk for unusual infectious causes of headache, which may present with deceptively low-grade symptomatology. Toxoplasmosis, cryptococcal meningitis, and abscess are very rare but may be seen in patients with a history of human immunodeficiency virus (HIV) or other immunocompromised state. This subset of patients may have a serious central nervous system infection without typical signs or symptoms of systemic illness (e.g., fever and meningismus).

Another special population to consider is the pregnant and peripartum woman. In addition to the typical causes of secondary headache, this population may have headache resulting from preeclampsia, and is more likely to have headache caused by idiopathic IIH and reversible cerebral vascular syndrome. Additionally, the more serious vascular causes of headache, including venous sinus thrombosis, pituitary apoplexy, arterial dissection, and stroke, are important considerations.[4] Symptomatic treatment and diagnostic assessment of pregnant patients is undertaken with consideration of potential teratogenic effects of medications, and of the effects of radiation and contrast exposure to the fetus.

TABLE 16.3 Signs and Symptoms Associated With Different Headache Etiologies

Sign	Finding	Possible Diagnoses
General appearance	Nonfocal mental status changes	Meningitis, encephalitis, SAH, subdural hematoma, anoxia, increased intracranial pressure, carbon monoxide poisoning
	Mental status changes with focal findings	Intraparenchymal bleed, tentorial herniation, stroke
	Severe nausea, vomiting	Increased intracranial pressure, acute-angle closure glaucoma, SAH, carbon monoxide poisoning
Vital signs	Hypertension with normal heart rate or bradycardia	Increased intracranial pressure, SAH, tentorial herniation, intraparenchymal bleed, preeclampsia, reversible cerebral vasoconstriction syndrome
	Tachycardia	Anoxia, anemia, febrile headache, exertional or coital headache
	Fever	Febrile headache, meningitis, encephalitis
HEENT	Tender temporal arteries	Temporal arteritis
	Increased intraocular pressure	Acute angle closure glaucoma
	Loss of venous pulsations on fundoscopy or papilledema	Increased intracranial pressure, mass lesions, subhyaloid hemorrhage, SAH, cerebral venous thrombosis
	Acute red eye (severe ciliary flushing) and poorly reactive pupils	Acute angle closure glaucoma
Neurologic	Enlarged pupil with third nerve palsy	Tentorial pressure cone, mass effect (aneurysm, bleed, abscess, or tumor)
	Lateralized motor or sensory deficit	Stroke, subdural hematoma, epidural hematoma, hemiplegic or anesthetic migraine (rare), reversible cerebral vasoconstriction syndrome, central venous thrombosis
	Balance and coordination deficits	Cervical artery dissection, acute cerebellar hemorrhage, acute cerebellitis (mostly children),[9] chemical intoxication of various types
	Extraocular movement deficits (CN III, IV, and VI)	Mass lesion, neurapraxia (post-traumatic headache), IIH

CN, Cranial nerve; *HEENT,* head, eyes, ears, nose, and throat; *IIH,* idiopathic intracranial hypertension; *SAH,* subarachnoid hemorrhage.

Patients on medications containing estrogen are also at higher risk for thrombotic events, such as cavernous venous thrombosis, and this is considered in the formulation of the differential diagnosis.

7. A *prior history* of headache, although helpful, does not rule out current serious problems. One important consideration is the association of migraine headaches and stroke, with particular consideration of carotid dissection.[5] Previous testing for serious disease can be useful to guide the current evaluation. Prior visits to an ED or outpatient setting, CT, magnetic resonance imaging (MRI), and other forms of testing can provide support for, or help rule out, a specific diagnosis. Patients with migraine, cluster, and tension headaches tend to have stereotypical recurrent patterns. Concordance of current symptoms with prior episodes can help inform the decision to pursue additional testing versus a strategy of symptom control. A typical recurrent episode can warrant symptom control alone, whereas an atypical presentation will prompt consideration of a broader differential and care pathway.
8. Additionally, risk of a secondary medication overuse headache is an important consideration in patients taking medications for headaches more than 10 to 15 times per month, and should be considered after the presence of underlying emergent conditions is eliminated.[6]

Signs

Vital signs may be normal in headache, despite significant discomfort. There are signs that may be elicited on physical examination that can be particularly high yield. For example, deficits of extraocular movements localizing to cranial nerves (CNs) III, IV, and VI, or papilledema noted on CN II assessment, may indicate the presence of increased intracranial pressure due to a mass lesion or IIH. When headache is associated with an acutely red eye, consideration of acute angle closure glaucoma should prompt testing of intraocular pressure. Signs of meningeal irritation (nuchal rigidity, jolt accentuation, or Kernig and Brudzinski signs) are concerning for SAH or meningitis. Any focal neurological deficit found on examination, regardless of subtlety, warrants further investigation. Not all signs associated with headache contribute greatly to final determination of diagnosis, but they may serve as cues to trigger further consideration of a serious intracranial process. Presence of fever raises the suspicion of a primary infectious etiology. Nausea and vomiting are often associated with migraine, but they are also associated with intracranial mass, acute angle closure glaucoma, intracranial bleeding, and carbon monoxide poisoning. Alteration of mental status may indicate serious underlying causes of headache, including hemorrhage and infection. Additional physical examination findings associated with various forms of headache are listed in Table 16.3.

Ancillary Testing

The vast majority of headache patients do not require additional testing (Table 16.4). Advanced imaging is directed toward the specific disease of concern in the differential diagnosis, and not as a default process in the investigation of headache in general. For example, a head CT scan is not indicated for muscle tension headache or recurrent migraine, and it may not be sufficient to assess for cerebral venous thrombosis or for a posterior circulation stroke. Instead, use of CT venogram (CTV) or magnetic resonance venogram (MRV) for cavernous thrombosis, or MRI for posterior circulation disorders, are more appropriate.

A CT scan performed within 6 hours of onset of headache has been shown to be sufficiently sensitive to exclude the diagnosis of SAH when using a third-generation CT scanner.[7] Outside this window, sensitivity declines, and additional testing must be undertaken for appropriate evaluation for SAH.[8] However, there are other causes of sudden severe headache beyond SAH that must be considered in select patients. Overall, judicious use of imaging and selection of an advanced imaging study that will answer a specific question is the optimal approach.

LP with measurement of the opening pressure and cerebrospinal fluid (CSF) analysis is indicated when assessing for an infectious process, IIH, or SAH. In evaluation for SAH outside the 6-hour window, utilization

TABLE 16.4 Diagnostic Findings in Emergent Causes of Headache

Diagnosis	Test	Finding
Temporal arteritis	Erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)	ESR greater than 50 mm/H Elevated CRP
SAH Increased intracranial pressure	Electrocardiogram (ECG)	Nonspecific ST/T wave changes
Anoxia	Complete blood count (CBC)	Severe anemia
Increased intracranial pressure	Computed tomography (CT) scan: Head	Increased ventricular size
SAH		Blood in subarachnoid space
Epidural or subdural hematoma		Blood in epidural or subdural space
Intraparenchymal hemorrhage		Bleeding into parenchyma of brain
Pale infarct		Areas of poor vascular flow
Traction headache secondary to mass effect		Structural, mass lesion
IIH Mass lesion Shunt failure Cryptococcal meningitis	Lumbar puncture (LP) and cerebrospinal fluid (CSF) analysis	Increased opening pressure
Tumor or other structural lesions, infection		Increased protein
SAH		Increased RBCs
Infection		Increased WBCs
Infection		Positive Gram's stain
Infection		Decreased glucose

IIH, Idiopathic intracranial hypertension; *RBC,* red blood cell; *SAH,* subarachnoid hemorrhage; *WBC,* white blood cell.

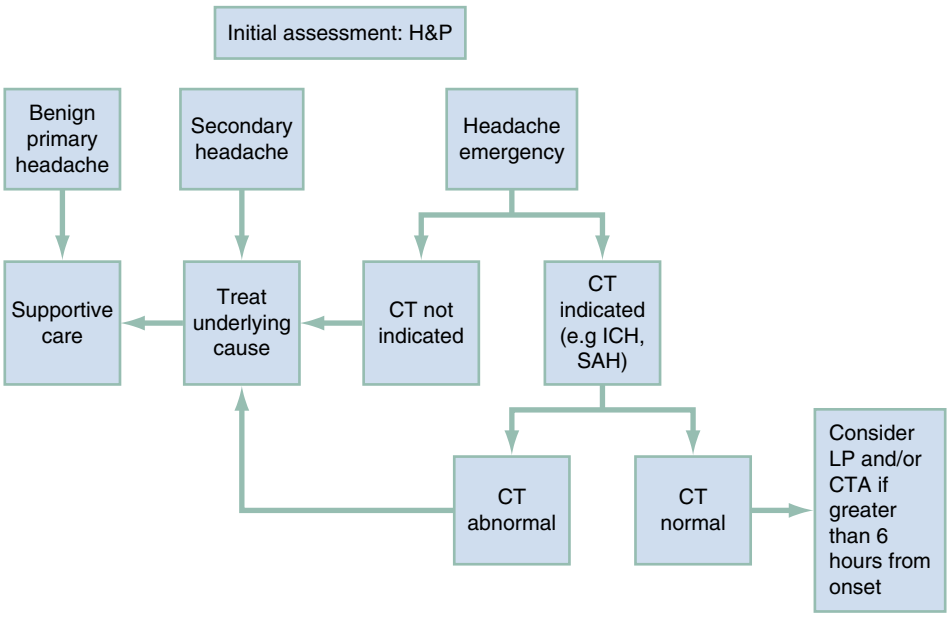

Fig. 16.1 Evaluation Algorithm for Presentation of Headache. *CO,* Carbon monoxide; *CT,* computed tomography; *CTA,* computed tomography angiography; *HA,* headache; *H&P,* history and physical examination; *ICH,* intracranial hemorrhage; *LP,* lumbar puncture; *SAH,* subarachnoid hemorrhage.

of CTA in lieu of LP has been proposed, but there is not yet sufficient evidence to definitively advocate this diagnostic pathway to confirm or rule out SAH.[3] It is widely believed that LP may increase the likelihood of herniation in certain cases with elevated intracranial pressure caused by a mass lesion, though supportive evidence is scant. This belief is the genesis of the common dictum of "CT before LP" when a mass lesion or abscess is a consideration. In reality, this concern is likely misguided, and the compelling reason to obtain a CT scan first in such patients is that it may provide the diagnosis and make the LP unnecessary.

DIAGNOSTIC ALGORITHM

Key elements of the history of present illness, past medical history, and examination are used to narrow the differential diagnosis and choose the appropriate diagnostic pathway. Fig. 16.1 outlines a diagnostic algorithm for assessment of headache patients.

When a primary headache disorder is clinically suspected, or when the etiology of a headache is uncertain but there are no signs or symptoms suggestive of a significant underlying cause (minor severity,

gradual onset, absence of meningeal signs, and normal funduscopic and neurological examination), then symptomatic treatment is provided without need for further diagnostic evaluation.

When a particular etiology of concern is identified based on the clinical history or physical examination, additional directed testing to confirm or exclude the diagnosis is warranted. Examples include intraocular pressure determination for acute glaucoma and LP for meningitis.

In considering the potential diagnosis of SAH, utilization of the Ottawa Subarachnoid Hemorrhage Rule is recommended to help guide evaluation. This decision rule has been shown to have a high sensitivity and low specificity, allowing for decreased unnecessary testing when appropriately applied (Box 16.2).[8]

Cases in which there are highly concerning elements of history but no definitive diagnosis are the most challenging in terms of choosing the appropriate evaluation. Signs and symptoms that indicate patients are at higher risk for serious causes of headache and therefore candidates for more comprehensive evaluation include: (1) sudden onset of headache, (2) patient description of the headache as "the worst ever," (3) altered mental status, (4) meningismus, (5) unexplained fever, (6) focal neurological deficit on examination, (7) symptoms refractory to appropriate treatment or worsening despite treatment, (8) onset of headache during exertion, (9) history of immunosuppression, or (10) pregnancy or peripartum state.

Sequential evaluation of the patient's condition and assessment of ancillary data will confirm a working diagnosis or trigger a reconsideration of alternatives, including more serious conditions (Table 16.5).

BOX 16.2 Ottawa Subarachnoid Hemorrhage Rule

Inclusion: patients age 15 and over, nontraumatic headache, peak intensity within 1 h of onset

Exclusion: New neurological deficits, prior aneurysm, prior SAH, known intracranial mass, chronic recurrent headaches

If none of the following are present, SAH can be reasonably ruled out:

a. Age >40 years
b. Neck pain or stiffness
c. Witnessed loss of consciousness
d. Headache onset during exertion
e. Thunderclap headache (immediate peak pain)
f. Limited neck flexion

EMPIRICAL MANAGEMENT

Headache, although a frequent chief complaint, is a nonspecific symptom. The speed and intensity of the initial evaluation and treatment are guided by the presentation and the patient's mental status. Fig. 16.2 represents a treatment algorithm with recommendations for immediate management pending completion of a full diagnostic evaluation.

Pain is treated as soon as possible. The pain medication of choice depends on the working diagnosis of a patient's headache. For primary headache and nonspecific mild to moderate headache, oral NSAIDs are appropriate in analgesic doses (e.g., 500 mg of naproxen). Primary headaches that are severe or not responsive to NSAIDS can be treated with parenteral nonnarcotic medications. Recommended options include three classes of medication: intravenous (IV) antiemetic dopamine antagonists, such as metoclopramide (10 mg) or prochlorperazine (10 mg); subcutaneous (SC) migraine-specific agents, such as Sumatriptan (6 mg); and an intramuscular (IM) or IV NSAID, such as Ketorolac (15 mg). Opioids are not considered first-line management for any type of primary or nonspecific headache. Secondary headaches, including those caused by infection, hemorrhage, or intracranial mass, may warrant use of opioids as initial therapy.

There is no contraindication to immediate and appropriate treatment of headache while initiating evaluation. Additionally, if bacterial meningitis is under consideration as a possible cause, empiric

TABLE 16.5 Causes and Differentiation of Potentially Catastrophic Illness Manifesting With Nontraumatic Headache

Disease Entities	Pain History	Associated Symptoms	Support History	Prevalence
Carbon monoxide poisoning	Usually gradual, subtle, dull, nonfocal throbbing pain	May wax and wane as individual leaves and enters the involved area of carbon monoxide; throbbing may vary considerably	Exposure to engine exhaust, old or defective heating systems, most common in winter months	Rare
Subarachnoid hemorrhage (SAH)	Sudden onset, "thunderclap," severe throbbing	Symptoms variable; may present from relatively asymptomatic to altered mental status or focal neurological deficit	History of polycystic kidney disease; history of HTN	Uncommon
Meningitis, encephalitis, abscess	Gradual; as general symptoms increase, headache increases. Nonfocal pain	Decreased mentation prominent, irritability prominent. With abscess, focal neurologic findings may be present	Recent infection, recent facial or dental surgery or other ENT surgery, unimmunized state	Uncommon
Temporal arteritis	Pain often develops over a few hours from mild to severe, almost always localized to temporal area(s)	Decreased vision, nausea, vomiting may be intense and confound diagnosis	Age over 50; other collagen vascular diseases or inflammatory diseases	Uncommon
Acute angle closure glaucoma	Sudden in onset	Nausea, vomiting, decreased vision	History of glaucoma; history of pain increasing in dark areas	Rare
Increased intracranial pressure syndromes	Gradual, dull, nonfocal	Vomiting, decreased mentation	History of CSF shunt or congenital brain or skull abnormality	Uncommon

CSF, Cerebrospinal fluid; *ENT,* ear, nose, and throat; *HTN,* hypertension.

antibiotic therapy should be provided as soon as possible, as the treatment is time-sensitive. It is appropriate to begin treatment of potential bacterial meningitis prior to completion of confirmatory CSF testing.

Patients who are thought to have a benign cause for their head pain not requiring hospitalization, but who are without a specific diagnosis, should be provided with appropriate return precautions and recommendations for follow-up care. Some patients may benefit from beginning a headache journal to facilitate further outpatient evaluation.

CHAPTER 16: QUESTIONS AND ANSWERS

1. Of the following, which is most appropriate in the initial evaluation of a patient with nontraumatic headache?
- **a.** Computed tomography (CT) scan of brain
- **b.** Electroencephalogram (EEG)
- **c.** Magnetic resonance imaging scan of brain
- **d.** Thorough neurological evaluation

Answer: d. A thorough neurological examination may reveal deficits not seen on gross evaluation, prompting expansion of the differential diagnosis to include more concerning etiologies. Depending on the history and remainder of the physical, a normal neurological examination may be reassuring and obviate need for advanced imaging studies.

2. In the setting of headache, the presence of nausea and vomiting are diagnostic of which of the following underlying causes?
- **a.** Glaucoma
- **b.** Increased intracranial pressure
- **c.** Migraine
- **d.** None of the above

Answer: d. Nausea and vomiting are completely nonspecific. Migraine headaches, increased intracranial pressure, temporal arteritis, and glaucoma can all be manifested by severe nausea and vomiting, as can some systemic viral infections with headache. Such factors may point toward the intensity of the discomfort but are not specific in establishing the diagnosis.

3. Which of the following is the most appropriate initial diagnostic study for a pregnant woman with normal vital signs and a presentation concerning for a headache emergency?
- **a.** Computed tomography (CT)
- **b.** Inflammatory markers (e.g. erythrocyte sedimentation rate [ESR], C-reactive protein [CRP])
- **c.** Magnetic resonance angiography (MRA)/magnetic resonance venogram (MRV)
- **d.** No studies are indicated

Answer: a. CT studies with and without contrast are able to identify many vascular causes of headache, for which pregnancy is a risk factor. Iodinated contrast is safe in pregnancy. Magnetic resonance imaging (MRI) without contrast is another option; however, MRA and MRV are relatively contraindicated due to use of gadolinium contrast, which has not been shown to be safe in pregnancy. Inflammatory markers are nonspecific and will not confirm or rule out important emergency headaches in this population. For emergency headaches in pregnancy deferral of additional studies is not appropriate.

4. A 42-year-old male patient presents with the sudden onset of severe headache that worsened over the 30 minutes while at rest 4 hours prior to arriving in the emergency department (ED). His examination reveals only mild distress, no neck stiffness or meningismus, and normal funduscopic and neurological examinations. What is the most appropriate diagnostic test?
- **a.** Intraocular pressure determination
- **b.** Sphenopalatine block
- **c.** Computed tomography
- **d.** Lumbar puncture

Answer: c. The patient has a sudden onset severe headache and Ottawa Subarachnoid Hemorrhage Rule can be applied. However, his age being greater than 40, the rule is unable to exclude subarachnoid hemorrhage (SAH). Next step is computed tomography (CT) because he is within the 6-hour window. Lumbar puncture and or/ CT angiography can be considered if initial noncontrast CT is normal.

17

Diplopia

Ashley Booth Norse

KEY CONCEPTS

- The diagnostic approach to diplopia is aimed at determining (1) if the diplopia is monocular, (2) if there is a restrictive or mechanical issue in the orbit or orbital structures, (3) if there is a palsy of one or more of the oculomotor cranial nerves, (4) if there is a neuroaxial process involving the brainstem and related cranial nerves, or (5) if there is a systemic neuromuscular process.
- Monocular diplopia is most commonly caused by an ophthalmologic problem related to refractory distortions or retinal buckling.
- Binocular diplopia resolves when either eye is closed and is the result of a misalignment in the visual axes.
- Important historical features in assessing diplopia includes onset, directionality and orientation of the diplopia; presence of pain, and the presence of other associated symptoms.
- An isolated CN III palsy presents with diplopia in all directions of gaze, except on lateral gaze to the affected side; the eye is deviated down and out; ptosis and a dilated pupil may also be present.
- A CN IV palsy results in vertical or torsional diplopia that worsens on looking down and toward the nose.
- A CN VI palsy will cause the affected eye to turn inward and results in diplopia that worsens on lateral gaze toward the affected side.
- Cavernous sinus or posterior orbit disease (orbital apex syndrome) may present with ipsilateral diplopia involving CN III, IV and or VI; associated symptoms may include pain, exophthalmos, chemosis, and possibly ipsilateral periorbital facial numbness or dysesthesia.
- Multiple sclerosis or localized pathology in the brainstem, such as tumor, lacunar infarct, basilar artery thrombosis, vertebral artery dissection or ophthalmoplegic migraine, may present with focal lesions presenting as diplopia.
- The diplopia caused by myasthenia gravis is associated with ptosis, gets worse as the patient fatigues, and improves with rest or on placing ice over the eye.
- Initial treatment for diplopia is directed toward imminent threats to airway and ventilation (e.g., with botulism and myasthenia gravis) and immediate or rapidly evolving threats to the central nervous system (CNS) (e.g., stroke, meningoencephalitis or Wernicke encephalopathy).

FOUNDATIONS

Diplopia (double vision) can be either monocular or binocular. Although life-threatening diagnoses are rare, ED patients have a higher incidence of harboring a serious neurological process than patients presenting in the ambulatory setting. Most ED cases are binocular, with cranial nerve palsies being the most common cause.[1]

Pathophysiology

Double vision or diplopia is seeing two or more images. The etiology can be from systemic disease or pathology in the eye or brain. Monocular diplopia does not correct when one eye is closed and is usually caused by intraocular pathology, for example, lens subluxation, retinal abnormalities, or a refractive error, in which case the diplopia should resolve with pinhole testing.

Binocular diplopia is double vision that resolves when one eye is closed. It is caused by misalignment of the visual axes, and has an extensive differential diagnosis: see Table 17.1. Approximately one-third of patients presenting to the ED with binocular diplopia have a secondary cause, such as stroke, multiple sclerosis, brain tumors, and cerebral aneurysms.

Cerebral diplopia, or polyopia, is seeing many images and can be monocular or binocular. It is rare and associated with stroke, vascular spasm, tumor, multiple sclerosis, trauma, infections, or seizures, primarily involving the occipital or temporal lobes.

DIAGNOSTIC APPROACH

Differential Considerations

Monocular diplopia is an ophthalmologic problem related to distortions in the light path from dry eyes, a corneal irregularity, cataract, lens dislocation, or retinal wrinkles involving the macula. In rare cases, monocular diplopia may be the presenting complaint in conversion disorder, but this is a diagnosis of exclusion. Box 17.1 outlines some key causes of monocular diplopia.[2]

Binocular diplopia may be due to a mechanical or restrictive process in the orbit or structures of the orbit, a palsy of one or more of the oculomotor cranial nerves, a proximal neuroaxial process involving the brainstem and related cranial nerves, a systemic neuromuscular process, or trauma. Table 17.1 outlines some key causes of binocular diplopia.

The clinical approach in the ED entails narrowing the differential diagnosis to those diagnoses that may result in rapid and profound morbidity, in distinction from those that are less acute. In most cases a systematic history and physical exam will elicit the underlying etiology.

Pivotal Findings

History. The history begins by determining if the diplopia is monocular or binocular. Additional information helpful in formulating the differential diagnosis in diplopia includes: (1) the timing of onset and symptoms; (2) directionality and orientation of the diplopia (horizontal, vertical, or torsional); (3) presence of pain; and (4) presence of other associated symptoms. In terms of the timing, sudden onset suggests an ischemic, cerebrovascular, or microvascular cause, especially if the intensity or degree of diplopia is maximal at onset. A fluctuation of symptoms over time may suggest transient ischemic attacks or an impending stroke, but more generally implies a neuromuscular disease.

The directionality of the diplopia is as important as the type of diplopia. The directions of gaze that elicit or worsen the diplopia and the

TABLE 17.1 Differential for Binocular Diplopia

Structural Orbitopathy:	Trauma Infection/abscess Craniofacial masses
Orbital Myositis:	Thyroid eye disease Wegener granulomatosis Giant cell arteritis Systemic lupus erythematosus Dermatomyositis Sarcoidosis Rheumatoid arthritis Idiopathic orbital inflammatory syndrome (orbital pseudotumor)
Isolated Oculomotor Nerve Palsy: Cranial nerve III Cranial nerve IV Cranial nerve VI	Multiple sclerosis Hypertensive vasculopathy Diabetic vasculopathy Idiopathic intracranial hypertension Compression Trauma
Multiple Oculomotor Nerve Palsies:	Cavernous sinus infection, mass, vasculitis or thrombosis Orbital apex syndrome
Neuroaxial Process Involving the Brainstem and Related Cranial Nerves:	Focal: • Multiple sclerosis Localized brainstem process: • Tumor • Stroke • Hemorrhage • Basilar artery thrombosis • Vertebral artery dissection • Ophthalmoplegic migraine Diffuse (involving the brainstem and/or CNs III, IV, and VI) • Infectious: basilar meningoencephalitis • Autoimmune: Miller-Fisher or Guillain-Barré syndrome • Metabolic: Wernicke encephalopathy
Neuromuscular Disorder:	Myasthenia gravis Botulism

CN, Cranial nerve.

general orientation of that diplopia—horizontal, vertical, torsional—should be carefully determined to localize the problem. Diplopia can be horizontal with the images side by side, vertical with the images above and below each other, or torsional. Horizontal diplopia, without vertical separation, is often indicative of medial or lateral rectus muscle pathology, whereas torsional diplopia is more commonly caused by superior or inferior oblique muscle dysfunction or lateral medullary syndrome. Vertical diplopia is most commonly associated with brain or brainstem pathology but can been seen with CN IV palsy.

Important associated symptoms include vision changes, periorbital pain, pain with eye movement, ptosis, and systemic symptoms such as headache, nausea, vomiting, generalized weakness, and neurological deficits. In the absence of trauma, the presence of pain suggests an inflammatory or infectious process and narrows the differential significantly. Associated neurological symptoms concerning for cerebrovascular disease include vertigo, dizziness, ataxia, or aphasia.[3]

BOX 17.1 Key Causes of Monocular Diplopia

Dry eyes
Corneal irregularity
Cataract
Lens dislocation
Retinal wrinkles
Conversion disorder

Other critical components of the history include: progression of the symptoms, relieving or exacerbating symptoms, trauma, and past medical and family history. A history of progressive symptoms raises concern for a compressive lesion, whereas intermittent diplopia, especially if associated with ptosis, raises concerns for a neuromuscular junction disorder such as myasthenia gravis. In addition, a history of worsening symptoms throughout the day that improve with rest also raises concerns for myasthenia gravis. Past medical history should focus on immune system compromise and vascular risk factors such as hypertension, diabetes, coronary artery disease, and smoking. Family history should include questions about multiple sclerosis, lupus, and vascular diseases.

Physical Exam

The physical exam includes a complete neurological exam with particular attention on the cranial nerves. The provider should focus on any subtle findings, including head positioning, facial asymmetry, cranial nerve abnormalities, extremity weakness, and sensory deficits. Binocular diplopia, due to cranial nerve pathology on one side of the body, with neurological deficits involving the contralateral side of the body, raises the suspicion for brainstem pathology.

The eye exam should include the external eye exam, a visual acuity and visual field exam, a pupil exam, the extraocular muscle exam, a funduscopic exam, and a slit lamp exam to look at the anterior chamber as well as intraocular pressure measurements. If there is concern for increased intracranial pressure, a bedside ultrasound can be done to look for papilledema.

The external eye exam. The external eye exam includes an exam of the orbital and periorbital structures. The conjunctiva is examined for signs of injection, inflammation, chemosis, or hemorrhage. Document head positioning, proptosis, ptosis, and lid lag, as well as evidence of trauma. A patient presenting after trauma to the eye may have orbital fractures causing entrapment of the extraocular muscles, most commonly the inferior rectus muscle, which prevents the affected eye from tracking with the nonaffected eye on upwards gaze, resulting in diplopia, or a proptotic eye secondary to a retrobulbar hematoma. In addition, space-occupying lesions of the orbit can cause unilateral proptosis, and systemic diseases—for example, thyroid disease—can cause bilateral proptosis or myopathy resulting in diplopia.

Pupil exam. The patient should undergo a careful pupillary examination, looking for signs of asymmetry. Patients with a CN III palsy may have pupil dilation due to ischemia or a compressive lesion, most commonly an aneurysm at the junction of the posterior communicating artery and the internal carotid artery.[4]

Extraocular muscle exam. The extraocular muscles of the eye include the lateral rectus, which is innervated by the abducens nerve (cranial nerve VI), the superior oblique, which is innervated by the trochlear nerve (cranial nerve IV), and the inferior, superior, and medial rectus muscles, all innervated by the oculomotor nerve (cranial nerve III). An extraocular muscle injury or cranial nerve palsy in one eye will prevent both eyes from moving and tracking together. Examination of the extraocular muscles should be performed in the "H pattern"

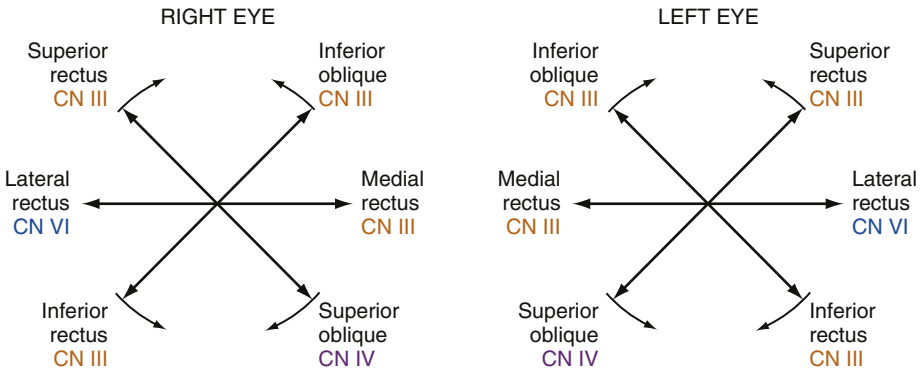

Fig. 17.1 Cardinal movements of the eyes, with the oculomotor muscles that create them and the nerves that supply those muscles. *Small curved arrows* denote intorsion or extorsion of the eye by the muscle indicated. *CN,* Cranial nerve.

(Fig. 17.1) while holding the head steady, with close observation of both eyes through the full range of motion.

Injury to the lateral rectus muscle or a palsy of CN VI will cause the affected eye to turn inward and patients will have limited abduction of the affected eye with horizontal diplopia that is worse when looking toward the affected side. Injury to the superior oblique or palsy of CN IV will cause the affected eye to be displaced slightly upwards and have vertical or torsional diplopia. Patients may compensate with a head tilt to the side of the palsy, making an isolated CN IV palsy difficult to diagnosis. Palsy of CN III results in the affected eye turning down and outwards. Patients are unable to supraduct, infraduct, or adduct the affected eye. Patients with a complete CN III palsy will also have ptosis and may have a dilated pupil.

The diplopia from a cranial nerve palsy is different from that resulting from a myositis or structural process involving the orbit and orbital structures. It can be identified during range of motion testing. Ocular myositis abruptly restricts eye movement away from the muscle, whereas a cranial nerve palsy smoothly and progressively impairs movement toward the weakened muscle. Entrapment of the inferior rectus muscle after trauma to the eye prevents the affected eye from tracking with the nonaffected eye, especially on upward gaze.

Funduscopic exam (posterior chamber exam). Structures of the posterior chamber include the retina, the optic nerve, the optic disk, the central retinal artery, the retinal veins, and the vitreous. A funduscopic exam should be performed on patients presenting with diplopia to look for signs of retinal pathology and papilledema.

Slit lamp exam (anterior chamber exam). Structures of the anterior chamber include the sclera, conjunctiva, cornea, iris, lens and the aqueous humor. Examination includes an assessment for irregularities of the pupil, inflammatory changes in the anterior chamber and abnormalities in the lens such as opacification (cataract) and positional changes. Subluxation of the lens can occur spontaneously or after trauma and the displaced lens can cause monocular diplopia. The abnormal lens is apparent on direct visualization or ultrasonography.

Signs and Symptoms

Monocular diplopia. Monocular diplopia is present only if the patient complains that the diplopia persists in the affected eye with the normal eye closed. Monocular diplopia is most commonly due to abnormal refraction, in which case it will resolve with having the patient look through a pinhole; diplopia due to a retinal abnormality or lens dislocation will not resolve with pinhole testing.

Binocular diplopia

Structural orbitopathy or myositis. An orbitopathy refers to any disease that affects the orbit and its contents. A structural orbitopathy can be caused by orbital myositis, trauma, infection/abscess, or craniofacial masses, any of which can directly restrict movement of the eye. A structural restriction of motion of a single eye, typically gradual in onset, may cause diplopia in a single direction of gaze or in multiple directions, depending on the type and extent of muscular involvement. A sensation of mass effect, discomfort, or pain in the culprit eye are characteristic symptoms. If the cause is infectious, the patient may have a history of a fever. Patients with orbital myositis due to giant cell arteritis will classically have a headache as well. Giant cell arteritis should be suspected in older patients presenting with any combination of headache, scalp tenderness, jaw claudication, or vision changes.

Signs of a structural orbitopathy or myositis include proptosis, periorbital swelling, edema, conjunctival or scleral hyperemia, and palpebral swelling involving a single eye. Diplopia due to a mass in the orbit may appear as a mechanical diplopia, in which having the patient attempt to look in the direction of the problem induces the most diplopia. This can also be seen in patients with significant periorbital swelling from trauma. In contrast, diplopia due to a process in any of the individual extraocular muscles, except for the lateral or medial recti muscles, may present with a torsional diplopia, based on the direction of pull and therefore restriction by each muscle (see Fig. 17.1). There is a mismatch between the primary direction of diplopia and primary direction of movement, possibly improved by head tilt. Although findings may mimic a neurogenic palsy to some extent, the signs induced on testing extraocular eye movements will not reflect the stereotyped deficits typical of palsies of the oculomotor cranial nerves.

Thyroid related eye disease results from the enlargement or fibrosis of the extraocular muscles and is most commonly seen in Graves disease; however, it can also be seen in other autoimmune thyroid conditions. Patients may present with isolated diplopia prior to the onset of systemic symptoms. Stigmata of thyroid eye disease includes proptosis, eyelid retraction, diffuse conjunctival edema, and vascular injection. Thyroid eye disease typically affects the inferior and medial recti muscles, first causing restriction of elevation and abduction of the eye leading to diplopia.

Isolated oculomotor nerve palsy. There are multiple causes of an isolated oculomotor nerve palsy including hypertensive or diabetic vasculopathy, a demyelinating process (multiple sclerosis), idiopathic intracranial hypertension, trauma, or compression. Isolated oculomotor nerve palsies present with typical findings as outlined in Fig. 17.2. The patient with a CN III palsy typically reports diplopia in all directions of gaze, except on lateral gaze to the affected side, and an eye that is deviated down and out. Patients may also have a dilated pupil and ptosis since CN III also innervates the levator palpebrae superioris muscle, which lifts the upper eyelid and provides parasympathetic innervation to two intrinsic ocular muscles, the ciliary and constrictor pupillae muscles. In patients

NERVE PALSY	MUSCLE(S) "OFF"	SYMPTOMS	EXAMINATION FINDINGS
Normal	N/A	N/A	
Oculomotor (CN III)	Medial, inferior, and superior rectii muscles • Inferior oblique muscle • Levator palpebrae (eyelid) • Ciliary and constrictor pupillae muscles (pupil)	Multidirectional horizontal and vertical diplopia, except on lateral gaze to the affected side • Eyelid "droop"	Trochlear (CN IV)	Superior oblique muscle	Rotational diplopia that worsens on looking down and toward the nose	Abducens (CN VI)	Lateral rectus muscle	Horizontal diplopia on gaze toward the affected side	
Fig. 17.2 Corresponding muscle dysfunction, symptoms, and examination findings for each oculomotor cranial nerve palsy. *CN,* Cranial nerve.

with microvascular ischemia to CN III due to hypertension and diabetes, the pupil may be spared but patients presenting with a compressive lesion, such as an aneurysm, will often have pupillary mydriasis due to the compression of pupillomotor parasympathetic fibers in the exterior of the nerve. However, this is not a hard and fast rule and should not be solely used to rule out a compressive lesion such as an aneurysm, as there are rare reports of patients with a compressive third nerve palsy having pupil sparing.[4]

A vertical or sometimes torsional diplopia that worsens on looking down and toward the nose implies a superior oblique (CN IV) palsy. A CN IV palsy makes descending stairs, reading, and watching television in bed difficult. CN IV is more susceptible to trauma because it sits against the tentorium. Diplopia that worsens on lateral gaze to one direction implies an issue with the abducens nerve (CN VI). Due to the length of the nerve, CN VI is the most common cranial nerve palsy, accounting for 50% of all CN palsies. In addition, a CN VI palsy may present with bilateral findings due to its susceptibility to increased intracranial pressure.

A patient with diplopia from an isolated palsy of CN III, IV, or VI should not have other associated symptoms. Pain and speed of onset are differentiators. A sudden isolated CN III, CN IV, or CN VI palsy associated with orbital discomfort in a patient with chronic diabetes or hypertension strongly suggests microvascular ischemia as the cause, with a caveat that a headache or eye pain may also be present in a CN III palsy caused by an aneurysmal compression. An isolated VI palsy associated with a change in vision, headaches, nausea and vomiting, with papilledema on physical exam, point to idiopathic intracranial hypertension as the diagnosis.

In contrast to an isolated cranial nerve palsy, the combination of ipsilateral palsies of CN III, IV, and VI raises a concern for cavernous sinus or orbital apex pathology, since the nerves run in close proximity in those areas. The orbital apex is the posterior part of the orbit and houses the extraocular rectus muscles, CN III, CN IV, CN V, and CN VI as well as the optic nerve. The cavernous sinuses are located in the base of the skull with CN III, CN IV, CN V, and CN VI plus the internal carotid artery traversing the cavernous sinus on each side. Trauma, infection, tumor/mass, vasculitis, and thyroid disease can all cause pathology in the orbital apex or cavernous sinus. There will typically be associated findings of exophthalmos, chemosis, and injection. Since the V1 and V2 branches of the trigeminal nerve travel though these structures, the patient may also have associated ipsilateral periorbital facial numbness or dysesthesia. An orbital apex syndrome can be differentiated from cavernous sinus pathology by decreased visual acuity since the optic nerve passes through the orbital apex.[5] Herpes zoster ophthalmicus is a well-described cause of orbital apex syndrome.

Cavernous sinus pathology may present initially with isolated CN VI involvement because it traverses through the cavernous sinus, as opposed to CN's III and IV, which are located within its wall. In addition, bilateral eye findings may be present in cases of cavernous sinus thrombosis because the cavernous sinuses directly communicate. A complex palsy in the cavernous sinus may also be iatrogenic due to intravascular injection from an intraoral dental anesthetic nerve block.

Neuroaxial process involving the brainstem and related cranial nerves. A focal brainstem lesion, seen in multiple sclerosis, may result in isolated diplopia. However, localized brainstem lesions usually present with other signs and symptoms from anatomically contiguous involvement. Additional symptoms of nausea, vertigo, or slurred speech are concerning for an impending basilar artery occlusion, especially if symptoms are sudden in onset, painless, and fluctuate. Gradual and progressive symptoms point more toward a brainstem mass. A young person with an ophthalmoplegic migraine may present in a similar fashion to someone with a brainstem stroke but will typically develop an associated ipsilateral headache.

Diplopia from a more diffuse neurologic syndrome involving the brainstem is usually gradual in onset and manifests with various other discordant symptoms. A gradually evolving combination of double vision, slurred speech, and problems swallowing suggests foodborne botulism. These patients have a descending flaccid paralysis that begins with multiple cranial nerve palsies. There may also be autonomic signs such as dry mouth, ileus, postural hypotension, respiratory muscle weakness, and pupillary abnormalities.

Nystagmus, ataxia, and altered mentation in a patient with chronic alcoholism, malnutrition, or history of bariatric surgery should raise the possibility of Wernicke encephalopathy. Most patients with Wernicke encephalopathy have ocular abnormalities, including nystagmus and ophthalmoplegia, usually from a CN VI palsy, due to metabolically induced lesions in the pontine tegmentum, abducens nucleus, and oculomotor nucleus.

In multiple sclerosis, diplopia may present as a clinically isolated syndrome or may be associated with additional neurologic findings, for example, optic neuritis with blurred vision and eye pain, focal motor findings, or sensory abnormalities. An internuclear ophthalmoplegia (INO), suggested by an inability to adduct the eye on one side in the contralateral direction during lateral gaze that resolves during convergence, implicates a lesion in the medial longitudinal fasciculus (MLF) and is typically found in patients with multiple sclerosis.

Diplopia and other cranial nerve symptoms, together with headache, photophobia, stiff neck, and fever are suspicious for a basilar meningoencephalitis. A brainstem lacunar stroke may present as any of a number of identifiable syndromes but usually presents with "crossed finding"—neurological deficits on the contralateral side of the body.

Patients with Miller-Fisher syndrome may present with an isolated ophthalmoplegia, but more typically have the classic triad of ophthalmoplegia, ataxia, and areflexia. Muscle weakness should not be present. If muscle weakness is present, the case is better classified as Guillain-Barré syndrome with ophthalmoplegia.

Neuromuscular disorder. Diplopia that is variably triggered in multiple directions, without a distinct structural or neuropathic cause, implies a neuromuscular cause such as myasthenia gravis. However, a mild neuromuscular manifestation of myasthenia may present with a diplopia isolated to one direction. In myasthenia gravis, the diplopia generally fluctuates over time, worsens with fatigue, and improves with rest. Patients with myasthenia gravis may have unilateral or bilateral ptosis, weakness on forced eyelid closure, and proximal or generalized muscle weakness, but with normal reflexes and no sensory abnormalities. There may be associated symptoms of shortness of breath or difficulty swallowing; however, approximately 50% of patients with myasthenia present with purely ocular symptoms. The diplopia may represent a myasthenic crisis, possibly associated with occult respiratory muscle weakness and ventilatory insufficiency.

Ancillary Testing

In addition to a thorough history and physical examination, additional testing may be needed in patients presenting with binocular diplopia. Patients presenting with a suspicion for systemic pathology such as hypertension, diabetes mellitus, myasthenia gravis, multiple sclerosis, thyroid disease, vascular disorders, or stroke should have lab work ordered. If thyroid disease is suspected, labs should include a thyroid panel. The inflammatory markers erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are nonspecific but should be considered in patients over 50 years old presenting with new onset binocular diplopia to rule out vasculitis and other inflammatory conditions. Patients with an ESR greater than 50, a CRP greater than 20, and other systemic symptoms of vasculitis or giant cell arteritis may need a temporal artery biopsy as well.[6,7]

If myasthenia gravis is suspected in a patient with diplopia or ptosis, a bedside ice test may be diagnostic. The test is performed by applying an ice-filled glove or bag to the patient's closed eye for 5 minutes; a positive test is an improvement in the ptosis (typically ≈5 mm) or diplopia. Cold temperatures mitigate the effect of myasthenia-related acetylcholine receptor blockade by decreasing cholinesterase activity and promoting the efficacy of acetylcholine at the endplate. The ice test has a sensitivity of 80% and specificity of 25%; another bedside test for ocular myasthenia gravis is testing for fatigability on sustained upward gaze, which has a sensitivity of 80%, and a specificity of 63%.[8] An edrophonium (Tensilon) challenge is no longer performed as the drug is not available.

Most patients presenting with binocular diplopia will undergo computed tomography (CT) or magnetic resonance imaging (MRI) imaging. Imaging will be directed by the history and physical examination; however, patients presenting to the ED with diplopia are more likely to have pathology that is better visualized by MRI, making MRI more definitive imaging and the study of choice in most cases. Patients with a history of trauma and diplopia should undergo CT and/or MRI imaging.

For an isolated neuropathy of CN III, IV, or VI presenting without evidence of an aneurysm, the optimal study is MRI of the brain and orbits with fat-suppressed orbital imaging to assess for inflammation, neoplasm, or demyelination along the course of the nerves. Isolated CN IV and VI palsy in adults, especially in adults over 50, are most commonly caused by microischemia (hypertensive or diabetic) and imaging may be deferred in patients presenting with vascular risk, absent other red flags, and only performed if symptoms persist past 3 months. However, younger patients, or those without vascular risk factors, may require initial neuroimaging and should undergo evaluation for undiagnosed hypertension and diabetes, as isolated cranial nerve palsy can be the initial clinical presentation of underlying disease. Children presenting with new onset diplopia and cranial nerve IV or VI palsy should undergo emergent MRI since compression is the most common cause of pathology in the pediatric population.

There is some controversy as to whether patients presenting to the ED with an isolated cranial nerve III palsy, with vascular risk factors and no associated signs and symptoms of compression, need emergent imaging. Patients presenting with a complete CN III palsy (complete ptosis and no adduction, depression, or elevation) and a normal reactive isocoric pupil may not need emergent imaging, as a complete CN III palsy with pupil sparing essentially excludes the diagnosis of aneurysm. However, one study found that other compressive lesions presented with pupil sparing in a small number of cases.[4] Patients without vascular risk factors and patients with an incomplete CN III palsy, regardless of pupil involvement, should undergo magnetic resonance angiography (MRA) or CT angiography to rule out a mass lesion. Patients that do not undergo emergent imaging should have close follow-up to monitor for delayed pupil involvement and progression of symptoms.[4,9]

Orbital infectious processes are readily visualized on contrasted CT of the orbits; however, extraocular muscles are best imaged by MRI of the orbits with gadolinium and high-resolution cuts through the brainstem. If MRI of the orbits is not available, a contrast-enhanced cranial CT scan with fine cuts through the orbit can be used as a second-line option. The same imaging paradigm applies to localization of the process within the cavernous sinus or orbital apex, because an MRI will highlight infiltrative, inflammatory, or compressive pathology. A CT and CT venogram of the brain and orbits should be ordered if MRI is not available. An MRI should be ordered when symptoms suggest a demyelinating process.

Lumbar puncture is diagnostic for CNS infections involving the eye and useful for inflammatory conditions that extend to the CNS. Lumbar puncture is also indicated in cases of suspected idiopathic intracranial hypertension.

DIAGNOSTIC ALGORITHM

The critical, emergent, and urgent diagnoses applicable to each of the differential considerations noted are outlined in Table 17.2. Narrowing the differential diagnosis for the ED patient with diplopia involves determining the nature of the diplopia and finding the secondary or underlying cause. Most of this diagnostic evaluation is done via the history and physical, followed by targeted imaging, as indicated. A diagnostic algorithm is presented in Fig. 17.3, using a systematic approach that incorporates the following queries, taking into consideration the symptoms and signs described earlier (see Signs and Symptoms section):

1. Is the diplopia monocular?
2. Is the diplopia due to a structural orbitopathy or orbital myositis?
3. Is the diplopia due to a palsy of the oculomotor cranial nerves (CN III, IV, VI) in a single eye?
4. Is the diplopia due to a neuroaxial process involving the brainstem and related cranial nerves?
5. Is the diplopia due to a neuromuscular disorder?

The first step is to determine if diplopia is purely monocular. In the absence of trauma, the evaluation of monocular diplopia that corrects with a pinhole essentially ends with a referral to ophthalmology. However, lens dislocation or retinal pathology diagnosed on physical examination may prompt an Ophthalmology consult.

In contrast, if the diplopia is determined to be binocular, the next question is whether or not there is an orbital myositis or structural orbitopathy, from an inflammatory, traumatic, neoplastic, or infectious cause directly restricting the movement of a single eye. If both eyes are involved, thyroid disease (Graves orbitopathy) should be considered. If an orbital mechanical problem is clearly apparent, with no neuroophthalmologic findings (including ptosis, pupillary abnormality, and anisocoria) or

TABLE 17.2 Important Causes of Diplopia

Diplopia-Causing Entity	Mechanism and Mortality	Distinguishing Features
Tier 1—Critical		
Basilar artery thrombosis	Impending thrombosis of the basilar artery with brainstem ischemia; untreated mortality, 70%–90%	Vertigo, dysarthria, other cranial nerve involvement; risk factors for stroke
Botulism	Toxin inhibits release of acetylcholine at cholinergic synapses and presynaptic myoneural junctions; untreated mortality, 60%	Dysarthria, dysphagia, autonomic dysreflexia, pupillary dysfunction
Basilar meningitis	Infection; untreated mortality, close to 100% if bacterial (15%–20% if treated)	Headache, meningismus, fever
Aneurysm	Enlarging aneurysm directly compresses cranial nerve; mortality, 26%–67% with rupture	CN III palsy with pupillary involvement
Tier 2—Emergent		
Vertebral artery dissection	Dissection causes vertebrobasilar ischemia; acute untreated mortality, 28% (2%–5% if neurologically asymptomatic)	Neck pain, vertigo; risk factors for vertebral dissection
Myasthenia gravis	Autoantibodies develop against acetylcholine (ACh) nicotinic postsynaptic receptors; untreated crisis mortality, 42% (5% if treated)	Fluctuating muscle weakness, ptosis, and diplopia worsen with activity, improve with rest
Wernicke encephalopathy	Thiamine-dependent metabolic failure and tissue injury; untreated mortality, 20%	Nystagmus, ataxia, altered mental status, ophthalmoplegia; alcoholism and nutritional deficiency
Orbital apex syndrome, cavernous sinus process	Inflammation or infection in the orbital apex or cavernous sinus directly affects oculomotor cranial nerves; acute mortality low unless infectious and complicated by meningitis	Combination of palsies of CN III, IV, or VI, with retro-orbital pain, conjunctival injection, possible periorbital, facial numbness
Tier 3—Urgent		
Brainstem tumor	Tumor involvement at the supranuclear level; acute mortality low (long-term mortality variable)	Skew deviation—vertical diplopia, internuclear ophthalmoplegia
Miller-Fisher syndrome	Autoantibodies develop to a cranial nerve ganglioside, GQ1b; acute mortality low (if fully differentiated from Guillain-Barre Syndrome (GBS);	Ophthalmoplegia, ataxia, areflexia
Multiple sclerosis	Demyelinating lesions; acute mortality low	Internuclear ophthalmoplegia
Thyroid myopathy (Graves disease)	Autoimmune myopathy; acute mortality low in regard to ocular complaints	Proptosis, restriction of elevation and abduction of the eye, signs of Graves disease
Ophthalmoplegic migraine	Inflammatory cranial neuropathy; low mortality, self-limited disease	Ipsilateral headache, CN (usually III) palsy
Ischemic neuropathy	Microvascular ischemia; mortality low, self-limited disease	Isolated CN palsy (pupil-sparing if CN III)
Orbital myositis, pseudotumor	Autoimmune or idiopathic myositis; acute mortality low in regard to ocular complaints	Eye pain, restriction of movement, periorbital edema; exophthalmos and chemosis when more severe
Orbital apex mass	Tumor, infiltration, or mass effect in orbital apex or cavernous sinus directly compresses oculomotor cranial nerves; acute mortality low	A combination of palsies of CN III, IV, or VI and possible periorbital, facial numbness, with retro-orbital pain, proptosis, signs of venous congestion

CN, Cranial nerve.

neurologic findings (including cranial nerve abnormalities), a contrast-enhanced MRI (or CT) is indicated.[9]

If the diplopia does not appear to be strictly mechanical or structural, the next question is whether there is unilateral oculomotor cranial nerve palsy in the oculomotor (CN III), trochlear (CN IV), or abducens (CN VI) nerve, from trauma, compression, or microvascular ischemia. An older patient, with vascular risk factors (hypertension, diabetes, smoking) and a classic presentation of CN IV, CN VI, or a complete CN III palsy with pupil sparing due to microvascular ischemia, does not need emergent neuroimaging if specialty follow-up is arranged. If there is

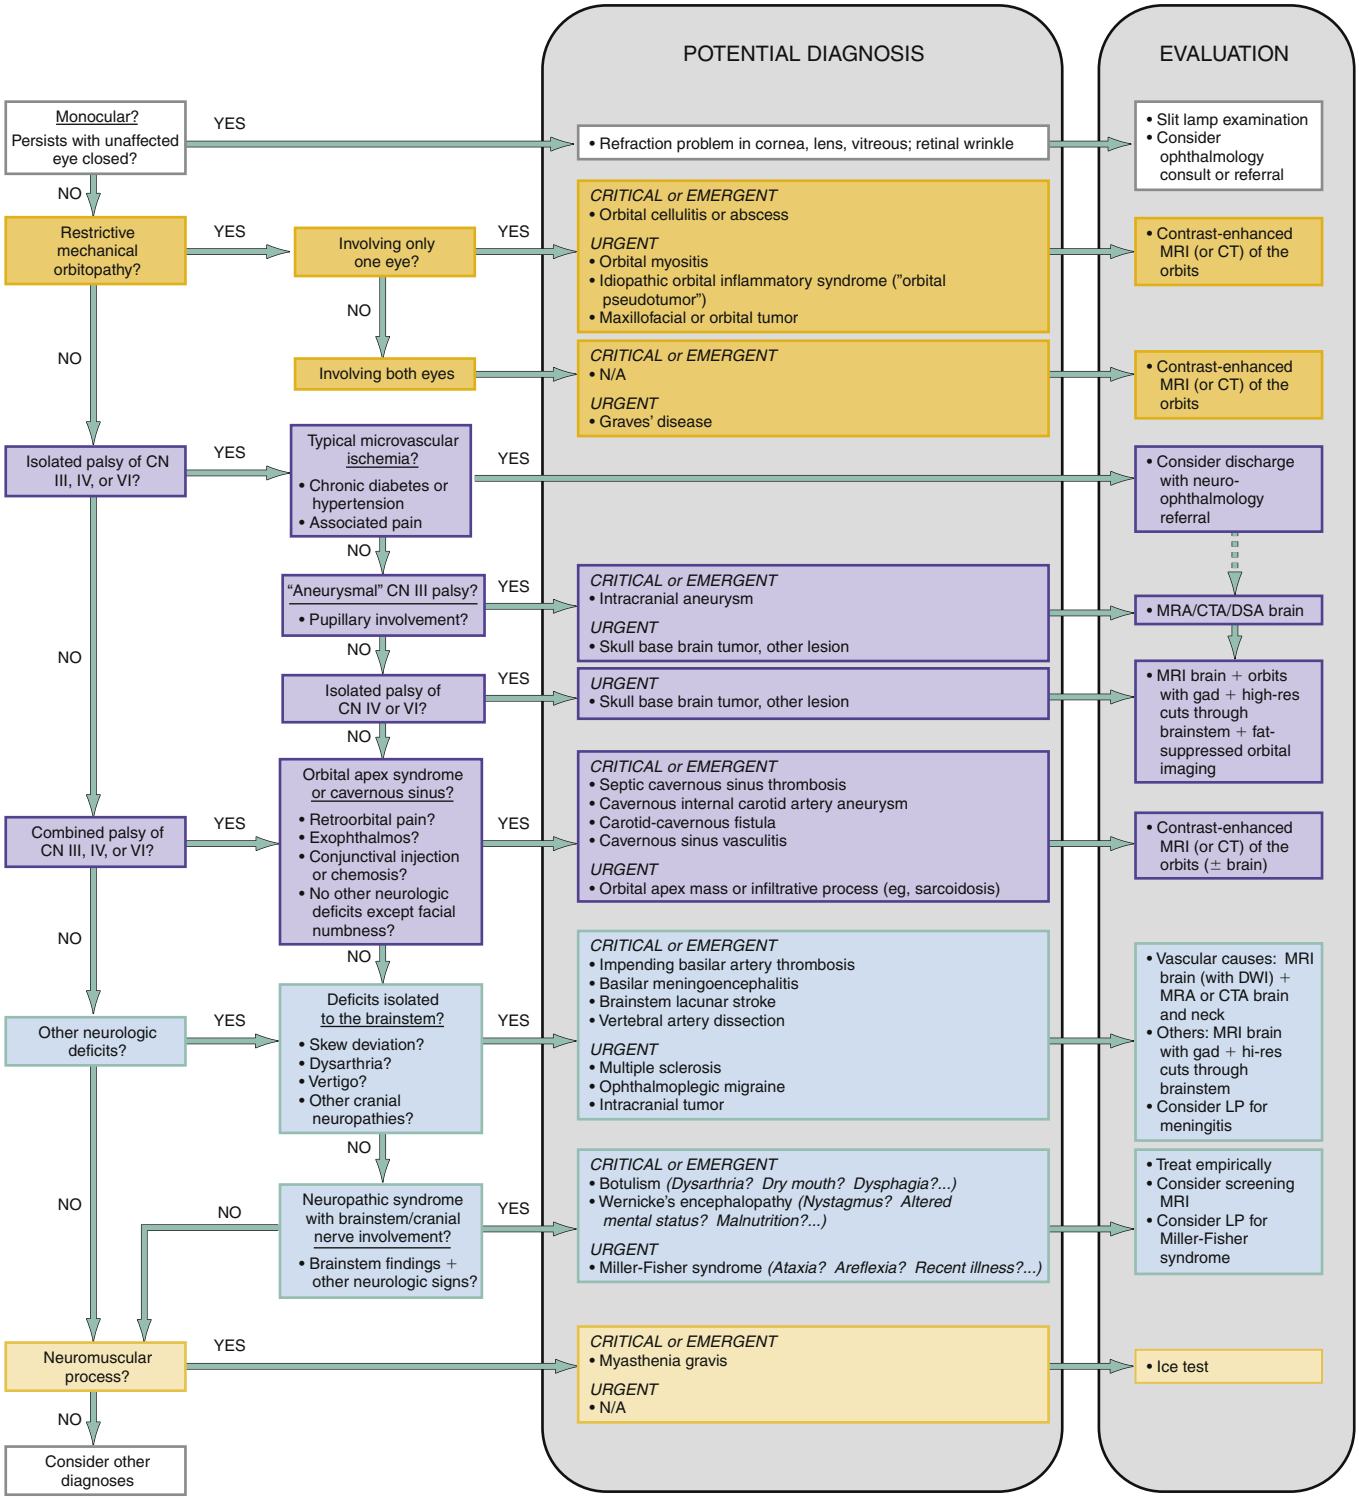

Fig. 17.3 Algorithm for the diagnostic approach to diplopia in the emergency department, a guideline. *CN,* Cranial nerve; *CNS,* central nervous system; *CT,* computed tomography; *CTA,* computed tomography angiography; *DSA,* digital subtraction angiography (conventional angiography); *DWI,* diffusion-weighted imaging; *gad,* gadolinium; *High-res,* high-resolution; *LP,* lumbar puncture; *MRA,* magnetic resonance angiography; *MRI,* magnetic resonance imaging.

any equivocation, imaging should be obtained in the ED since there is a small percentage of patients with risk factors who have a cause other than microvascular ischemia. Pediatric patients with a new-onset CN III, CN IV, or CN VI palsy and patients with ipsilateral involvement of more than one oculomotor nerve should undergo emergent imaging.

Assuming that a unilateral process, limited exclusively to the orbit or oculomotor cranial nerves, is not clearly identifiable, a neuroaxial process involving the brainstem and related cranial nerves should be considered. Brainstem lesions from multiple sclerosis, brainstem tumor, brainstem lacunar stroke, impending basilar artery thrombosis, vertebral artery dissection, or ophthalmoplegic migraine prompts an MRI of the brain plus MRA or CTA of the brain and neck. More diffuse neurologic syndromes involving the brainstem and/or CNs III, IV, and VI due an infectious, autoimmune, neurotoxic, or metabolic process (e.g., basilar meningoencephalitis, botulism, Miller-Fisher or Guillain-Barré syndrome, Wernicke encephalopathy) should be treated empirically based on signs and symptoms while the workup is obtained. Diplopia may be the first, primary, or only symptom of these diseases, and neurological signs suggesting a focal brainstem process may actually be a mild or an early presentation of a diffuse neurologic syndrome.

Finally, if the presentation of the diplopia does not fit into an anatomically congruent process, a neuromuscular cause such as myasthenia gravis or other diseases such as botulism or multiple sclerosis should be considered.

EMPIRICAL MANAGEMENT

Because the treatment of diplopia depends entirely on the cause, there are few primary treatments for diplopia in the ED. Treatment is aimed at addressing the secondary cause of the diplopia. Such approaches are outlined elsewhere in this text.

Management Algorithm

The management of diplopia centers on the diagnosis of the underlying cause. Certain emergent therapeutic measures may be indicated in the context of potentially serious underlying causes, as outlined in the algorithm in Fig. 17.4. The priority is to assess for any airway or

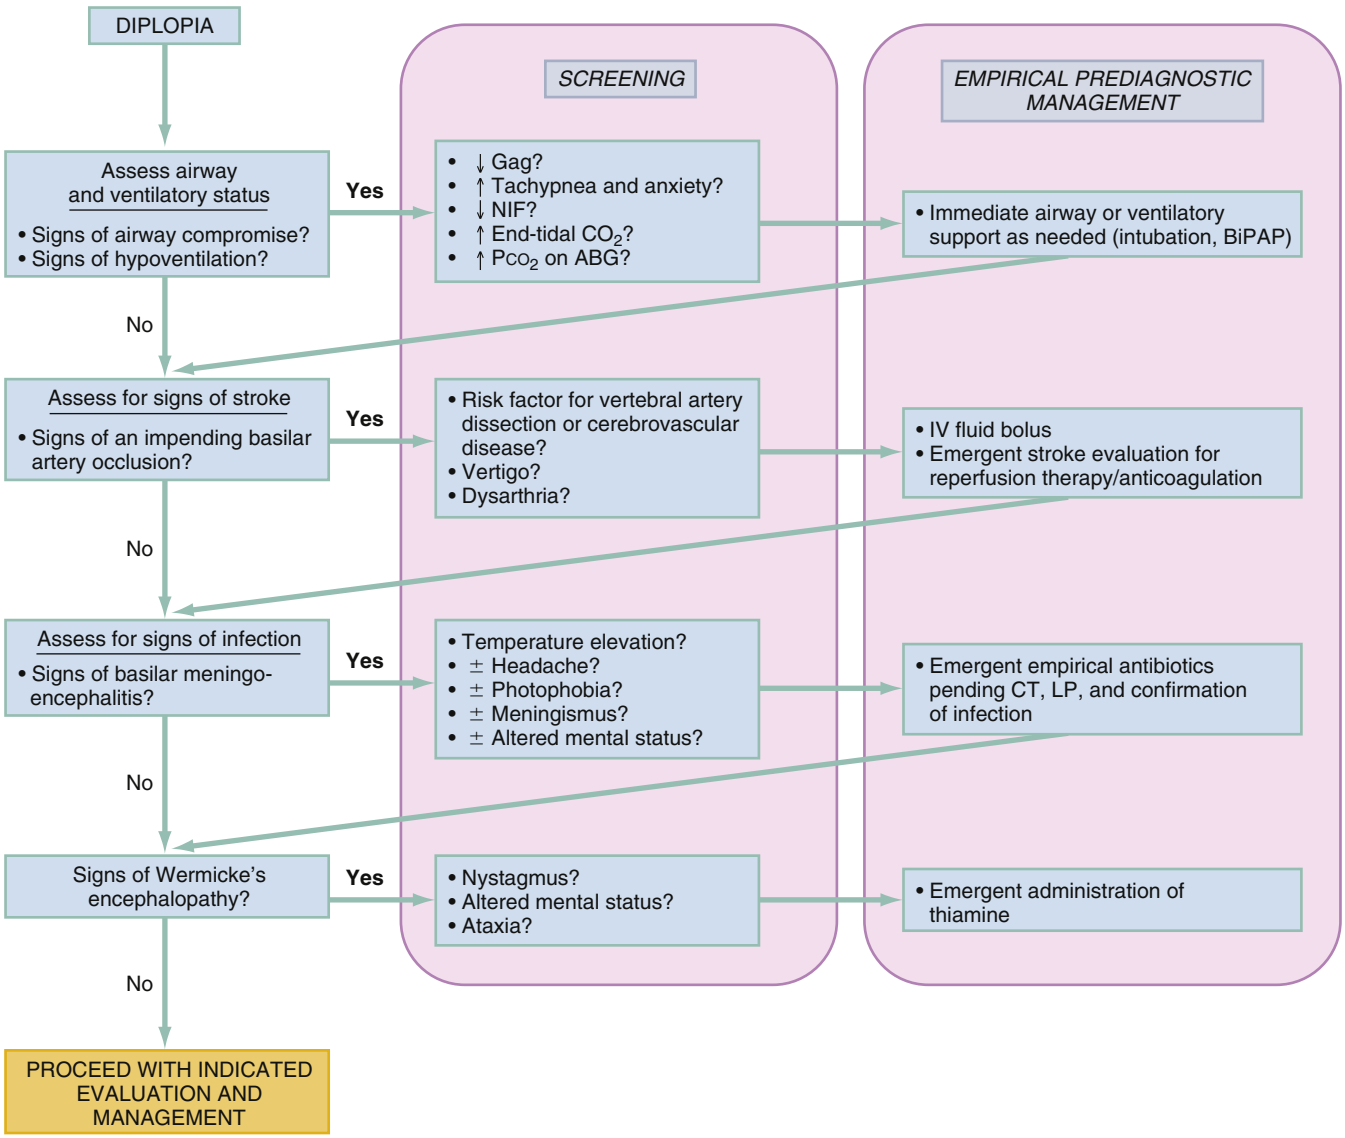

Fig. 17.4 Algorithm for the initial stabilization of the patient with diplopia in the emergency department, a guideline. *ABG,* Arterial blood gas; *BiPAP,* biphasic positive airway pressure; CO_2, carbon dioxide; Pco_2, partial pressure of carbon dioxide; *CT,* computed tomography (of the cranium); *LP,* lumbar puncture; *NIF,* negative inspiratory force.

ventilatory compromise that may be present. If the patient's airway and breathing are not compromised, the next consideration should be imminent threats to CNS tissue viability, such as an impending basilar artery thrombosis, and rapidly evolving threats to CNS tissue viability, such as botulism, meningoencephalitis, or Wernicke encephalopathy. Appropriate treatments should be started empirically either before or as the evaluation gets underway. Monitoring and frequent reassessment are indicated in patients at risk of respiratory and neurologic deterioration, for example, botulism, Guillain-Barré syndrome, brainstem strokes or intracranial hemorrhage. Patients with any suspicion for infection should be treated with antibiotics. Patients with a history of alcohol abuse or bariatric surgery should be given thiamine empirically.

The patient with binocular diplopia will typically require admission for further evaluation and treatment of the underlying disorder, unless diagnosed with a low-acuity condition such as microvascular ischemia. A CN III, IV, or VI palsy from microvascular ischemia is generally self-limited; the pain usually resolves after a few days, and complete spontaneous resolution is the norm, occurring in up to 95% of patients. These patients can typically be discharged home, with close outpatient follow-up.

CHAPTER 17: QUESTIONS AND ANSWERS

1. A 65-year-old man with a longstanding history of diabetes and hypertension presents with sudden onset of persistent diplopia that began a few hours before arrival. He describes left retro-orbital discomfort, and his examination is notable for a left eye that is deviated laterally and downward, with a palsy of movement medially and upward. He also has a left-sided ptosis but no conjunctival injection, chemosis, or proptosis. His pupils are equal in size at 4 mm, round, and equally reactive to light in both a direct and consensual reflex, and his examination is otherwise unremarkable. What is the most likely cause of the diplopia?

a. Brain tumor
b. Cerebral aneurysm
c. Microvascular ischemia
d. Orbital apex syndrome

Answer: c. Based on examination, this is a patient who has a pupil-sparing complete CN III (third nerve) palsy. Because his pupillary examination is normal, with an otherwise complete CN III palsy, the palsy is very unlikely to be due to external compression from a brain tumor, aneurysm, or orbital apex process. It is a typical presentation of microvascular ischemia, to which the patient is predisposed, given his history of diabetes and hypertension.

2. A 56-year-old woman presents with recurrent episodes of diplopia that have been ongoing for a week. She describes double vision that gradually comes and goes, typically worse at the end of the day, with no particular direction or orientation to the diplopia. The patient's coworker, who is present in the emergency department (ED) with her, states that the patient's eyes "looked droopy" during an animated staff meeting they attended that afternoon but look normal now. The patient also describes waxing and waning general muscular weakness that has also been present this past week but denies any other symptoms and states that when she rests, she feels better. With which entity are her symptoms most consistent?

a. Botulism
b. Hypothyroidism
c. Miller-Fisher syndrome
d. Myasthenia gravis

Answer: d. The patient and coworker are describing what appears to be an activity-related diplopia, with generalized muscle weakness and lack of other focal symptoms, all very suggestive of a possible neuromuscular process (myasthenia gravis). Miller-Fisher syndrome would not be associated with muscle weakness and would not wax and wane. Botulism would typically have a more progressive course, with other associated bulbar symptoms. Diplopia may be associated with hypothyroidism if it is a presentation of or treatment complication of Graves disease but would not change so markedly with activity.

3. A 76-year-old man with hypertension, hypercholesterolemia, and diet-controlled diabetes presents with a sudden onset of diplopia that developed 30 minutes before arrival. Paramedics state that the patient's wife reported that he suddenly began staggering around the room, unable to bear weight on his left side. On examination, the patient has normal vital signs except for mild hypertension and has a right CN III palsy, with left arm and leg weakness. He has no airway complaints and denies any pain. What is the most appropriate initial response?

a. Checking blood gas levels and assessing the patient's negative inspiratory force
b. Emergent treatment with botulinum antitoxin
c. Initiating broad-spectrum antibiotics to cover upper respiratory pathogens
d. Initiating clinical measures to address an acute ischemic stroke

Answer: d. The paroxysmal onset of the patient's symptoms, with focal neurologic symptoms and signs, suggests an ischemic event. His crossed deficits and discrete CN III palsy suggest localization in the brainstem.

4. Which constellation of symptoms is most concerning for foodborne botulism?

a. Double vision, headache, and right leg weakness
b. Double vision, left eye discomfort, and periorbital swelling
c. Double vision, nystagmus, and confusion
d. Double vision, slurred speech, difficulty swallowing, and dry mouth

Answer: d. Double vision, slurred speech, difficulty swallowing, and dry mouth would be present with foodborne botulism.

5. A 45-year-old woman presents with progressively worsening double vision and the inability to adduct the eye on one side in the contralateral direction during lateral gaze that resolves during convergence on physical examination. What disease should be suspected with these findings?

a. Multiple sclerosis
b. Botulism
c. Myasthenia gravis
d. Idiopathic intracranial hypertension

Answer: a. An internuclear ophthalmoplegia (INO), suggested by an inability to adduct the eye on one side in the contralateral direction during lateral gaze that resolves during convergence, implicates a lesion in the medial longitudinal fasciculus (MLF) and is typically found in patients with multiple sclerosis.

18

Red and Painful Eye

Alan A. Dupré and Leslie R. Vojta

KEY CONCEPTS

- Critical diagnoses, such as caustic injury, orbital compartment syndrome, and narrow angle (acute angle closure) glaucoma, require immediate treatment and ophthalmology consultation.
- Prompt and prolonged irrigation is essential for patients who experience caustic injury to the eye.
- Headache and nausea may be prominent symptoms in patients with narrow angle glaucoma.
- Complete abolition of a foreign body sensation after instillation of local anesthetic solution indicates a high likelihood of a superficial corneal lesion.
- Keratitis, inflammation of the cornea, is most commonly caused by a viral infection, but may also be caused by recent ultraviolet light exposure, chemical injury, or hypoxic injury from contact lens use.
- A localized corneal defect with edematous, inflammatory changes may signal corneal ulceration.
- A corneal dendritic pattern may signal a herpetic infection, which can progress to corneal opacification and visual loss.
- Pain, consensual photophobia, perilimbic conjunctival injection, and a miotic pupil could signal iritis or uveitis. The cause may be trauma or an underlying autoimmune disease. The presence of cell and flare in the anterior chamber can help identify these conditions.
- Conjunctivitis is usually self-limited and rarely requires antibiotic treatment.

FOUNDATIONS

Epidemiology and Pathophysiology

Most eye complaints are not immediately sight-threatening and can be managed by an emergency clinician; however, some require immediate recognition, emergent intervention, and consultation. In the United States from 2006 to 2011, the three most prevalent emergency department (ED) ocular complaints were conjunctivitis, corneal abrasion, and corneal foreign body.[1] As more outpatient ophthalmological surgeries are performed, more patients with postoperative complications can be expected to present to the ED. Nontraumatic diseases, such as glaucoma and peripheral vascular disease leading to retinal ischemia, are more common with advancing age.

The external and internal anatomy of the eye is depicted in Fig. 18.1. The globe has a complex layer of blood vessels in the conjunctiva, sclera, and retina. Redness reflects vascular dilation and occurs with processes that produce inflammation of the eye or surrounding tissues. Eye pain may originate from the cornea, conjunctiva, iris, vasculature, or optic nerve. Each is sensitive to processes causing irritation or inflammation.

DIAGNOSTIC APPROACH

Rapid and accurate triage is the most critical consideration in the approach to the red and painful eye. Critical conditions are time sensitive and can rapidly lead to progressive visual loss without immediate intervention in the ED. Urgent conditions are managed in the ED before discharge. The remainder of conditions require supportive management, such as conjunctivitis and spontaneous subconjunctival hemorrhage. Even low-acuity ocular complaints can benefit from evaluation and management by the emergency physician.

Visual acuity is the vital sign of the eye. Rare situations preclude early and accurate visual acuity testing. Patients with complaints of contamination with an acid, alkali, or other caustic substance; sudden visual loss, especially if unilateral and painless; and significant trauma, especially with retrobulbar hematoma causing orbital compartment syndrome, should have only a gross visual acuity examination performed as interventions are simultaneously prepared. When not being actively examined or treated, injured eyes with concern for globe rupture should be protected with a rigid shield to prevent inadvertent external pressure that could cause additional damage.

Differential Considerations

The diagnostic approach to the red or painful eye typically begins with categorization into traumatic and nontraumatic causes. Patients almost always can report whether or not their eye was injured—even indirectly, such as injury from reflected sunlight.

Traumatic pain and redness can be caused by caustic fluids and solid materials, low-velocity contact with a host of materials that can fall or be rubbed into the eye, higher velocity blunt-force impacts to the orbit or globe, or potentially penetrating injuries. Caustic contamination is discussed under critical diagnoses. Other traumatic complications that must be considered early in the course of care include retrobulbar hematoma, abscess, or emphysema with orbital compartment syndrome and suspicion of an open globe from either blunt or penetrating trauma.

The first triage question for any eye complaint should be, "Did anything get in your eye?" If so, attempt to identify the nature of the substance or foreign body. Specifically, this question seeks to quickly identify eyes that may have been exposed to a caustic substance. Patients exposed to acids, alkalis, and other caustic substances require rapid decontamination before additional evaluation to potentially prevent permanent loss of visual acuity.

The possibility of an open globe must be considered following any traumatic injury, regardless of the mechanism. Findings may be obvious, subtle, or occult. Blunt trauma may rupture the globe. Penetrating trauma can result from obvious causes identified through determining the events leading to injury, but it can also be unknown to the victim,

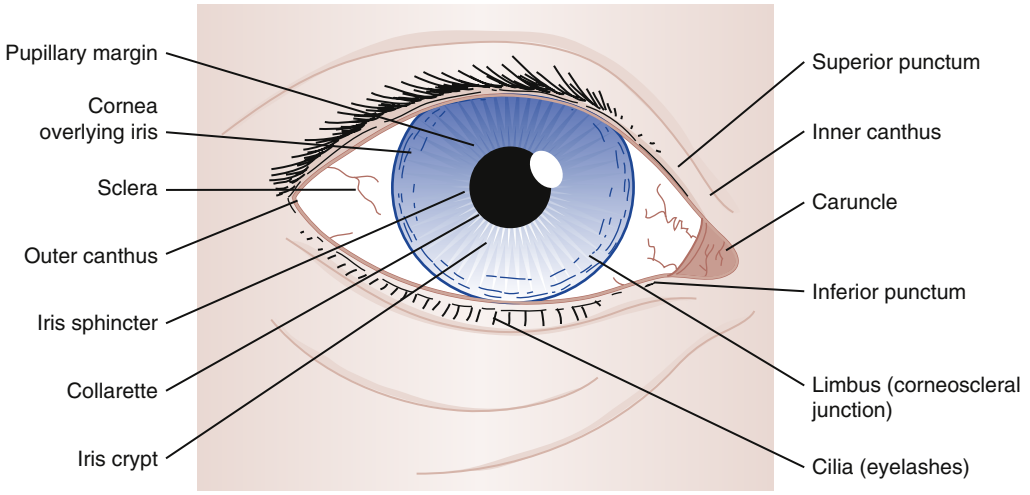

Fig. 18.1 External (A) and internal (B) anatomy. (From Ragge NK, Easty DL. *Immediate Eye Care*. St Louis, MO: Mosby-Year Book; 1990.)

such as if the patient did not realize a tiny ballistic metal fragment may have penetrated the eye while walking near a person hammering metal or using a high-speed grinder.

Causes of nontraumatic pain and redness are diverse but are mostly infectious and inflammatory, although these may be due to processes intrinsic to the globe and adjacent structures, neurologic conditions, or be due to ocular manifestations of systemic illness (e.g., giant-cell arteritis). Exposure history and review of systems are helpful when infection is suspected (e.g., concomitant upper respiratory tract infections making a viral etiology of conjunctivitis more likely). Questions related to recent surgery and contact lens wear and cleaning practices must be asked. Therefore, nontraumatic eye complaints require a more detailed history than would be necessary following a known traumatic etiology.

Not all visual disturbances are due to conditions that cause ocular inflammation resulting in pain or redness. Two conditions that are essential to consider are retinal detachment and central or branch retinal artery occlusion. Only rapid diagnosis by funduscopic or ultrasound examination and immediate intervention offer the possibility to restore sight. Retinal artery occlusion is readily apparent as a diffusely pale retina with indistinct or unseen retinal arteries (Fig. 18.2). Because these conditions do not typically present with either pain or external signs such as redness, diagnosis and treatment of retinal artery occlusion and retinal detachment are detailed in Chapter 57. Diplopia is covered in Chapter 17.

Pivotal Findings

Measurement of the patient's best corrected visual acuity (with glasses on if available) with each eye individually provides vital information when evaluating eye complaints and may be prognostic in some situations. Only a few situations, discussed earlier, preclude obtaining visual acuity using a chart. Decreased visual acuity caused by abnormal refraction (e.g., chronic myopia) can be detected by using a pinhole device during acuity testing, because central vision remains intact despite refractive errors. If there is nonrefractive pathology, such as retinal edema or aqueous hemorrhage, causing the acuity deficit, pinhole testing will show no improvement in the (poor) visual acuity.

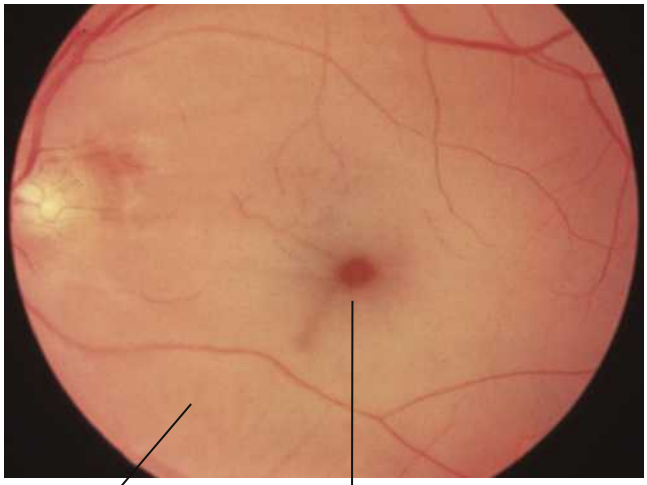

Fig. 18.2 Key funduscopic findings in acute central retinal artery occlusion include general pallor of the retina (except for a characteristic cherry-red spot where the perfused choroid shows through the thinner fovea) and attenuation of retinal arteries (possibly with retinal veins preserved as in the photograph). (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004:297.)

Symptoms and signs that are more likely to be associated with a serious diagnosis in patients with a red or painful eye are listed in Box 18.1.

Symptoms

When the presenting complaint is pain, the first step is to characterize it: itching, burning, dull pain, sharp pain, diffuse, or localized. Two factors of the history are particularly important: suddenness of onset and perception of a foreign body. A foreign-body sensation, particularly when it can be localized, is a strong indicator of corneal origin to the pain (foreign body, corneal abrasion, ulcer, or viral or ultraviolet keratitis). Itching is more often due to irritation by blepharitis, conjunctivitis, or dry eye syndrome. Burning is associated with these conditions and with other superficial problems, such as irritation of a pterygium or pinguecula, episcleritis, or limbic keratoconjunctivitis. Sharp pain generally results from abnormalities of the anterior eye, such as the cornea and uvea. Dull pain, which may be severe, is usually generalized throughout the eye (and may be reported as "headache"). It is typically a manifestation of increased intraocular pressure (IOP) (such as with narrow angle glaucoma), vitreous infection (e.g., endophthalmitis), or referred pain from an extra-orbital process (such as sinusitis, migraine headache, or temporal arteritis). Acute orbital compartment syndrome, caused by retro-orbital hematoma, presents with intense pain and progressive visual loss. These patients often present with head trauma that precludes them from reporting pain, emphasizing the importance of physical examination.

Rarely is there a chief complaint of redness that is not accompanied by pain, itching, irritation, or foreign body sensation. Completely asymptomatic "red eye" is almost always a spontaneous subconjunctival hemorrhage, which is benign but often alarming to the patient. Spontaneous subconjunctival hemorrhage may follow coughing or straining, but it most often occurs without any identifiable precipitating event and is simply noticed by the patient when looking in a mirror.

Symptomatic red eye commonly causes bulbar or limbal injection of the conjunctiva. Free blood noted behind the bulbar conjunctiva (i.e., subconjunctival hemorrhage) or in the anterior chamber (i.e., hyphema) may be spontaneous or post-traumatic. Spontaneous subconjunctival hemorrhage is painless, and the presence of pain raises concern for a more serious cause of the hemorrhage, such as direct globe injury or a retrobulbar process. Hyphema of sufficient size to be noted by the patient or bystander usually presents with pain and blurred vision.

Other symptoms include lid swelling, tearing, discharge, crusting, discomfort on blinking, or sensitivity to light. Lid swelling can be caused by inflammatory and noninflammatory processes. Concurrent erythema and tenderness of the lid favors the former. In the absence of trauma or other external irritant (e.g., contact dermatitis from eye makeup), inflammatory processes include primary lid problems, such as hordeolum (i.e., stye) or blepharitis, as well as extension from concomitant conjunctivitis or cellulitis in orbital or periorbital structures. When pain is present, tearing is usually secondary. Discharge and crusting are most commonly associated with conjunctivitis, whether allergic, chemical, viral, or bacterial. Blepharitis, dacryocystitis, and canaliculitis are other inflammatory processes that may create a discharge and subsequent crusting.

There is considerable debate within the published literature about the importance of eyelid matting as a predictor of a bacterial conjunctivitis. While some studies show that morning eyelid matting is predictive of positive bacterial cultures of ocular discharge,[2] the clinical significance of these cultures are unclear. The hazards of equating lid sticking with bacterial infection are underscored by the fact that viral conjunctivitis, particularly caused by subtypes of adenovirus, can cause dramatic symptoms with mucopurulent discharge, lid sticking, keratitis symptoms, and lid inflammation. There is a decreased likelihood of positive bacterial cultures if the redness is not observed at 20 feet, absence of morning eyelid matting, or presentation during the summer.[2] Even in the setting of a presumed bacterial conjunctivitis, most ophthalmology literature does not support the use of antibiotics in acute, mild conjunctivitis in patients who do not wear contact lenses, have a traumatic injury, and are immunocompetent.[3] Additional past ocular history questions are listed in Box 18.2.

Signs

A complete eye examination includes eight components, although many patients require only a limited or directed eye examination, depending on the presentation. The mnemonic *VVEEPP* (pronounced "veep") plus slit-lamp and funduscopic examinations represent these components (Box 18.3). We recommend slit-lamp examination for any complaint involving trauma, foreign-body sensation, or alteration of vision. Funduscopic examination is pursued if there is vision loss, visual alteration including clouding of vision, or suggestion of serious systemic pathology in the history and initial physical examination. A thorough

BOX 18.1 Pivotal Findings More Likely Associated With a Serious Diagnosis in Patients With a Red or Painful Eye

Severe ocular pain
Persistently blurred vision
Exophthalmos (proptosis)
Reduced ocular light reflection
Corneal epithelial defect or opacity
Limbal injection (also known as *ciliary flush*)
Pupil unreactive to a direct light stimulus

Adapted and reprinted with permission from Trobe JD. *The Physician's Guide to Eye Care*. San Francisco, CA: Foundation of the American Academy of Ophthalmology; 2001.

BOX 18.2 Past Ocular History Questions

1. Do you wear contact lenses? If so, what type, how are they cleaned, and how old are the lenses? How often is the lens solution changed?
2. Do you wear glasses? If so, when was your last evaluation for your glasses prescription? Do you have any changes in your vision?
3. Have you had previous eye injury or surgery?
4. What is your past medical history? Do you have any systemic diseases that may affect the eye? Do you have a weakened immune system?
5. What medications do you take?
6. Do you have any allergies?

BOX 18.3 Complete Eye Examination

*V*isual acuity (best possible using correction)
*V*isual fields (tested by confrontation)
*E*xternal examination
  Globe position in orbit
  Conjugate gaze
  Periorbital soft tissues, bones, and sensation
*E*xtraocular muscle movement
*P*upillary evaluation (absolute and relative)
*P*ressure determination (tonometry)
Slit-lamp examination
Funduscopic examination

Adapted from Wightman JM, Hurley LD. Emergency department management of eye injuries. *Crit Decis Emerg Med.* 1998;12:1–11.

physical examination can be conducted in the following order: *V*isual acuity, *v*isual field testing, *e*xternal examination, *e*xtraocular muscle movement, *p*upillary evaluation, and *p*ressure determination.

Visual Acuity

A patient's initial visual acuity provides a baseline from which deterioration or improvement may be followed. It is also predictive of functional outcome after ocular trauma. Visual acuity is quantitatively assessed by use of a Snellen chart at a distance of 20 feet (6 m) or a Rosenbaum chart at a distance of 14 inches. Young patients who cannot yet read letters and numbers should be tested with an Allen chart that depicts easily recognizable shapes. Each eye is tested separately with the opposite eye carefully covered. Patients who present without their prescribed corrective lenses are evaluated by having them view the chart through a pinhole eye cover, which improves most refractive errors in vision.

If the patient cannot distinguish letters or shapes on a chart, visual acuity must be determined qualitatively. Any printed material suffices. The result may be recorded as, for example, "patient able to read newsprint at 3 feet." If this is not possible, visual acuity is recorded as:

- Unable/able to count fingers (CF)
- Unable/able to perceive hand motion (HM)
- Unable/able to perceive light (LP)

Visual Field Testing

Confrontation is the most common method of testing visual fields in the ED, but it is unreliable for detecting anything short of an extensive field deficit. Thus, visual field examination rarely adds useful information in the evaluation of the acutely red and painful eye. Detection of a scotoma usually represents a retinal problem. However, glaucoma may cause scotomata that can be crescent-shaped, involve just the binasal visual fields, or affect all peripheral vision. Hemi- or quadrantanopia is more commonly a problem of the neural pathways to the brain.

External Examination

Gross abnormalities are assessed by a visual inspection of both eyes simultaneously. Findings are more apparent if compared with the opposite side.

Globe position is part of the external examination. Subtle exophthalmos and enophthalmos are rare and best detected by looking inferiorly, tangentially across the forehead, from over the patient's scalp. Exophthalmos may have traumatic or nontraumatic causes but may be due to increased pressure or a space-occupying lesion within the orbit, which may manifest as pain. Medical causes of exophthalmos include orbital cellulitis and intraorbital or lacrimal tumors. Hyperthyroidism may also cause enlargement of the extraocular muscles and fatty tissue within the orbit leading to exophthalmos. Orbital emphysema and inflammation caused by a retained foreign body behind the eye are other causes of exophthalmos.

The most important cause of exophthalmos in the ED is orbital compartment syndrome, which pushes the globe forward, stretching the optic nerve and retinal artery and increasing IOP. The resulting microvascular ischemia is sight-threatening if sufficiently severe and persistent. Other signs of orbital compartment syndrome include limited eye movement and a relative afferent pupillary defect (RAPD) described under ancillary testing. If retrobulbar hemorrhage is the cause, blood often dissects anteriorly to fill the subconjunctival potential spaces.

The discovery of exophthalmos should prompt ocular tonometry measurements to determine the urgency of intervention. Trauma, particularly penetrating globe injury with extrusion of vitreous, can cause the globe to recede into the orbit, but the most common cause of enophthalmos is actually pseudo-enophthalmos, when the contralateral globe is proptotic.

Inspection also involves examination of the upper and lower palpebral sulci for foreign bodies or other abnormalities. The lower sulcus is easily viewed after manual retraction of the lower lid toward the cheek and having the patient gaze upward. The upper sulcus is inspected by pulling its lashes directly forward and looking under the lid with a white light. The lid can then be everted by pressing a cotton-tipped applicator in the external lid crease and folding the lid margin over the applicator.

Conjunctivitis, with conjunctival injection and discharge, is a common diagnosis following evaluation of patients with red and painful eyes. The presence of punctate "follicles" (i.e., hypertrophy of lymphoid tissue in Bruch's glands) along the conjunctival surfaces of one or both lower lids has been touted to be relatively specific for a viral etiology (Fig.18.3). Trachoma, a chronic keratoconjunctivitis caused by *Chlamydia trachomatis,* is one notable nonviral cause of this follicular hypertrophy.

Any discharge present is assessed as serous, mucoid, or purulent. Both viral and bacterial infections can cause mucoid or purulent discharge, so it is not possible to clinically distinguish viral from bacterial conjunctivitis on this basis alone.

A red eye in a neonate or infant is always abnormal. It is usually caused by corneal abrasion or infection. Corneal abrasions can also be a cause of inconsolable crying in an infant. Fluorescein examination helps to identify traumatic abrasions and herpes keratitis acquired from the birth canal or transmitted from a caregiver's fingers. In the absence of a corneal abrasion, consider chemical conjunctivitis in the first 24 to 36 hours after birth, then consider conjunctivitis caused by *Neisseria gonorrhoeae* (2 to 5 days after birth), *C. trachomatis* (5 to 12 days after birth), and other bacterial or viral causes.[4] Early treatment is required to prevent longterm sequelae.

Extraocular Muscle Function

Limitation of ocular movement in one eye may be detected by having the patient follow the examiner's finger or a bright light through the

Fig. 18.3 Injection of the palpebral and bulbar conjunctiva plus hypertrophy of Bruch's glands in the lower eyelid. (Photograph courtesy Dr. John Wightman.)

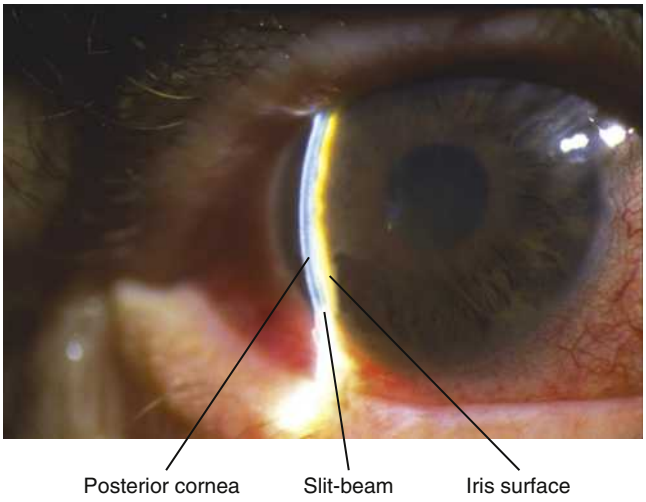

Fig. 18.4 Narrow angle-closure glaucoma with very shallow anterior chamber and iridocorneal touch (no space between slit-beam views of cornea and iris). (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004.)

cardinal movements of gaze. The eyes may move in a disconjugate fashion, or the patient may admit to diplopia if asked. Diplopia on extreme gaze in one direction may indicate entrapment of one of the extraocular muscles within a fracture site, but it is more often caused simply by edema or hemorrhage related to the injury and is functional rather than actual entrapment. In the absence of trauma, diplopia is rarely associated with redness or pain.

Pupillary Evaluation

The pupils are inspected for abnormalities of shape, size, and reactivity. These examinations are conducted with light specifically directed into the pupil and by means of the swinging flashlight test.

Blunt or penetrating trauma, previous surgery (e.g., iridotomy for cataract extraction), and synechiae from prior iritis or other inflammatory conditions are the most common causes of irregularly shaped pupils.

Asymmetrically sized pupils may represent normal or pathologic conditions. Physiological anisocoria is a slight difference in pupil size that occurs in up to 10% of the population. Topical or systemic medications, drugs, and toxins may cause abnormal pupillary constriction or dilation.

Pathologic reasons for failure of one pupil to constrict with a direct light stimulus include globe injury, abnormalities of afferent or efferent nerves, and paralysis of the ciliaris or sphincter pupillae muscles in the iris. Potentially serious problems, which also cause pain and redness, include uveitis and narrow angle glaucoma.

While examining the pupils, the anterior chambers can be visually inspected for hyphema or hypopyon. Blood in the anterior chamber is usually the result of direct ocular trauma and may be associated with traumatic mydriasis or an obvious tear of the iris. If penetration and rupture can be reasonably excluded, the hyphema should be graded and IOP determined. Inability to view posterior structures through the anterior blood may necessitate radiologic or ultrasonographic imaging. Point of care ultrasound is discussed below in the Imaging section.

Pressure Determination

Ocular tonometry is usually the last examination performed in the ED. Common methods of determining the IOP in the ED include use of electronic, manual (e.g., Schiøtz), or applanation tonometers. IOPs in the 10 to 20 mm Hg range are considered normal. Causes of intraocular hypertension include glaucoma in its many forms, suprachoroidal hemorrhage, and space-occupying retrobulbar pathology. Narrow angle glaucoma is a relatively rare but an important critical diagnosis to make in the ED. Patients present with pain, the onset of which is often sudden in low-light conditions causing pupillary dilation through contraction and thickening of the iris peripherally. The iris becomes immobile and often irregular, and the pupil is commonly fixed at 5 to 6 mm in diameter. Inability of the pupil to constrict may result in photophobia, and accommodation may be affected. These reactions and the increased IOP can lead to frontal headache, nausea, and vomiting. As inflammation progresses, limbal injection of the conjunctiva is almost universally seen. Fig. 18.4 demonstrates many of these findings. Patients presenting with IOPs exceeding 20 mm Hg should have ophthalmological consultation. Rapid treatment is usually not necessary unless the pressure exceeds 30 mm Hg.

Ancillary Testing

Physical examination can be augmented by a number of additional tests to assess the relative amount of light reaching the retina or being converted into neural signals, determine the IOP, and visually inspect the anterior and posterior globe with magnification. Imaging of internal anatomy and pathology can be accomplished at the bedside or in the radiology suite.

Swinging Flashlight Test

The swinging flashlight test is used to determine whether an RAPD exists (see https://youtu.be/soiKbngQxgw). An RAPD may be partial or complete and due to inhibition of light transmission to the retina because of vitreous hemorrhage, loss of some or all of the retinal surface for light contact because of ischemia or detachment, or the presence of lesions affecting the pre-chiasmal optic nerve (e.g., optic neuritis).

Slit-Lamp Examination

The slit lamp is used in the ED to examine anterior eye structures. It permits a magnified, binocular view of the conjunctivae and anterior globe for diagnostic purposes and to facilitate delicate procedures. It allows depth perception in otherwise clear structures, such as the cornea, aqueous humor, and lens. Fig. 18.5 shows the typical appearance of an angled slit beam reflecting from and passing through the cornea. Components of the slit-lamp examination are found in Box 18.4.

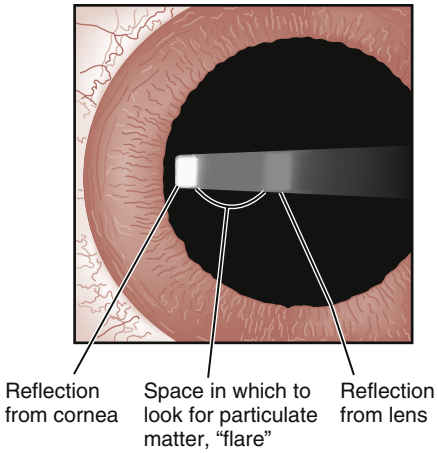

Fig. 18.5 Technique of slit-lamp examination with a short, narrow light beam projected from an extreme temporal angle across the contrasting black pupil to better find cells or "flare" indicative of acute anterior uveitis. (From Ragge NK, Easty DL. *Immediate Eye Care*. St Louis, MO: Mosby-Year Book; 1990.)

BOX 18.4 Slit-Lamp Examination

1. **Lids and lashes** inspected for blepharitis, lid abscess (i.e., hordeolum) and internal or external pointing, and dacryocystitis.
2. **Conjunctiva and sclera** inspected for punctures, lacerations, and inflammatory patterns.
3. **Cornea** (with fluorescein in some cases) evaluated for abrasions, ulcers, edema, foreign bodies, or other abnormalities.
4. **Anterior chamber** evaluated for the presence of cells (e.g., red and white blood cells) and "flare" (diffuse haziness related to cells and proteins suspended in aqueous humor), representing deep inflammation. Hyphema from surgery or trauma, hypopyon, or foreign bodies may also be noted.
5. **Iris** inspected for tears or spiraling muscle fibers noted in acute angle-closure glaucoma.
6. **Lens** examined for position, general clarity, opacities, and foreign bodies.

Fluorescein examination with cobalt blue light from the slit lamp identifies corneal defects. Fluorescein is not taken up by intact corneal epithelium but concentrates in areas where corneal epithelium is breached by an abrasion, foreign body, or ulcer (Fig. 18.6). If the patient cannot sit in front of a slit lamp, a Wood's lamp may be used for magnification and an alternative cobalt blue light source. When corneal perforation is suggested, the Seidel's test can be used to visualize anterior chamber leakage (see https://www.youtube.com/watch?v=GlFcAv0DR4c).

Ulcers can be large and easy to visualize (Fig. 18.7) or small and difficult to detect. They are best identified under slit-lamp examination by noting a denuding of epithelium with surrounding edema. Edema, in the form of increased interstitial water, is seen as whitish clouding of the normally clear tissue in the base of and adjacent to the lesion. This is best identified without fluorescein staining.

Direct Funduscopic Examination

Funduscopy is used to examine posterior eye structures. Emergency clinicians most commonly perform a nondilated funduscopic examination, because there are several eye conditions in which dilation may be harmful (e.g., narrow angle glaucoma). Iridodialysis, lens dislocation, and conditions requiring early intervention are usually identifiable along the visual axis. Inability to obtain a red reflex or visualize the fundus of the eye can be due to the causes listed in Box 18.5.

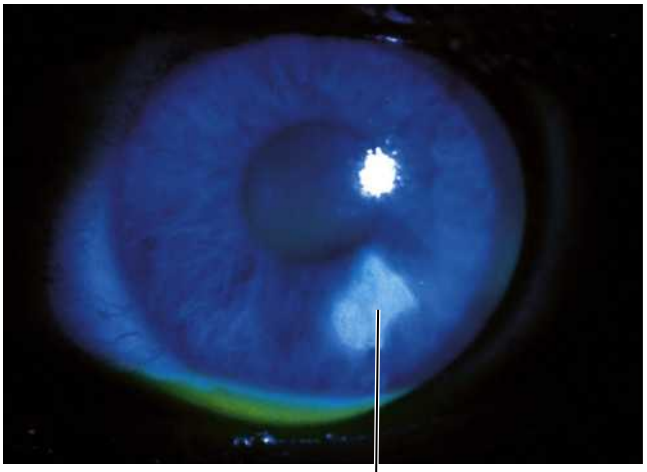

Fig. 18.6 Corneal abrasion demonstrating fluorescein pooling of a small inferior epithelial defect. (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004.)

In the absence of trauma, few posterior findings are associated with chief complaints of external redness. Findings associated with visual loss include pallor of the retina indicating ischemia, "cupping" of the optic disk indicating glaucoma, indistinctness of disk margins indicating papilledema or optic neuritis or neuropathy, air or plaque emboli in retinal arteries, and a host of other signs indicating more chronic ocular or systemic pathology not normally amenable to management in the ED.

Topical Anesthetics

Relief of discomfort after instillation of a topical anesthetic can be used as a diagnostic test for a superficial source of pain. In general, abolition of pain by local anesthetic drops indicates pain of corneal origin. Modest but incomplete relief suggests a conjunctival process. Intraocular pain, including pain associated with uveitis, is not diminished by local anesthetic solution.

Imaging

A penetrating wound that violates the sclera may be immediately obvious. In other cases, the penetration may have occurred elsewhere in the head or neck, then reach the orbit posterior to the orbital septum to injure the globe. In these cases, computed tomography (CT) or plain radiography is used to determine the presence of an intraocular or intraorbital foreign body.

Ultrasonography can be used in the ED when the patient condition precludes movement to the radiology suite, and it can be highly accurate in identifying ocular foreign bodies. In experienced hands, ultrasonography is an excellent bedside modality for evaluating pathology of the globe. Ultrasonography can be used to evaluate abnormalities of the anterior chamber, iris, ciliary body, lens, vitreous, retina, choroid, posterior wall, and optic nerve.

When used in traumatically injured patients, ultrasound can be successfully used to diagnose retinal detachment, lens dislocation, intraocular foreign body, globe rupture, retrobulbar hematoma, and vitreous hemorrhage.[5]

CT is the preferred modality for evaluating orbital trauma. Magnetic resonance imaging (MRI) clearly delineates orbital and retroorbital structures but is less rapidly obtained, with no advantages over

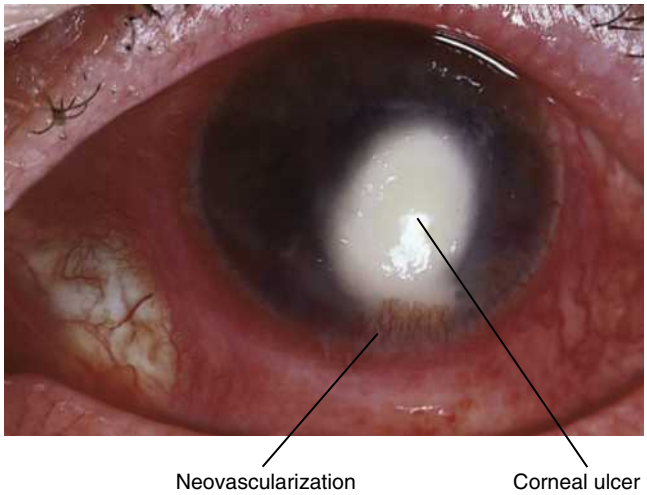

Fig. 18.7 Bacterial keratitis demonstrating a large, central *Streptococcus pneumoniae* corneal ulcer. Note the dense, white corneal infiltrate and the extreme conjunctival injection. (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004.)

BOX 18.5 Causes of Inability to Visualize a Red Reflex or the Otic Fundus

1. Opacification of the cornea, most commonly by edema secondary to injury or infection
2. Hyphema or hypopyon within the anterior chamber
3. Extremely miotic pupil
4. Cataract of the lens
5. Blood in the vitreous or posterior eye wall
6. Retinal detachment
7. Intraocular mass (e.g., retinoblastoma)

CT in trauma. MRI is contraindicated in cases of suspected metallic foreign body, and is reserved for ocular issues felt to be of neurological origin.

Laboratory Testing

Laboratory tests, such as a complete blood count, are generally not necessary in the evaluation of the red and painful eye. One notable exception is the evaluation of temporal arteritis. Temporal arteritis may present with eye pain and decreased visual acuity, but there may be no injection or other physical alteration of the eye. An erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are generally elevated in the acute phase, although one or both may be normal in up to 5% of biopsy-proven cases of temporal arteritis.[6] We recommend obtaining CRP and ESR in cases of suspected temporal arteritis.

Microbiologic cultures are rarely ordered in the ED, but an ophthalmologist may request them in select circumstances.

DIAGNOSTIC ALGORITHM

A recommended algorithmic approach to the patient with an acutely red or painful eye is provided in Fig. 18.8.

Critical Diagnoses

Critical diagnoses require immediate intervention in the ED. Ophthalmological consultation is mandatory but should not delay potentially sight-saving procedures. Critical ophthalmologic diagnoses that do not present with redness or pain are discussed in Chapter 57. Because of its prognostic value, a quick visual acuity should be obtained while the patient is being triaged and subsequently managed.

Caustic injury to the eye can rapidly lead to a destructive keratoconjunctivitis if the agent is not removed immediately (Fig. 18.9). Intervention is initiated on history alone, before any other examination is performed. Early and copious irrigation is indicated. Many patients have already undergone extensive irrigation at the job site, but when the exposure has occurred at home, adequate irrigation prior to arrival in the ED is uncommon. Alkaline caustic agents cause a liquefactive necrosis of the cornea by progressively reacting with the corneal layers, and destruction is severe and relentless. Acid injury causes coagulation necrosis, which tends to limit the depth of injury. Both types require copious irrigation with any clean, relatively neutral fluid (e.g., tap water, normal saline). Continuous irrigation until the pH of the tears is neutral is the only effective method to terminate these chemical reactions. Irrigation should be performed for a minimum of 30 minutes, using 1 to 3 L of irrigation fluid. Ideally, a physiologic buffered irrigation fluid (i.e., lactated Ringers solution) should be used to prevent further corneal edema, increase the rate of neutralization, and improve patient tolerance of the irrigation procedure, but it is more essential to rapidly irrigate the eye than to delay in search of the ideal irrigation fluid.[7] If post-irrigation examination reveals any abnormalities (except expected conjunctival injection) or if a normal pH cannot be reached, an ophthalmologist must evaluate the patient emergently. Orbital compartment syndrome can occur whenever intraorbital pressure increases to the point of causing dysfunction of the optic nerve. IOP can be used as a surrogate measure of intraorbital pressure, but this should only be safely measured when penetrating trauma is not suspected. Retrobulbar hematoma is usually caused by orbital trauma, but it can also occur spontaneously in patients with coagulopathy. Retrobulbar abscess or emphysema can also occur and increase intraorbital pressure. Elevated IOP in any of these conditions implies an orbital compartment syndrome and constitutes a surgical emergency. Intervention in the ED requires decompressing the orbit by performing lateral canthotomy and cantholysis (see https://youtu.be/bUAagMd_Q8A) to relieve the pressure on the optic nerve, and should be performed within 60 to 90 minutes of injury for the best chance of sight recovery.[8] These patients should be examined by an ophthalmologist as soon as possible afterward.

Patients with narrow angle glaucoma (see earlier) require prompt medical intervention to decrease IOP in the ED and urgent ophthalmologic consultation. Follow-up can be decided based on the patient's response to therapy and discussion with the ophthalmologist.

Emergent Diagnoses

Most emergent diagnoses involve inflammation secondary to trauma, infection, or systemic disease. These include keratitis, anterior uveitis, scleritis, and endophthalmitis. Any of these may be complications of surgical procedures, and an appropriate ophthalmological history must be obtained. Consultation with an ophthalmologist is appropriate for all emergent diagnoses.

If penetrating ocular trauma is suspected, a CT scan of the orbits should be obtained. If penetrating ocular trauma is confirmed, or if the possibility persists after evaluation, an ophthalmological consultation is indicated. The injured globe should be protected with a rigid eye shield.

Keratitis is treated with topical anesthesia, which provides immediate (but temporary) relief of pain, thus reinforcing the corneal origin of the process and facilitating examination and definitive diagnosis.

Following thorough irrigation, thermal and chemical burns must receive a careful slit-lamp examination for potential full-thickness

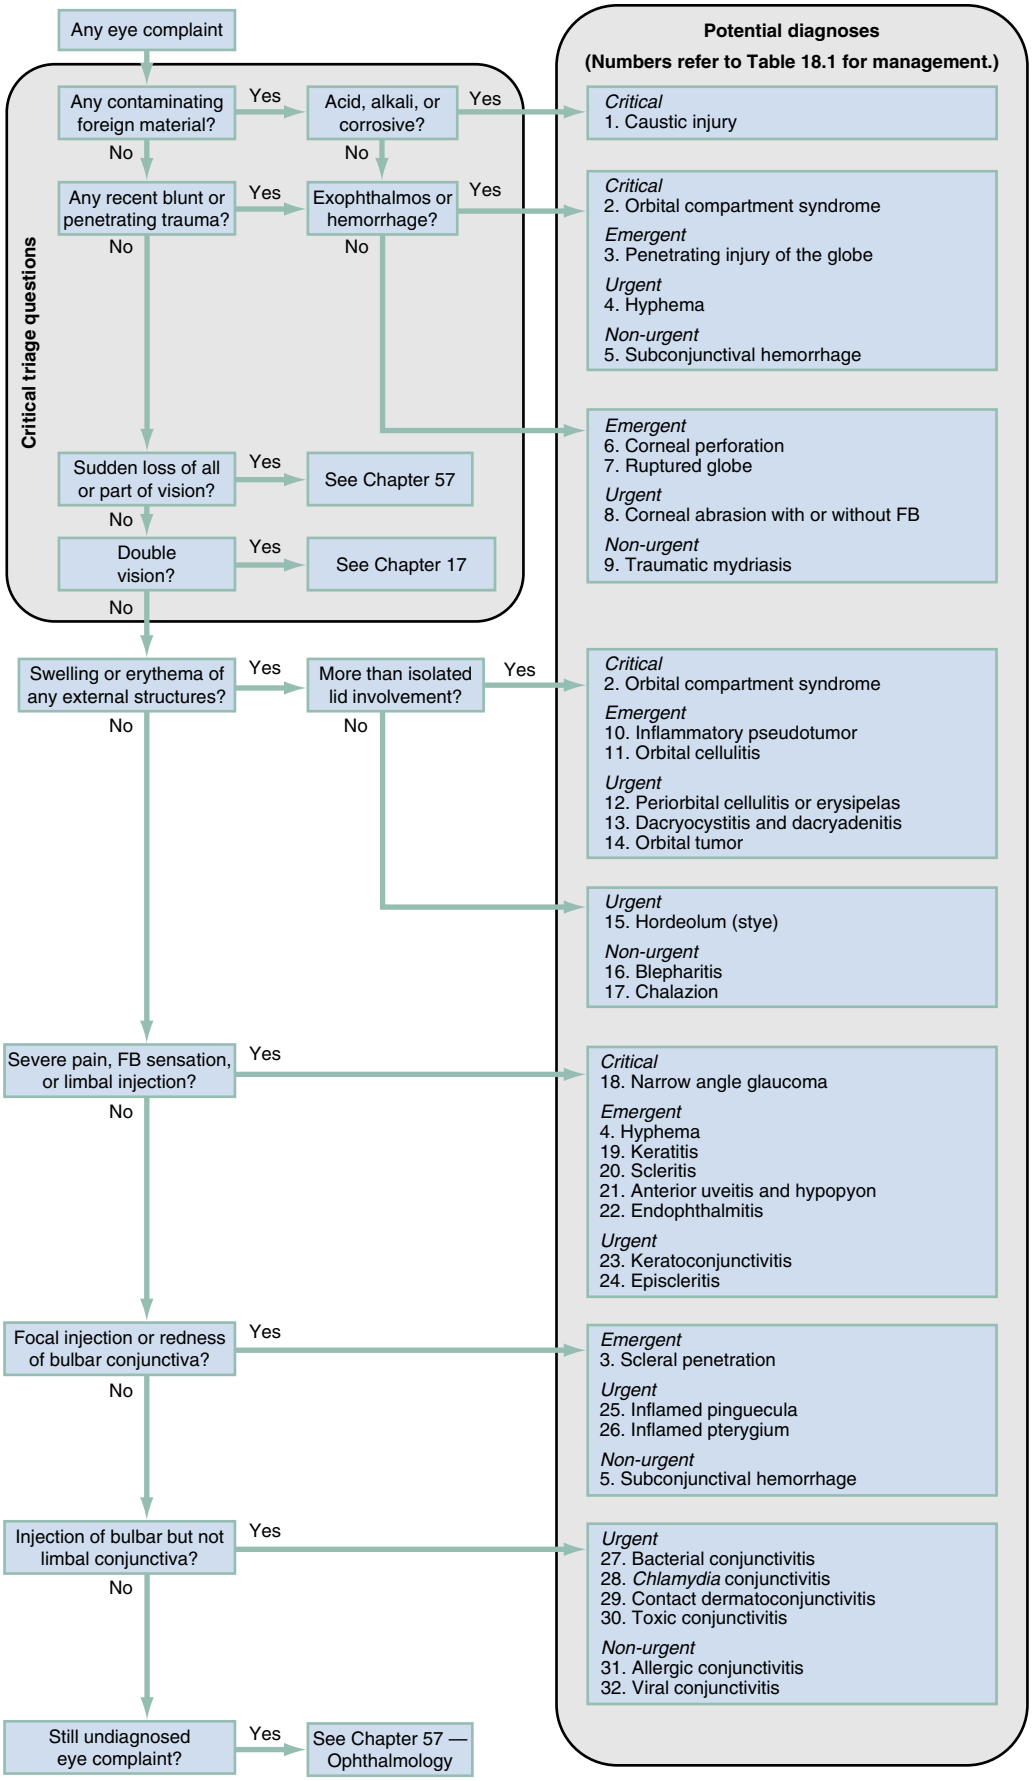

Fig. 18.8 Diagnostic Algorithm for Red and Painful Eyes. Numbers next to diagnoses correspond to Table 18.1 for management of each condition. *FB,* Foreign body.

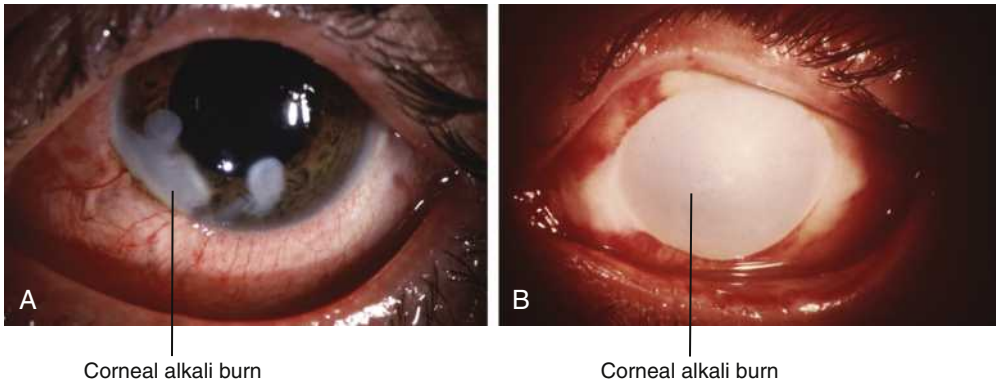

Fig. 18.9 (A) Alkali burn demonstrating corneal burns and conjunctival injection on the day of the accident. (B) Complete corneal tissue destruction 7 days after alkali burn. (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004.)

injury. If this is not found, superficial corneal burns may be treated similarly to abrasions. If full-thickness injury is identified, immediate ophthalmological consultation is indicated.

Corneal ulcerations caused by overuse of contact lenses are treated with prophylactic antibiotics and avoidance of the lenses for at least 72 hours. We recommend follow-up with an ophthalmologist or optometrist before contact lens use is resumed.

Infections of the cornea with herpes simplex virus can rapidly lead to opacification and significant visual loss. It is most commonly recognized by a characteristic dendritic pattern of fluorescein pooling under blue light (Fig. 18.10). Anterior uveitis, which includes iritis and iridocyclitis, often occurs secondary to a traumatic injury or infectious process or can be associated with serious systemic immune diseases, such as adult and juvenile rheumatoid arthritis, sarcoidosis, and ankylosing spondylitis. For these conditions, we recommend urgent ophthalmologic evaluation, either in the ED or by immediate evaluation in an ophthalmological clinic.

Scleritis is commonly idiopathic, but may be associated with a systemic inflammatory process, such as a connective tissue disease, gout, or infection (e.g., rheumatoid arthritis and granulomatosis with polyangiitis, Lyme disease, syphilis, tuberculosis). Scleritis can be divided into anterior scleritis (either diffuse, nodular, or necrotizing) or posterior scleritis and is distinguished from other causes of ocular redness by recognition of inflamed vasculature in the deeper sclera, sometimes appearing violaceous. Posterior scleritis is more difficult to diagnose because some patients do not have anterior signs of inflammation to accompany their history of dull, ocular pain. Diagnosis can be made using point of care ultrasound to visualize thickening of the posterior wall of the globe.[9] Often presenting without pain, episcleritis is a more common, superficial, and benign inflammatory process and less often associated with an underlying systemic infectious or inflammatory disease.

Endophthalmitis usually results from an infection of structures inside the globe. It is most common following penetrating trauma or after intraocular surgical procedures but may begin after hematogenous seeding from a remote or systemic infection, particularly in immunocompromised hosts. Unless it is detected early and is responsive to antimicrobial therapy, endophthalmitis is a devastating process that frequently requires enucleation.

Urgent Diagnoses

Foreign bodies on the cornea or under the lid are removed, as described in Chapter 57.

Fig. 18.10 Fluorescein pooling in the dendritic-shaped lesions of herpes simplex keratitis. (From Kaiser PK, Friedman NJ, Pineda R II. *The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology*. 2nd ed. Philadelphia, PA: WB Saunders; 2004.)

Superficial corneal abrasions, once universally patched, are now known to heal spontaneously without patching, prophylactic antibiotics, or prophylactic tetanus immunization.

Patients with hyphema are placed with the head of the bed elevated to 30 degrees, and they receive systemic analgesia and, if required, antiemetics, with emergent ophthalmologic consultation (see Chapter 57). Medications affecting platelet function should be avoided. If the iris is not injured, a long-acting cycloplegic agent (e.g., topical homatropine) may be recommended to prevent repetitive motion of the iris. After consultation by ophthalmology, outpatient therapy and follow-up are often sufficient for management with simple analgesia (e.g., acetaminophen) for pain. Though outpatient therapy is appropriate for most patients, some will require hospitalization, including patients with large hyphemas (>50%), increased IOP, history of sickle cell trait or disease, history of coagulopathy, or those who may have difficulty adhering to the treatment plan as an outpatient.[10] We recommend a rigid shield to protect the eye during sleep, but this should not be worn during the day. The patient should see the ophthalmologist or return to the ED if the patient experiences an increase in pain or decrease in visual acuity.

EMPIRIC MANAGEMENT

Management of the specific entities listed in the diagnostic algorithm presented in Fig. 18.8 is presented in Table 18.1. Specific management of ophthalmologic conditions is also discussed in Chapter 57.

Critical and emergent conditions are treated as described earlier. All other ocular emergencies are generally diagnosable in the ED, and treatment is initiated based on the diagnosis. Caustic exposures receive copious irrigation, but all chemical or liquid exposures should undergo irrigation unless 1 hour has passed since exposure and the patient is completely asymptomatic at the time of evaluation.

Foreign bodies should be removed, along with all fine particulate matter. Irrigation is advisable after foreign body removal if there is suspicion of remaining, very fine, foreign substance. After irrigation,

TABLE 18.1 Management Algorithm for Red Eyes Extended From Diagnostic Algorithm in Fig. 18.8[a]

Potential Diagnosis	Key Findings	Management	Consultation	Disposition
1. Caustic injury		Immediate and copious irrigation with tap water or sterile normal saline until tear-film pH = 7. Solids: Lift particles out with dry swab before irrigation Acids: Minimum of 2 L and 20 min Alkalis: Minimum of 4 L and 40 min	Ophthalmologist must come to ED if there is any abnormal visual acuity or objective finding on examination after sufficient irrigation, with exception of expected injection of conjunctiva secondary to treatment.	Discharge only if tear film pH = 7 and no abnormal findings on examination except conjunctival injection; then ophthalmologist can reevaluate next day.
2. Orbital compartment syndrome	Exophthalmos (proptosis), decreased visual acuity, painful or limited ocular mobility, and increased IOP	Measure IOP, unless the possibility of a ruptured globe. IOP >30 mm Hg may necessitate lateral canthotomy and cantholysis in ED.	IOP >20 mm Hg may be surgical emergency, may add medications used in glaucoma #18 to decrease IOP before decompression in ED. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses. Consider POCUS	Admit all cases of retrobulbar pathology causing increased IOP. Others might be candidates for discharge depending on the cause of the problem.
Retrobulbar hematoma	Occurs due to trauma, coagulopathy, or thrombocytopenia and associated with possible dissection of blood to potential space under bulbar conjunctiva	Correct any coagulopathy or thrombocytopenia. Consider performing lateral canthotomy and cantholysis in the ED.		
Retrobulbar emphysema	Occurs with forceful sneeze or occasionally happens spontaneously and associated with possible dissection of air to potential space under bulbar conjunctiva	Antibiotic prophylaxis to cover sinus flora.		
Retrobulbar abscess	Occurs with contiguous or occasionally hematogenously disseminated infection and associated with possible dissection of pus to potential space under bulbar conjunctiva	Antibiotics as in orbital cellulitis (see #11).		
3. Penetrating injury of the globe	Localized redness at site of entry plus possible teardrop pupil, blood in anterior chamber or loss of red reflex	Protect the eye from further pressure, provide pain relief, and prevent vomiting. Parenteral antibiotic and tetanus prophylaxis.	Ophthalmologist must come to ED if there is any concern for globe penetration.	Admit for continuation of antibiotics and possible procedural intervention.
4. Hyphema	Pain, decreased visual acuity, gross or microscopic blood in anterior chamber, may be associated with dilated and fixed pupil following blunt trauma Graded by amount of blood: • Percentage of vertical diameter of anterior chamber when blood layers with patient in upright position • Microhyphema shows no layering and only suspended red blood cells	First, rule out open globe. May require POCUS if cannot visualize posterior structures. Measure IOP unless the possibility of a ruptured globe. IOP >30 mm Hg may require acute treatment as in glaucoma (see #18). If IOP >20 mm Hg and no iridodialysis, may use cycloplegic to prevent iris motion.	Discuss findings and use of antifibrinolytics and steroids, other medical therapy, best disposition, and follow-up examination by ophthalmologist within 2 days. Some patients (e.g., those with sickle cell disease/trait, coagulopathy) may be admitted for observation, bed rest, head elevation, and frequent medication administration.	Most patients can be discharged with careful instructions to return for any increased pain or change in vision. Patients should decrease physical activity and sleep with an eye shield in place. Eyes should be left open while awake so that any change in vision can be immediately recognized. PO NSAIDs or narcotics should be given for analgesia.

TABLE 18.1 Management Algorithm for Red Eyes Extended From Diagnostic Algorithm in Fig. 18.8[a]—cont'd

5. Subconjunctival hemorrhage	Red blood beneath clear conjunctival membrane	Exclude coagulopathy or thrombocytopenia, if indicated by history.	None required if no concerns for underlying ocular pathology and no acute complications.	Reassure patient that discoloration should resolve over 2–3 weeks.
6. Corneal perforation	Direct visualization of full-thickness injury or positive Seidel's test	Protect eye from further pressure, provide pain relief, and prevent vomiting. Administer parenteral antibiotic and tetanus prophylaxis.	Ophthalmologist must come to ED to evaluate.	Admit for continuation of antibiotics and procedural intervention.
7. Ruptured globe	Misshapen cornea or globe following trauma	Protect eye from further pressure, provide pain relief, and prevent vomiting. Parenteral antibiotic and tetanus prophylaxis.	Ophthalmologist must come to ED to evaluate.	Admit for continuation of antibiotics and procedural intervention.
8. Corneal abrasion	History of direct trauma or foreign body plus direct visualization of defect in the corneal epithelium using white light, or fluorescein and blue light; any surrounding corneal edema indicates a concomitant keratitis (see #19)	Antibiotic prophylaxis with polymyxin-B/trimethoprim solution 1 drop every 3 h while awake and erythromycin ointment while sleeping. If contact lens wearer, consider fluoroquinolone	Discuss plan for follow-up in 1–3 days.	May discharge if no other findings. No patch.
9. Traumatic mydriasis	Nonreactive dilated pupil without any other identifiable eye abnormalities following blunt trauma	None once other abnormalities of the eye, cranial nerves, and brain have been reasonably excluded.	Discuss plan for follow-up evaluation of slowly developing hyphema and ensure resolution.	May discharge if no other findings.
10. Inflammatory pseudotumor	Nonspecific idiopathic retrobulbar inflammation with eyelid swelling, palpebral injection of conjunctiva, chemosis, proptosis, blurred vision, painful or limited ocular mobility, binocular diplopia, edema of optic disk, or venous engorgement of retina	Measure IOP. Evaluate for infection, diabetes mellitus, and vasculitis with CBC, BMP, UA, and CRP or ESR. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.	IOP >20 mm Hg may be surgical emergency, may add medications used in glaucoma #18 to decrease IOP before decompression in ED.	May discharge if no systemic problems, no findings of particular concern on CT, and IOP ≤20 mm Hg. Start high-dose PO steroids after discussion with ophthalmologist, and ensure reevaluation in 2–3 days.
11. Orbital cellulitis	Eyelid swelling, redness and warmth of skin overlying orbit, tenderness of skin overlying bone; palpebral injection of conjunctiva, and chemosis; differentiated from periorbital cellulitis by presence of any finding of fever, ill appearance, blurred vision, proptosis, painful or limited ocular mobility, binocular diplopia, edema of optic disk, or venous engorgement of retina	Measure IOP and rule out orbital compartment syndrome. Start parenteral antibiotics targeted at suspected infection source with vancomycin, ceftriaxone/cefotaxime and metronidazole (if need to cover anaerobes)	IOP >20 mm Hg may be surgical emergency, may add medications used in glaucoma #18 to decrease IOP before decompression in ED. Obtain blood cultures and start antibiotics. Axial and coronal CT of orbits and sinuses to rule out FB, retrobulbar abscess, orbital gas, subperiosteal abscess, osteomyelitis, and changes in cavernous sinus. Consider LP.	Admit all cases of orbital cellulitis.
12. Periorbital cellulitis or erysipelas	Eyelid swelling, redness and warmth of skin overlying orbit, tenderness of skin overlying bone, palpebral injection of conjunctiva, and chemosis; differentiated from orbital cellulitis by absence of any other finding listed in #11	First rule out orbital cellulitis (see #11). PO antibiotics for sinus and skin flora if not admitting.	Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient.	May discharge mild cases with PO antibiotics. Ophthalmologist must reevaluate next day to ensure no orbital extension.

Continued

TABLE 18.1 Management Algorithm for Red Eyes Extended From Diagnostic Algorithm in Fig. 18.8[a]—cont'd

13. Dacryocystitis and dacryoadenitis	Eye tearing and inflammation of lower eyelid inferior to lacrimal punctum finding redness and tenderness over nasal aspect of lower lid and adjacent periorbital skin	First rule out orbital cellulitis (see #11) and periorbital cellulitis (see #12). Inspect for obstruction of punctum by SLE, may express pus by pressing on sac, PO antibiotics for nasal and skin flora if not admitting.	Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient. Ask about culturing before prescribing medications if admitting, and then may add medications used in glaucoma #18 to decrease IOP before decompression.	May discharge mild cases with PO analgesics and antibiotics (e.g., amoxicillin/clavulanate), and instructions to apply warm compresses to eyelids for 15 min and gently massage inner canthal area four times a day.
14. Orbital tumor	Blurred vision, proptosis or other displacement of globe, painful or limited ocular mobility, or binocular diplopia (but can be asymptomatic)	Measure IOP. Evaluate for extraocular signs of malignancy. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.	IOP >20 mm Hg may be surgical emergency, prescribe to decrease IOP in ED. Ophthalmologist may want MRI, MRA, or orbital ultrasonography.	Based on findings and discussion with consultant.
15. Hordeolum (stye)	Abscess in eyelash follicle or modified sebaceous gland at lid margin: external or internal based on side of lid margin that abscess is pointing	External: Warm compresses often all that is needed, may prescribe anti-*Staphylococcus* ointment twice daily. Internal: PO antibiotics for β-lactamase–positive *Staphylococcus* such as amoxicillin/clavulanate	Outpatient referral only for treatment failure after 2 weeks.	Discharge with instructions to apply warm compresses to eyelids for 15 min and gently massage abscess four times a day.
16. Blepharitis	Inflammation of eyelid margins often associated with crusts on awakening, FB sensation, and tearing	Artificial tears, as needed for dry eye.	Outpatient referral only for treatment failure after 2 weeks.	Discharge with instructions to apply warm compresses to eyelids for 15 min four times a day and scrub lid margins and lashes with mild shampoo on washcloth twice daily.
17. Chalazion	Inflammation of meibomian gland causing subcutaneous nodule within the eyelid	None.	Outpatient referral only for treatment failure after 2 weeks.	Discharge with instructions to apply warm compresses to eyelids for 15 min and gently massage nodule four times a day.
18. Narrow angle glaucoma	Sudden-onset eye pain and blurred vision that may be associated with frontal headache, nausea, and vomiting; anterior eye may manifest shallow or closed angle between iris and cornea, pupil fixed at midsize, or limbal injection of conjunctiva	Administer medications below in ED if IOP >30 mm Hg Decrease production of aqueous humor: • Timolol 0.5% 1 drop • Apraclonidine 1% 1 drop • Dorzolamide 2% 1 drops or if sickle cell disease or trait, then methazolamide 50 mg PO Decrease inflammation: • Prednisolone 1% 1 drop every 15 min four times Constrict pupil: • Pilocarpine 1%–2% 1 drop after IOP <50, then repeat in 15 min Consider establishing osmotic gradient: • Mannitol 2 g/kg IV	Discuss any IOP >20 mm Hg with ophthalmologist.	Based on findings and discussion with consultant, which primarily depends on speed of onset and response to treatment.

TABLE 18.1 Management Algorithm for Red Eyes Extended From Diagnostic Algorithm in Fig. 18.8[a]—cont'd

19. Keratitis (abrasion or UV injury)	Pain, FB sensation, blepharospasm, tearing, photophobia, epithelial disruption on inspection under white light, or fluorescein pooling under blue light; SPK appears as stippling of corneal surface (often lower two-thirds of cornea if due to light exposure); if neglected for a time, may have surrounding edema appearing as white "cloudiness" in clear tissue	First, rule out corneal penetration employing Seidel's test. Relieve pain and blepharospasm with topical anesthetic. Inspect all conjunctival recesses and superficial cornea for any foreign material that can be removed by irrigation or manually lifted from surface.	Ophthalmologist must come to ED if there is any concern for globe penetration. Otherwise consult for follow-up examination in 1–2 days.	May discharge cases not infected or ulcerated. May provide topical antibiotic prophylaxis using polymyxin B combinations with bacitracin (ointment) or trimethoprim (solution). Erythromycin, gentamicin, and sulfacetamide are less desirable single-agent alternatives. PO NSAIDs or narcotics for analgesia. No patch.
Keratitis (ulceration)	Symptoms and signs as described previously; ulceration from complications of contact wear has "scooped out" epithelium with surrounding edema appearing as white "cloudiness" in clear tissue	Relieve pain and blepharospasm with topical anesthetic. *Staphylococcus* and *Streptococcus* species still most common organisms, but *Pseudomonas* greater percentage in existing infections (especially contact lens wearer), so prescription with topical fluoroquinolone is preferred.	Discuss with ophthalmologist any potential need to débride or culture before starting antibiotic.	Based on findings and discussion with consultant. Typically prescribe fluoroquinolone. For large ulcerations or ulcers near the visual axis, a fortified antibiotic, such as tobramycin, may be added.
Keratitis (herpetic infection):	Symptoms and signs as described previously Look for other signs of herpes, varicella, zoster (or CMV infection in immunocompromised patient) Look for "dendritic" defects of cornea with fluorescein under blue light	Relieve pain and blepharospasm with topical anesthetic. Prescribe acyclovir 5% ointment or trifluridine 1% solution Varicella-zoster and CMV not normally given antivirals if immunocompetent.	Discuss with ophthalmologist any potential need to débride or culture before starting antiviral.	Based on findings and discussion with consultant. Typical acyclovir dosing is five times a day for 7 days, then taper over 2 more weeks. Typical trifluridine dosing is 1 drop every 2 h for 7 days, then taper over 2 more weeks. PO NSAIDs or narcotics for analgesia. No patch.
20. Scleritis	Progressively increasing eye pain with radiation to ipsilateral face and decreasing vision, photophobia, tearing, and possible pain with eye motion	Decrease inflammation with PO NSAIDs.	Discuss findings and use of topical or PO steroids.	May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.
21. Anterior uveitis and hypopyon	Eye pain, photophobia, tearing, limbal injection of conjunctiva, and cells or flare in anterior chamber; hypopyon is layering of white cells (pus) in anterior chamber	First, rule out glaucoma with IOP measurement. Prescribe in ED if IOP >20 mm Hg. Otherwise okay to dilate pupil with 2 drops of cyclopentolate 1%.	Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist but range is every 1–6 h).	May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days. Patients with hypopyon are generally admitted.
22. Endophthalmitis	Progressively increasing eye pain and decreasing vision, diminished red reflex, cells and flare (and possibly hypopyon) in anterior chamber, chemosis, and eyelid swelling	Empirical parenteral antibiotic administration with vancomycin and ceftazidime to cover *Bacillus, enterococcus*, and *Staphylococcus* spp. Ciprofloxacin or levofloxacin are used when others contraindicated.	Ophthalmologist must admit for parenteral and possibly intravitreal antibiotics.	Admit all cases of endophthalmitis.

Continued

TABLE 18.1 Management Algorithm for Red Eyes Extended From Diagnostic Algorithm in Fig. 18.8[a]—cont'd

23. Keratoconjunctivitis	Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported	Treat for conjunctivitis by likely etiologic category (see #25 to #30).	Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).	May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.
24. Episcleritis	Rapid onset of localized pain, injection of episcleral vessels, and localized tenderness	Relieve irritation with artificial tears.	Outpatient referral only for treatment failure after 2 weeks.	Discharge patient with PO NSAIDs
25. Inflamed pinguecula	Inflammation of soft yellow patches in temporal and nasal edges of limbal margin	Decrease inflammation with naphazoline or ketorolac drops.	Outpatient referral only for treatment failure after 2 weeks.	Discharge to follow-up with ophthalmologist for possible steroid therapy or surgical removal.
26. Inflamed pterygium	Inflammation of firmer white nodules extending from limbal conjunctiva onto cornea			
27. Bacterial conjunctivitis	Hyperpurulent discharge not typical of common "pink eye" and more commonly unilateral in adults; inflammation of eyelid margins associated with lid edema, chemosis, and possibly subconjunctival hemorrhage, but usually little or no follicular "cobblestoning"	Topical polymyxin-B/trimethoprim in infants and children, because more *Staphylococcus* spp. Topical sulfacetamide or gentamicin clinically effective in 90% of uncomplicated adult cases. Use topical fluoroquinolone if Pseudomonas possible.	Culture drainage and ophthalmology consult in all neonates and those at risk for vision loss or systemic sepsis. *Neisseria gonorrhoeae* can be rapidly sight threatening.	Discharge uncomplicated cases with 10 days of topical antibiotics in both eyes, regardless of laterality of apparent infection. Use ointments in infants and drops in others.
28. Chlamydia conjunctivitis	Often bilateral palpebral injection of conjunctiva in neonate or other individual at risk for sexually transmitted disease	Empirical PO azithromycin for Chlamydia. Consider empirical parenteral ceftriaxone for concurrent *N. gonorrhoeae*.	Culture drainage and consult ophthalmology in all neonates and those at risk for vision loss or systemic sepsis.	Discharge uncomplicated cases on 3 days of PO azithromycin.
29. Contact dermatoconjunctivitis	Localized lid and conjunctival redness and swelling	Irrigation with tap water or sterile normal saline. Decrease irritation with naphazoline drops.	Outpatient referral only for severe cases or treatment failure after 2 weeks.	Identify offending agent and avoid subsequent exposure. Discharge uncomplicated cases on continued naphazoline.
30. Toxic conjunctivitis	Diffuse conjunctival injection, chemosis, and lid edema	Irrigation with tap water or sterile normal saline. Decrease irritation with naphazoline drops.	Outpatient referral only for severe cases or treatment failure after 2 weeks.	Identify offending agent and avoid subsequent exposure. Discharge uncomplicated cases on continued naphazoline.
31. Allergic conjunctivitis	Often bilateral palpebral injection of conjunctiva and chemosis that may be seasonal and associated with other allergic symptoms, such as rhinitis	Decrease irritation with naphazoline drops or consider ophthalmic antihistamine	Outpatient referral only for treatment failure after 2 weeks.	Identify antigen if possible. Consider treating other allergic symptoms with PO antihistamines.
32. Viral conjunctivitis	Often bilateral palpebral injection of conjunctiva and follicular cobblestoning of inner surface of lower lid; inflammation of eyelid margins often associated with crusts on awakening, FB sensation, and tearing	Decrease irritation with artificial tears, naphazoline, or ketorolac drops.	Culture drainage, and consult ophthalmology in all neonates and those at risk for vision loss or systemic sepsis.	Ask about pregnant mothers, infants, and immunocompromised individuals in close contact. Discharge uncomplicated cases with instructions on respiratory and direct-contact contagion for 2 weeks.

BMP, Basic metabolic profile (includes electrolytes, glucose, and renal function tests); *CBC*, complete blood count; *CMV*, cytomegalovirus; *CRP*, C-reactive protein; *CT*, computed tomography; *ED*, emergency department; *ESR*, erythrocyte sedimentation rate; *FB*, foreign body; *IOP*, intraocular pressure; *IV*, intravenous; *LP*, lumbar puncture; *MRA*, magnetic resonance angiography; *MRI*, magnetic resonance imaging; *NSAID*, nonsteroidal antiinflammatory drug; *PO*, per os (by mouth); *POCUS*, point of care ultrasound; *SLE*, slit-lamp examination; *SPK*, superficial punctate keratitis; *spp.*, species; *UA*; urinalysis; *UV*, ultraviolet.

[a]Antibiotic choices should be based on current practice.

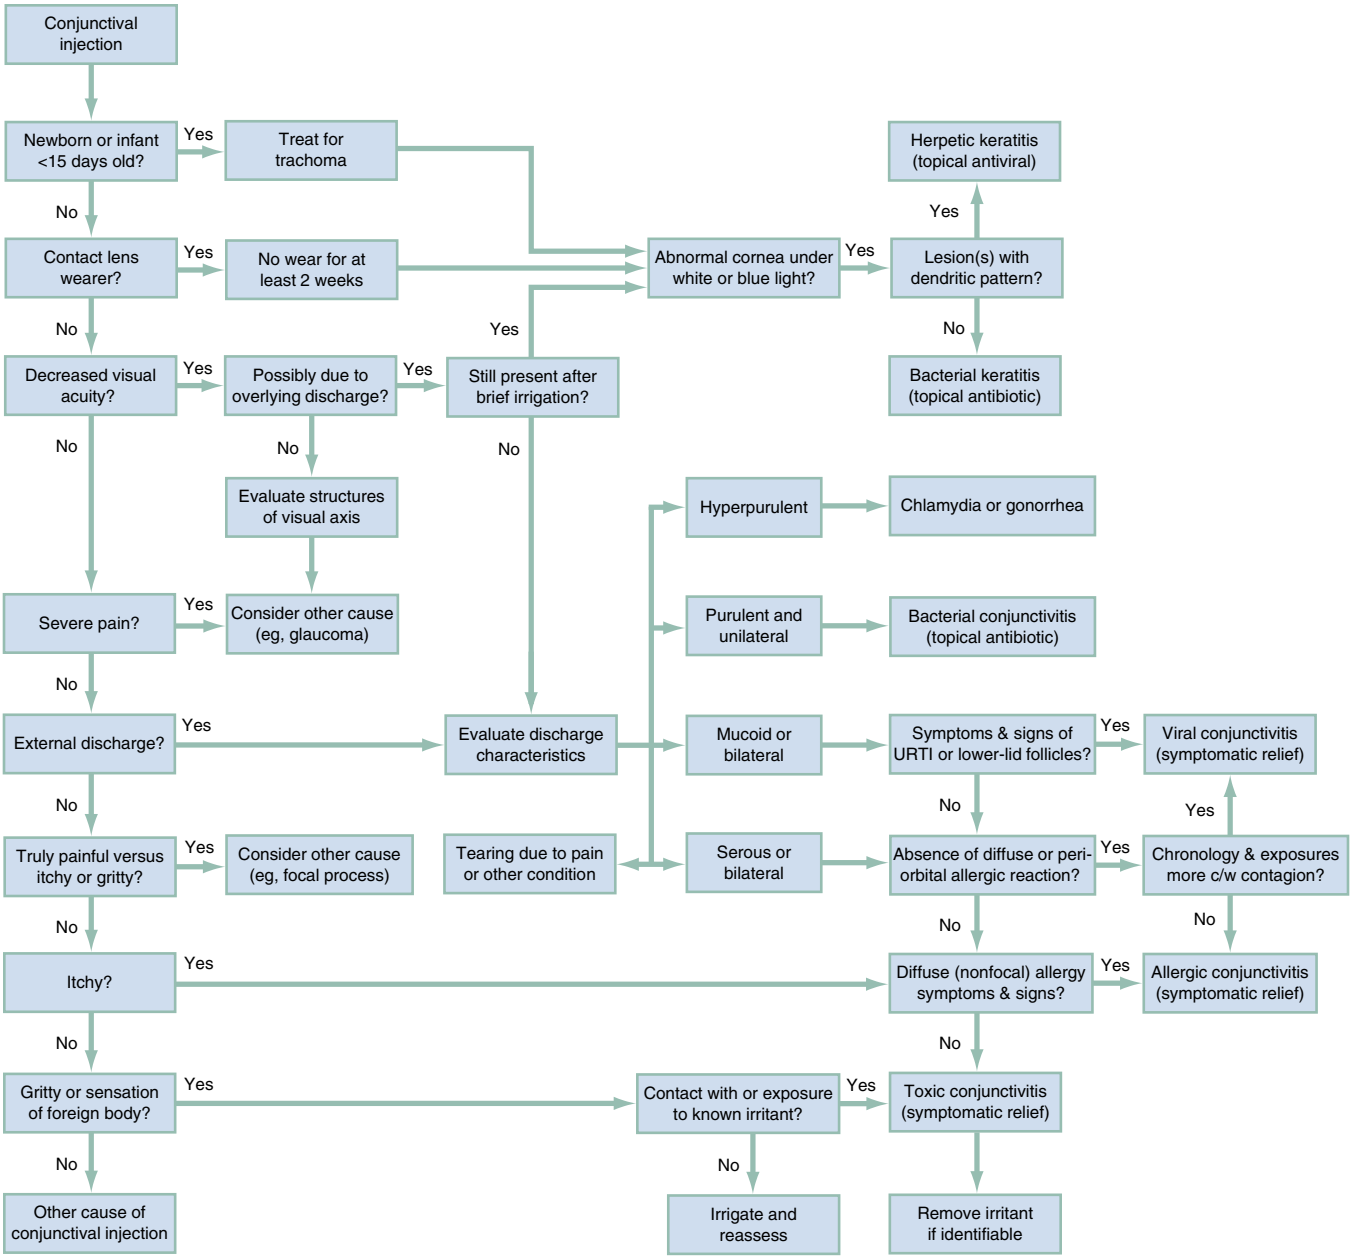

Fig. 18.11 Diagnostic Algorithm for Suspected Acute conjunctivitis. *c/w,* Consistent with; *URTI,* upper respiratory tract infection.

re-examine the eye to evaluate for iatrogenic injuries. Conjunctival injection is common, but symptoms are expected to be mild. Patching is not indicated. Topical nonsteroidal antiinflammatory analgesic solutions might play a role in decreasing pain, but studies do not provide strong evidence for their utility.[11] Topical anesthetics should be given sparingly and only to patients with simple corneal abrasions.[12] While studies performed in the ED show lack of poor outcome when limited to the appropriate use of topical anesthetics in simple corneal abrasions, there is not yet enough data to encourage home use of topical anesthetics as routine practice.[13] This practice is discouraged by many ophthalmologists. Since controversy remains about prescribing topical anesthetics for home use, we do not recommend this practice unless the topical anesthetics are prescribed in conjunction with ophthalmologic consultation.[14]

An algorithm for the treatment of acute conjunctivitis is presented in Fig. 18.11. We do not recommend topical antimicrobial or corticosteroid treatment for conjunctivitis or keratoconjunctivitis. This is an area in which antibiotic misuse is widespread. There is no good medical evidence to support the requirements of most daycare and school facilities to mandate antibiotic treatment for acute conjunctivitis before returning to activities with other children. First, some causes of "pink eye" are not infectious. Second, in patients enrolled in clinical trials for acute infectious conjunctivitis, bacteria continue to be cultured many days after treatment is started, and viruses continue to be shed for 2 weeks or more, with or without antibiotics. Unless a patient with conjunctivitis might potentially expose an immunocompromised individual, there is no medical reason not to return to daycare or school with or without treatment. If bacterial,

only direct eye-to-hand-to-eye exposure will result in transmission. If viral, others have likely already been exposed. In immunocompetent patients, bacterial conjunctivitis is likely to be self-limited and does not require antibiotic therapy.[3] Topical corticosteroids should be avoided because they can prolong viral infection.[15] Because many schools and daycares mandate antibiotic treatment of conjunctivitis before children are allowed to return to school, in practice, antibiotics are frequently prescribed contrary to antibiotic stewardship best practices.

Topical acyclovir, 5% ointment, is indicated for herpes keratitis, in conjunction with ophthalmologic or infectious disease consultation. Azithromycin is indicated for trachoma, again with consultation.

Topical antimicrobial prophylaxis is similarly not indicated for superficial epithelial defects of the cornea, although this also is common practice despite an absence of supporting evidence. There is also no evidence supporting the practice of administering tetanus immunization to patients with superficial corneal abrasions, other than as a general public health measure. However, true open wounds of the adnexa or globe do require tetanus prophylaxis if the patient's immunization status is not up to date.

Mydriatic and cycloplegic agents are also commonly prescribed but rarely are indicated. Mydriatic agents are contraindicated in patients with narrow-angle glaucoma. Larger corneal lesions sometimes require a cycloplegic agent for pain relief, but this should be prescribed only for the few patients experiencing refractory iris spasm and not prophylactically. Treatment of bacterial keratitis and endophthalmitis is described in Chapter 57.

Most ED patients with eye complaints are candidates for discharge and, if indicated, follow-up in the ED or with an ophthalmologist in 1 to 2 days. Others may require referral only if there is lack of resolution or treatment fails. A few patients require admission for procedural intervention, parenteral antibiotic regimens, management of intractable pain, or further diagnostic evaluation. General consultation and disposition considerations for the most important entities are outlined in Table 18.1.

The opinions and assertions expressed herein are those of the author(s) and do not necessarily reflect the official policy or position of the Uniformed Services University or the Department of Defense.

CHAPTER 18: QUESTIONS AND ANSWERS

1. A patient who normally wears contact lenses is diagnosed with bacterial conjunctivitis. Which of the following is the preferred treatment in this patient?
   a. Bacitracin
   b. Chloramphenicol
   c. Erythromycin
   d. Moxifloxacin

Answer: d. Patients who wear contact lenses are at increased risk for infections with *Pseudomonas* and, in the setting of bacterial conjunctivitis, should be prescribed a quinolone, barring any contraindications.

2. A 15-year-old boy presents to the emergency department (ED) after having been shot in the face with a BB gun. He has a solitary penetrating wound just inferior to his left eye. His visual acuity in the left eye is limited to light perception, but he reports having normal vision prior to the injury. He has significant proptosis of his left eye, and his fundus is clearly seen with direct ophthalmoscopy. Intraocular pressure (IOP) of the affected eye is 50 mm Hg. His mental status is normal. What is the most appropriate next step in the management of this patient?
   a. CT scan of the head and face
   b. ED observation with repeated neurologic examinations
   c. Lateral canthotomy and inferior cantholysis
   d. Plain radiography of the face

Answer: c. The described patient likely has a retrobulbar hematoma with visual acuity changes and an elevated IOP. The elevated IOP with a clear fundoscopy are findings consistent with no penetration into the globe. Although CT scan of the head and face is indicated to further delineate specific injuries, lateral canthotomy and inferior cantholysis is emergently necessary for orbital decompression in an attempt to salvage vision. This sight-saving procedure should not be delayed more than 90 minutes after injury when severe findings (decreased visual acuity and significantly increased IOP) are present. Ophthalmology consultation would be indicated emergently.

3. A collection of pus in the anterior chamber of the eye is known as which of the following?
   a. Cotton wool spot
   b. Dacryocystitis
   c. Hyphema
   d. Hypopyon

Answer: c. A collection of layered pus in the dependent portion of the anterior chamber is called a hypopyon.

4. Which of the following results from inflammation of a meibomian gland?
   a. Blepharitis
   b. Chalazion
   c. Dacryocystitis
   d. Hordeolum

Answer: b. Inflammation of a meibomian gland with the subsequent formation of a subcutaneous nodule within the eyelid is known as a chalazion. This condition typically resolves spontaneously over several days. Authorities often recommend warm compress application and gentle massage of the nodule several times a day, although there is no evidence supporting this. If complete resolution does not occur within 2 weeks, the patient should be referred to an ophthalmologist.

5. A neonate presents 7 days after birth with a unilateral red eye. Further examination reveals inflamed conjunctiva, purulent discharge and negative uptake on fluorescein examination. The child was born full term after a pregnancy complicated by poor prenatal care. Which of the following diagnoses is most likely in this patient?
   a. Chemical conjunctivitis
   b. *Chlamydia trachomatis*
   c. Corneal abrasion
   d. *Neisseria gonorrhoeae*

Answer: b. Neonates are at high risk for serious ophthalmologic diseases. Typically, they present with chemical conjunctivitis from antibacterial prophylaxis (i.e., erythromycin ointment) at birth within 2 days. Gonococcal conjunctivitis is seen 2 to 5 days after birth. Chlamydial conjunctivitis is seen 5 to 12 days after birth. Corneal abrasions, while common in this age group, will most likely be evident on fluorescein examination of the cornea.

19

Sore Throat

Elizabeth P.D. Pontius and Kevin C. Reed

KEY CONCEPTS

- Sore throat can indicate a range of pathology, from simple pharyngitis to deep space infection, with or without airway compromise.
- Physical examination, supplemented by nasopharyngoscopy when appropriate, is key to determining threats to the airway and establishing a diagnosis.
- If oropharyngeal examination reveals minimal findings, lower or deeper structures may be involved, and endoscopic examination of the upper airway is recommended.
- The modified Centor criteria can help identify adult patients with a higher likelihood of Group A Streptococcus (GAS) infection. Patients with a score of –1 to 1 are unlikely to have GAS infection (10% to 15% likelihood, 95% confidence interval 5% to 25%), while a score of 4 or 5 corresponds to a 40% to 50% likelihood of GAS infection (95% confidence interval 31% to 51%).
- Viral pharyngitis, the most common cause of pharyngitis, is self-limiting and antibiotics are more harmful than helpful in its management.
- For GAS-positive pharyngitis, a single injection of penicillin or a 10-day course of oral penicillin may decrease the duration of symptoms, transmission to close contacts, and prevent rare suppurative and nonsuppurative complications.

FOUNDATIONS

Epidemiology

Patients of all ages present to the emergency department (ED) and outpatient settings with sore throat and throat-related complaints. While the vast majority of simple pharyngitis is caused by viruses, approximately 15% have an alternate cause.[1] Certain pathogens affect children and adolescents more commonly than infants or older adults. For example, Group A Streptococcus primarily affects those between the ages of 5 and 15 years and is rarely seen in children under the age of 3 years.[2]

Pathophysiology

Sore throat, or pharyngitis, results from inflammation of the soft tissue of the pharynx. The pharynx has three distinct regions: the nasopharynx, oropharynx, and hypopharynx (Fig. 19.1). Though these regions are distinct, they are contiguous, and inflammation can affect more than one region. Inflammation in any region can cause a sore throat. The nasopharynx includes the area superior to the oral cavity from the base of the skull to the soft palate and includes the opening of the eustachian tubes. The oropharynx is the area immediately visible when a patient opens their mouth, behind the oral cavity. Its borders are the uvula superiorly, the hyoid inferiorly, and the tonsillar pillars laterally. The oropharynx includes the vallecula and epiglottis. The hypopharynx lies inferior to the epiglottis and terminates at the vocal cords. When viewing a patient, the hypopharynx is posterior and slightly superior to the thyroid cartilage. The retropharyngeal and submandibular spaces surround the pharynx, and disease in these areas may cause pain and possible airway compromise.

Pharyngitis and *tonsillitis* are often used interchangeably; however, they are two distinct processes, with pharyngitis affecting the pharyngeal tissues, and tonsillitis affecting the tonsillar tissues. The pharyngeal tonsillar ring is composed of distinct areas of lymph tissue located throughout the pharynx, including the pharyngeal (adenoid), tubal, palatine, and lingual tonsils. The palatine tonsils are located on either side of the oropharynx, and infection here, whether viral or bacterial, can trigger inflammation which can also cause a sore throat. Cranial nerves IX and X supply sensory innervation to the region.

Sore throat with associated dysphagia and odynophagia may also result from mass lesions. These patients can present with hoarseness, weight loss, and lymphadenopathy. Inflammatory or mechanical complications from other neck structures, such as thyroiditis or an aortic ring, can also present with sore throat. Patients with referred throat pain from acute coronary syndrome may also have chest pain, diaphoresis, dizziness, or shortness of breath.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis of a sore throat is quite broad (Box 19.1). Three major categories to consider as the cause of a sore throat are infectious, noninfectious (neoplastic, inflammatory, traumatic), and referred pain from the chest, such as acute coronary syndrome, pericarditis, and myocarditis.

Pivotal Findings

Symptoms and Signs

The first priority is to simultaneously assess the patient's airway and overall appearance. Patients with impending airway compromise can present sitting upright or leaning forward, with neck extension and the jaw thrust forward, and may often appear restless and agitated. The patient may be unable to swallow oral secretions secondary to inflammation in the oropharynx or hypopharynx, leading to drooling. Drooling is indicative of an advanced airway process and should prompt emergent airway evaluation and possible intervention. Patients with a muffled voice should be evaluated for a supraglottic process, including visualization of the floor of the mouth and palpation of the submental region. Induration and tenderness in this region are associated with Ludwig angina, typically the result of odontogenic extension.[3] Inflammation in the glottic or infraglottic structures causing a partial obstruction leads to stridor, a high-pitched inspiratory noise. Unless the patient is a child less than 10 years presenting with suspected croup,

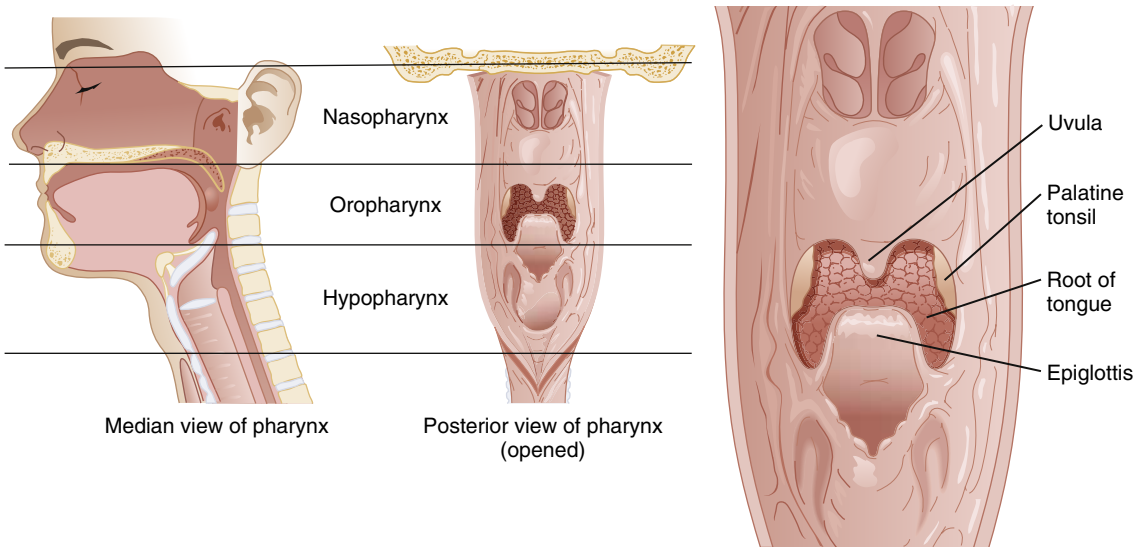

Fig. 19.1 Anatomy of the Nasopharynx, Oropharynx, and Hypopharynx.

BOX 19.1 Differential Diagnosis in Patients Presenting With Sore Throat

Critical
Trauma causing an expanding neck hematoma
Epiglottitis causing airway compromise
Retropharyngeal or parapharyngeal abscess causing airway compromise
Peritonsillar abscess causing airway compromise
Ludwig angina
Angioedema
Croup causing stridor at rest
Lemierre syndrome from septic internal jugular thrombophlebitis
Acute coronary syndrome presenting with referred throat pain

Emergent
Trauma causing a nonexpanding neck hematoma
Mass lesion in the neck causing sore throat (tongue, larynx, thyroid, leukemia)
Epiglottitis, retropharyngeal, parapharyngeal, or peritonsillar abscess not causing airway compromise
Stevens-Johnson syndrome

Urgent
Group A streptococcal pharyngitis
Retained foreign body
Kawasaki disease
Thyroiditis
Laryngeal fracture
Pericarditis or myocarditis presenting with referred throat pain

stridor is a sign of a true airway emergency. Critical conditions such as epiglottitis, retropharyngeal abscess, and angioedema can present with stridor. It is important to determine the severity, rate of onset, and progression of symptoms, as this may guide the urgency of intervention.

While evaluating the patient's overall appearance, emphasis should be placed on the patient's hydration status and signs of systemic toxicity. Pain from even simple uncomplicated pharyngitis may impede a patient's ability to tolerate oral intake, particularly in children, leading to dehydration. Fever and mild tachycardia are common vital sign abnormalities, and do not typically indicate serious pathology.

TABLE 19.1 Modified Centor Criteria (McIsaac Score) and Likelihood of Streptococcal Infection

Criteria (1 Point Each)	# of Criteria Present	GABHS
History of fever (>38°C)	0 or –1	7%
Tonsillar exudates	1	13%
Tender cervical LAD	2	22%
Absence of cough	3	38%
Age 3–14: +1, Age >45: –1	4–5	>50%

GABHS, Group A beta-hemolytic streptococci; *LAD* lymphadenopathy. Data from Nadeau N, Kimia A, Fine AM. Impact of viral symptoms on the performance of the modified Centor score to predict pediatric group A streptococcal pharyngitis. *Am J Emerg Med*. 2019. https://doi.org/10.1016/j.ajem.2019.10.026[published Online First: Epub Date].

It is imperative to visualize the pharyngeal structures. Patients with lingual resistance may require coaching to help minimize the gag reflex, and those with trismus should receive analgesia to allow complete visualization. If examination reveals tonsillar erythema or exudates in a symmetric fashion, without signs of airway compromise, acute tonsillitis is present and generally no further investigation is warranted. Various scoring systems exist to estimate the likelihood of Group A Streptococcal infection (GAS) based on elements of the history and physical exam; the most common of these is the Centor criteria (Table 19.1).[1] The four Centor criteria are a history of fever, tonsillar exudates, tender anterior cervical lymphadenopathy, and absence of a cough; a later modification (the McIsaac score) added a fifth criterion (add one point for age 3 to 14 years, subtract 1 point for age >45 years). Recent studies report the prevalence of GAS as greater than 50% in patients with a score of 4 or higher, 33% with a score of 3, 20% to 30% with a score of 2, 10% to 15% with a score of 1, and 5% to 10% with a score of 0 or −1. This prevalence of GAS at low scores is higher than originally reported by Centor or McIsaac.[4] If ulcerations are visualized, or if rhinorrhea, sneezing, cough, hoarseness or conjunctivitis are present, a viral etiology is more likely.[5] The vast majority of pharyngitis is due to either viral or streptococcal causes, though less common causes such as gonococcal infection and mononucleosis should be considered (Table 19.2).

TABLE 19.2 Differential Diagnosis for Infectious Pharyngitis

	AEROBIC BACTERIA			
Viral	**Common**	**Uncommon**	**Anaerobic Bacteria**	**Fungal**
Rhinovirus	*Streptococcus pyogenes* (GABHS)	*Haemophilus influenzae*	*Bacteroides* spp.	*Candida* spp.
Adenovirus	GABHS	*Haemophilus parainfluenzae*	*Peptococcus* spp.	
Coronavirus	*Coccidioides* spp.	*Corynebacterium diphtheriae*	*Clostridium* spp.	
Herpes simplex virus 1, 2	Non–group A streptococcus	*Streptococcus pneumoniae*	*Fusobacterium* spp.	
Influenza A, B	*Neisseria gonorrhoeae*	*Yersinia enterocolitica*	*Prevotella* spp.	
Parainfluenza	*Neisseria meningitides*	*Treponema pallidum*	*Peptostreptococcus* spp.	
Cytomegalovirus	*Mycoplasma pneumoniae*	*Francisella tularensis*		
Epstein-Barr virus	*Arcanobacterium haemolyticum*	*Legionella pneumophila*		
Varicella-zoster virus	*Chlamydia trachomatis*	*Mycobacterium* spp.		
Hepatitis virus	*Staphylococcus aureus*			

GABHS, Group A beta-hemolytic streptococci.

A prolonged fever of more than 5 to 7 days in children may indicate Kawasaki disease; cervical lymphadenopathy is seen in approximately 50% of patients.[6] Periodic episodes of fevers, aphthous lesions, and cervical lymphadenitis are consistent with periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) syndrome; episodes typically occur every 3 to 6 weeks.[7] Unilateral swelling and contralateral uvular deviation suggest peritonsillar abscess; typically no exudates are present. If the patient has significant symptoms and examination of the oropharynx reveals minimal pathology, direct or indirect visualization of the hypopharynx, particularly the epiglottis, is indicated. Retropharyngeal and parapharyngeal abscesses may also present with significant symptoms and a relatively normal oropharyngeal exam. Lemierre syndrome, or septic thrombophlebitis, can complicate an episode of acute pharyngitis or a peritonsillar abscess, and affects the ipsilateral internal jugular vein. In addition to sore throat, fever, and neck pain, patients can present with arthralgias and pulmonary symptoms from septic emboli.

Ancillary Testing

A rapid antigen detection test (RADT) or culture can distinguish patients with GAS from non-GAS pharyngitis. In the setting of acute pharyngitis, this can help select patients for whom antibiotic treatment is beneficial. If the patient presents with a clear viral etiology (oral ulcers, cough, rhinorrhea, hoarseness), then no testing or treatment is indicated. GAS and rheumatic fever are rare in children under the age of three years, so testing and treatment for GAS are not indicated in this age group, unless the child has an older sibling with a recent GAS infection.[5] In most patients, it is difficult for the clinician to distinguish between GAS and viral pharyngitis, even with the use of the Centor criteria, which can lead to overtreatment. It is important to make an accurate diagnosis, as overtreating for GAS pharyngitis can lead to overprescribing of antibiotics for viral pharyngitis, leading to undesirable adverse effects and antimicrobial resistance. However, undertreatment can lead to both suppurative complications (peritonsillar abscess, cervical lymphadenitis, mastoiditis, internal jugular septic thrombophlebitis) and non-suppurative complications (acute rheumatic fever).[1,8] The Infectious Disease Society of America (IDSA) does not recommend RADT testing or initiating antimicrobial treatment in children or adults with clinical features strongly suggesting a viral etiology, such as rhinorrhea, cough, oral ulcers and hoarseness. If the clinical picture is not clearly viral, the IDSA recommends RADT testing for all patients, regardless of the Centor criteria. The Centers for Disease Control and Prevention (CDC) and the European Society for Clinical Microbiology and Infectious Diseases (ESCMID) recommend using the Centor score to determine which patients should be tested, with the recommendation that adult patients with a Centor score of 0 to 2 should not be tested, because the risks of testing and treatment outweigh the benefits. Testing is recommended over empiric treatment by all organizations.[1,5,9] The IDSA recommends that a negative RADT should be followed with a throat culture in children and adolescents, as the sensitivity of the RADT is only 70% to 90%, but that this is not necessary in adults as the incidence of GAS and the risk of subsequent rheumatic fever is much lower.[5] In contrast, the ESCMID does not recommend following a negative RADT with throat culture in any age group.[9] We recommend RADT testing in all children greater than 3 and adolescents with fever and pharyngitis, and in adult patients with a Centor score of ≥3, with follow-up throat culture testing only in children and adolescents who have a negative RADT. The specificity of the RADT is 95%, so a positive RADT requires no additional testing.[5] A number of newer nucleic acid amplification tests (NAATs) are commercially available and can be used in place of RADT and throat culture. These tests take between 15 minutes and 2 hours to result and have higher sensitivity and specificity than both RADT and throat culture, though their cost is higher. The use of NAATs to diagnose GAS is rising, and although they are not yet part of formal guidelines, their use may reduce inappropriate antimicrobial administration, as there is no need for follow-up culture testing in the setting of a negative NAAT.[10–12]

Clinicians can consider heterophile antibody testing for mononucleosis, testing for acute retroviral syndrome, or additional tests in patients with a prolonged course, unusual features, or treatment failure, in order to exclude other causes and guide advice regarding contagiousness and activity limitation.

Imaging

Direct visualization of pharyngeal structures is recommended, as it can provide a definitive diagnosis, assessment of potential threats to the patient's airway, and the ability to secure the airway by endotracheal intubation. However, radiographs can assist in assessment of the epiglottis and structures of the hypopharynx. If epiglottitis is suspected, in adult patients, examination either by nasopharyngoscopy at the bedside or direct visualization with laryngoscopy in the operating room is recommended. Before visualization, preparation for an emergent airway intervention, typically cricothyroidotomy, should occur—the

Fig. 19.2 Soft tissue lateral neck x-ray demonstrating thumb sign or widening of the epiglottis silhouette *(arrow)*.

Fig. 19.3 Computed Tomography Scan of Retropharyngeal Abscess *(arrow)*.

so-called double setup—as manipulation of the upper airway tissues may lead to laryngospasm and obstruction. Endoscopic examination is preferred over plain radiographs, as endoscopic examination can also identify other life-threatening causes of airway obstruction, such as foreign bodies and angioedema, and is more sensitive for the diagnosis. If, however, endoscopy is not available or feasible, and the patient has a stable airway, plain film radiography can assist in the diagnosis of epiglottitis, as widening of the epiglottis silhouette, or thumb sign, may be appreciated (Fig. 19.2).[13]

Computed tomography (CT) provides the most detailed information regarding deep infections of the neck in both adult and pediatric patients. It is important to ensure that the patient's airway is either patent or secure before sending a patient to CT, as lying the patient flat may compromise the airway. CT is highly accurate for detecting infection in the deep tissues and is the definitive test for evaluation of deep neck infection (Fig. 19.3).[14] In addition, CT can provide additional information regarding alternate diagnoses, such as tumors or hemorrhage, and can delineate invasion of nearby structures.

Ultrasound is emerging as a useful tool to evaluate oropharyngeal and hypopharyngeal disease, and using ultrasound in place of CT can reduce both radiation exposure to patients and overall cost.[15] In peritonsillar and parapharyngeal abscesses, ultrasound can not only identify the abscess, but can also guide needle aspiration or incision and drainage if indicated (Fig. 19.4).[16,17] Ultrasound is also useful not only for evaluation of parapharyngeal and peritonsillar abscess, but also to evaluate a visible neck mass, as well.

DIAGNOSTIC ALGORITHM

Critical and Emergent Diagnoses

In patients with a sore throat, airway compromise can result from a number of critical and emergent conditions (see Box 19.1). During the diagnostic evaluation, the clinician must assess whether or not an emergent airway needs to be established. The immediate examination should focus on identifying edema, masses, an abscess, or foreign body (Fig. 19.5).

In patients without impending airway compromise, a more deliberate evaluation is warranted. One important question is whether or not signs of pharyngitis exist. Findings consistent with pharyngitis include exudates, erythema and cobblestoning of the posterior pharyngeal wall. In the absence of features pointing to an unusual cause, management should focus on viral or streptococcal causes.[1]

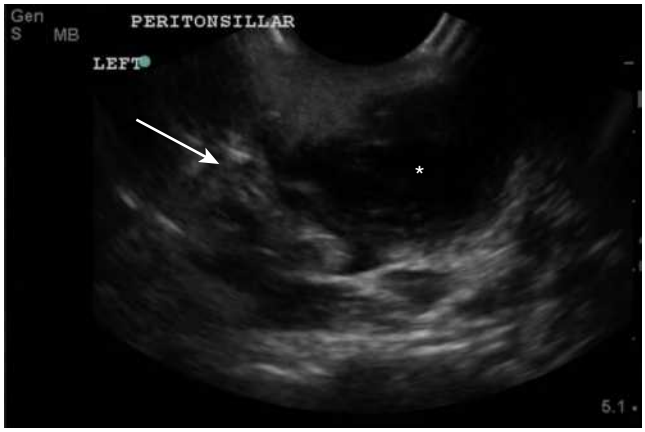

Fig. 19.4 Ultrasound image of peritonsillar abscess (*), a fluid collection adjacent to the tonsil *(arrow)*.

EMPIRIC MANAGEMENT

Fig. 19.5 describes a management algorithm for the patient with a sore throat. First and foremost, airway compromise and impending airway compromise must be identified and managed. Patients should be evaluated for signs of severe infection or sepsis and managed accordingly. In patients who have no signs of airway compromise or invasive disease, management should treat the underlying presumptive cause.

The most common cause of sore throat is a viral pharyngitis, and symptomatic treatment with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) is the only recommended treatment. For all causes of pharyngitis, patients can take these medications around-the-clock, rather than on an as-needed basis, to help keep symptoms at bay.[9,18] Overuse of antibiotics for self-limited, often viral, upper respiratory infections is a common practice across many outpatient settings despite messaging on antibacterial stewardship. This leads to increased antibiotic resistance and higher rates of adverse events, often resulting in return ED visits.[1,19–21] In summary, antibiotics for viral pharyngitis should be avoided to reduce individual adverse effects as well as for public health reasons.

A common perception is that patients expect or desire antibiotics. Because of this, patient education is a crucial component of sore throat management. Education should include both positive and negative

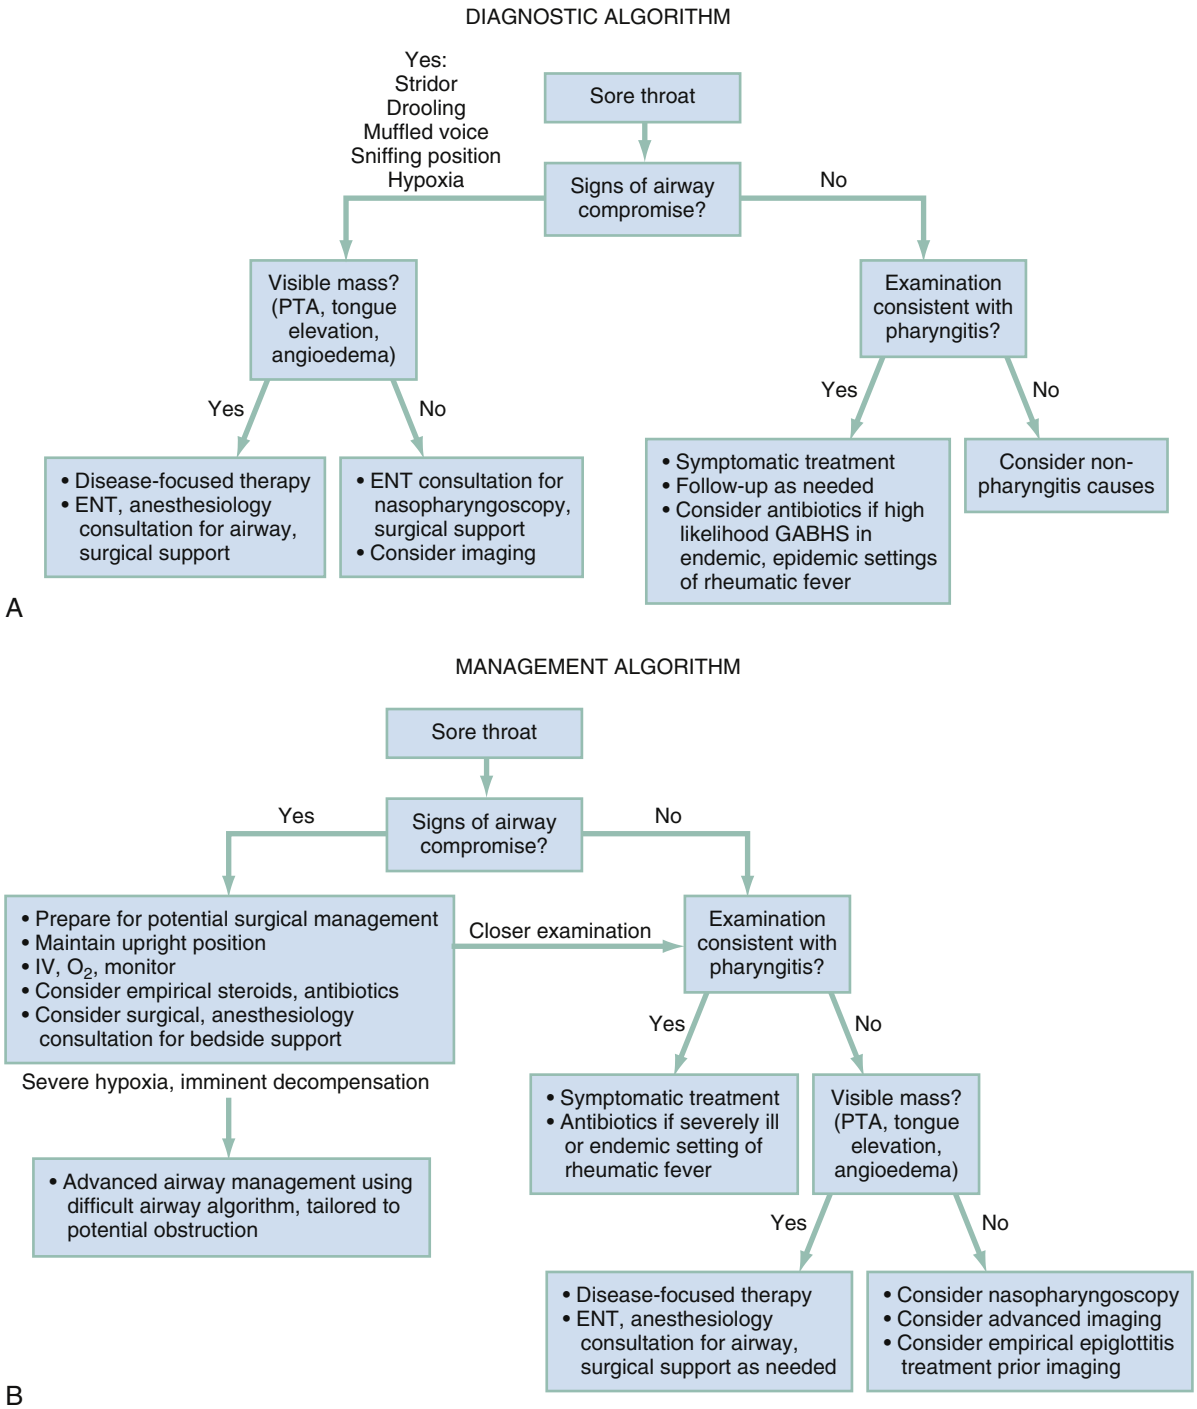

Fig. 19.5 Approach to the Patient With Sore Throat, Diagnostic and Management Algorithms. *ENT,* Ear-nose-throat; *GABHS,* Group A beta-hemolytic streptococci; *IV,* intravenous; *PTA,* peritonsillar abscess.

recommendations: explanation of both what the patient can do to improve symptoms (positive recommendations) and explanation of why antibiotics are inappropriate (negative recommendations), including the lack of symptomatic benefit with antibiotics and the potential harm of antibiotics (for example, gastrointestinal side effects, rashes, fungal infections in women, increased antibiotic resistance, and potentially dangerous allergic reactions). Emphasis on symptomatic treatment and reduction in pain, with NSAIDs or acetaminophen, is the most important educational aspect, reducing antibiotic prescribing by half.[22] Corticosteroid therapy may reduce pain and duration of pain in patients greater than 5 years of age with severe pharyngitis causing difficulty swallowing; most studies use 0.6 mg/kg (maximum dose, 10 mg) of dexamethasone, either orally or parenterally, in a one-time dose.[23] While not routinely recommended by the IDSA or ESCMID for cases of routine pharyngitis, we recommend consideration of corticosteroids for patients greater than 5 years of age with significant swelling or dysphagia, in line with the ESCMID guidelines.[5,9,23] The presence of pain necessitating opioid therapy should prompt evaluation for a more severe cause, such as an abscess or epiglottitis. Achieving pain control allows patients to resume oral intake, maintain hydration, and take additional medications that may be necessary to treat the underlying condition.

In patients who test positive for GAS by RADT, NAAT, or throat culture, we recommend treatment with intramuscular penicillin G or a 10-day course of oral penicillin VK, due to penicillin's proven efficacy and low cost. Alternative regimens, and options for patients allergic to penicillin, can be found in Box 19.2. Antimicrobial treatment may also decrease the duration and severity of illness and reduce the risk of transmission to close contacts.[1]

A fluctuant, unilateral peritonsillar mass should be drained whenever possible, as drainage is the definitive treatment. Peritonsillar cellulitis, or unilateral swelling and redness that is not fluctuant, can be treated with the same antibiotics as those used for GAS pharyngitis, though there are few data to support this practice.[24] For patients with signs of severe, systemic illness or airway compromise, antibiotic treatment for streptococcal and anaerobic bacteria may be helpful; we recommend parenteral clindamycin (10 mg/kg/dose or 900 mg tid) and a third-generation cephalosporin such as ceftriaxone (50 mg/kg or 1000 mg q24h), though there is very little evidence to support or refute this practice.[25,26] Unusual or severe presentations may require additional diagnostic studies, specialty consultation, or other empiric antibiotic treatment.

Signs of airway compromise, or impending airway compromise, should prompt preparation for emergent advanced airway management, as well as otolaryngology and surgical services consultations if available (see Chapter 1). Airway compromise can result from epiglottitis, retropharyngeal or parapharyngeal abscess, Ludwig angina, angioedema, and expanding hematomas. After securing the airway, disease-specific treatment can be initiated.

Since the introduction of the *Haemophilus influenzae* type B vaccine, epiglottitis is predominantly caused by *Streptococcus*, *Staphylococcus,* and nontypeable *Haemophilus* species, and we recommend parenteral treatment with ceftriaxone (50 mg/kg or 1000 mg qd), ampicillin/sulbactam (50 mg/kg of ampicillin component or 3000 mg q6h), or levofloxacin (750 mg qd) in penicillin-allergic patients. For the treatment of retropharyngeal or parapharyngeal abscess and Ludwig angina, we recommend broad antibiotic coverage, such as ampicillin/sulbactam (50 mg/kg or 3000 mg q6h of penicillin G (4 million units or 50,000 units/kg qid) and metronidazole (500 mg or 7.5 mg/kg qid), until culture results are available. For Lemierre syndrome, preferred agents include piperacillin/tazobactam (3.375 gm qid) or the combination of ceftriaxone 1000 mg q24h and metronidazole 500 mg q8h.

It is important to review local antibiotic resistance patterns to ensure appropriate antibiotic selection. Medical treatment of angioedema depends on the underlying cause. Treatment of anaphylaxis or allergen-induced angioedema includes epinephrine, antihistamines, and glucocorticoids; treatment of angiotensin-converting enzyme inhibitor (ACEI)-induced angioedema includes discontinuing the causal medication and supportive care; treatment of hereditary angioedema can include purified C1 inhibitor concentrate, fresh frozen plasma, and either ecallantide or icatibant, if available. Because the cause of angioedema in the emergency setting is often unknown, we recommend treatment with antihistamines and glucocorticoids in all patients, and intramuscular epinephrine if impending airway compromise exists. (See Chapter 106.)

Sore throat caused by an expanding neck hematoma or an aortic ring should prompt surgical consultation, as patients may require definitive surgical treatment.

The vast majority of patients with sore throat will be able to manage their illness as an outpatient. Patients with airway compromise or impending airway compromise are typically managed in the intensive care unit for close monitoring of the patient's airway. In these cases, as well as in cases of deep space infections, surgical consultation for possible operative intervention or for nasopharyngoscopy can be helpful. Patients with pharyngitis who are unable to tolerate oral medication or nutrition, or who have signs of systemic illness, may benefit from inpatient management.

The references for this chapter can be found online at ExpertConsult.com.

BOX 19.2 Antibiotic Regimens for Proven Group A Streptococcus

Benzathine penicillin G, intramuscular, 600,000 U for <27 kg and 1.2 million U for >27 kg

Penicillin V, oral, children <27 kg 250 mg 2 to 3 times daily; children ≥27 kg 500 mg 2 times daily; adolescents and adults 250 mg 4 times daily or 500 mg twice daily × 10 days

Amoxicillin, oral, 50 mg/kg once daily (max = 1000 mg); or 25 mg/kg (max = 500 mg) twice daily × 10 days

If penicillin-allergic:

Clindamycin, oral, 7 mg/kg/dose 3 times daily (maximum, 300 mg/dose) × 10 days

Cephalexin, oral, 20 mg/kg/dose twice daily (maximum, 500 mg/dose) × 10 days

Azithromycin, oral, 12 mg/kg/day × 5 days

CHAPTER 19: QUESTIONS AND ANSWERS

1. A 20-year-old female presents to the emergency department complaining of a sore throat. She has a temperature of 39°C, tender cervical lymphadenopathy, exudates on exam and denies any history of cough, rhinorrhea, nausea, vomiting or diarrhea. Her modified Centor score is which of the following?
   a. 2
   b. 3
   c. 4
   d. 5

Answer: c. This patient meets four Centor criteria: fever, tender cervical lymphadenopathy, exudates, and absence of a cough. The age criteria is +1 point for age 3 to 14 years, and −1 point for age greater than 45 years.

2. A 39-year-old male presents to the emergency department complaining of a sore throat. He is sitting forward on the stretcher, drooling, with inspiratory stridor. His oropharynx exam shows minimal erythema and no exudate. Which of the following conditions is the likely diagnosis?
   a. Epiglottitis
   b. Group A streptococcal pharyngitis
   c. Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) syndrome
   d. Viral pharyngitis

Answer: a. Simple pharyngitis, either bacterial or viral, and PFAPA syndrome do not cause airway compromise. Drooling and inspiratory stridor are symptoms of airway compromise, and epiglottitis is the only diagnosis on this list that results in airway compromise.

3. In adult patients who test positive for Group A streptococcal (GAS) pharyngitis who have no allergies, which of the following is the most appropriate antibiotic choice?
   a. Azithromycin 12 mg/kg/day (max dose, 500 mg) × 5 days
   b. Clindamycin 7 mg/kg/dose (max dose, 300 mg) TID × 10 days
   c. Metronidazole 30 mg/kg/day divided TID × 10 days
   d. Penicillin VK 50 mg/kg/day divided QID × 10 days

Answer: d. Penicillin VK is the first-line treatment for GAS pharyngitis in patients without allergies. Clindamycin and azithromycin are options in penicillin allergic patients. Metronidazole is not a treatment of GAS pharyngitis.

4. A 24-year-old female presents for sore throat, difficulty swallowing, and a muffled voice. On examination, she has fullness, swelling and induration of the left posterior peritonsillar area with uvular deviation to the right. What is the next step in the management of this patient?
   a. Computed tomography imaging
   b. Discharge with antibiotics, clindamycin 300 mg TID × 10 days
   c. Drainage either by needle aspiration or incision and drainage
   d. Rapid Antigen Detection Test for Group A Streptococcus

Answer: c. This patient has a peritonsillar abscess. In a clear-cut case such as this, no imaging is needed. Definitive treatment is with either needle aspiration or incision and drainage.

5. In which age group is Group A streptococcal infection most common?
   a. Age <3 years
   b. Age 5–15 years
   c. Age 15–45 years
   d. Age >45 years

Answer: b. GAS pharyngitis is most common in children aged 5 to 15 years. It is less common in young adults, and rare in children less than three, or adults over the age of 45.

Hemoptysis

Calvin A. Brown III

KEY CONCEPTS

- Hemoptysis is caused by infection, trauma, cancer, or coagulopathy or as a complication of invasive pulmonary procedures.
- "Massive hemoptysis" is defined as greater than 100 mL of blood loss or approximately ½ cup of blood in a 24-hour period or a bleeding rate ≥100 mL/h.
- Plain radiographs are the initial screening test in most cases of massive hemoptysis, although high-resolution chest computed tomography scans are more sensitive and can supplant plain chest x-rays as the initial diagnostic test.
- Bronchial artery embolization is highly effective, with hemostasis rates ranging from 85% to 95%.
- With massive hemoptysis, hypoxia is the more immediate concern rather than volume resuscitation, and early intubation to ensure adequate oxygenation is paramount. Most causes of mortality are a result of asphyxiation.
- If a tracheo-innominate artery fistula (TIF) is suspected, then overinflation of the tracheostomy balloon or digital pressure at the site of bleeding should be performed for immediate hemorrhage control.

FOUNDATIONS

Epidemiology

Hemoptysis is defined as the expectoration of blood from the respiratory tract below the vocal cords. Most cases seen in the emergency department (ED) are minor episodes of small-volume hemoptysis, typically consisting of either blood-tinged sputum or minute amounts of frank blood, most often associated with bronchitis. Although hemoptysis is commonly seen in the ED, only 1% to 5% of hemoptysis patients have massive or life-threatening hemorrhage. Many definitions exist, but *massive hemoptysis* is generally accepted as greater than 100 mL or greater than ½ cup of blood loss in any 24-hour period or a bleeding rate ≥100 mL/h, which may result in hemodynamic instability, shock, or impaired alveolar gas exchange and has a mortality rate approaching 80%. The average blood volume of the tracheopulmonary tree is 150 mL; therefore what might be considered small-volume bleeding from another location could be lethal when it occurs in the lungs. In patients admitted with hemoptysis to an intensive care unit (ICU), overall mortality is approximately 6.5%. Highest short-term mortality is found in patients with alcoholism, active cancer, aspergillosis, pulmonary artery involvement, multifocal pulmonary infiltrates, and need for mechanical ventilation at the time of admission.

Large, contemporary series of patients with massive hemoptysis are lacking. Previously, tuberculosis (TB), bronchiectasis, and lung abscesses were responsible for the majority of cases. Contemporary causes of hemoptysis, especially in developed nations, include cancer, cystic fibrosis, arteriovenous malformations, pneumonia, anticoagulant use, and postprocedural complications. Pediatric hemoptysis is rare but can be caused by infection, congenital heart disease, cystic fibrosis, or bleeding from a preexisting tracheostomy. Major causes of hemoptysis are listed in Box 20.1.

Pathophysiology

Minor hemoptysis typically originates from tracheobronchial capillaries that are disrupted by vigorous coughing or minor bronchial infections. Conversely, massive hemoptysis nearly always involves disruption of bronchial or pulmonary arteries, which are the two sets of vessels that constitute the lung's dual blood supply. Bronchial arteries, which are direct branches from the thoracic aorta, are responsible for supplying oxygenated blood to lung parenchyma, and disruption of these vessels from arteritis, trauma, bronchiectasis, or malignant erosion can result in sudden and profound hemorrhage. Although small in caliber, the bronchial circulation is a high-pressure system and the culprit in nearly 90% of the cases of massive hemoptysis requiring embolization. Pulmonary arteries, although transmitting large volumes of blood, do so at much lower pressures and, unless affected centrally, are less likely to cause massive hemoptysis.

Nearly all causes of hemoptysis have a common mechanism—vascular disruption within the trachea, bronchi, small-caliber airways, or lung parenchyma. Modes of vessel injury include acute and chronic inflammation (from bronchitis and arteritis), local infection (especially lung abscesses, TB, and aspergillosis), trauma, malignant invasion, infarction following a pulmonary embolus, and fistula formation (specifically aortobronchial fistulae).

Bronchiectasis, a chronic necrotizing infection resulting in bronchial wall inflammation and dilation, is one of the most common causes of massive hemoptysis worldwide. As tissue destruction and remodeling occur, rupture of nearby bronchial vessels can result in bleeding. Bronchiectasis can complicate chronic airway obstruction, necrotizing pneumonia, TB, or cystic fibrosis. Broncholithiasis, the formation of calcified endobronchial lesions following a wide array of granulomatous infections, is an uncommon problem with a similar propensity to erode nearby vessels. Hemorrhage control often requires surgical intervention.

Iatrogenic hemoptysis complicates 2% to 10% of all endobronchial procedures, especially percutaneous lung biopsies. Right (pulmonary artery) heart catheterization using a Swan-Ganz catheter can cause iatrogenic pulmonary artery perforation especially in patients with pulmonary hypertension. Although this complication is rare, the mortality is between 50% to 70%. Diffuse alveolar hemorrhage can be seen with autoimmune vasculitides, such as Wegener's granulomatosis, systemic lupus erythematosus (SLE), and Goodpasture syndrome. An uncommon cause of hemoptysis occurs when ectopic endometrial tissue within the lung results in monthly catamenial episodes of bleeding. Less common causes include pulmonary hereditary telangiectasias

BOX 20.1 Differential Diagnosis of Hemoptysis

Airway Disease
Bronchitis (acute or chronic)
Bronchiectasis
Neoplasm (primary and metastatic)
Trauma
Foreign body

Parenchymal Disease
Tuberculosis (TB)
Pneumonia, lung abscess
Fungal infection
Neoplasm

Vascular Disease
Pulmonary embolism
Arteriovenous malformation
Aortic aneurysm
Pulmonary hypertension
Vasculitis (Wegener's granulomatosis, systemic lupus erythematosus [SLE], Goodpasture syndrome)

Hematologic Disease
Coagulopathy (cirrhosis or warfarin therapy)
Disseminated intravascular coagulation (DIC)
Platelet dysfunction
Thrombocytopenia

Cardiac Disease
Congenital heart disease (especially in children)
Valvular heart disease
Endocarditis

Miscellaneous
Cocaine
Postprocedural injury
Tracheal-arterial fistula
SLE

and hydatidiform infections. Any episode of hemoptysis can be exacerbated by intrinsic or acquired coagulopathy and thrombocytopenia.

DIAGNOSTIC APPROACH

Differential Considerations

First, the clinician should be convinced that the source of the bleeding is pulmonary. Distinguishing hemoptysis from hematemesis is accomplished by the clinician working with the patient to clarify details of the history, particularly differentiation between coughing and vomiting or spitting. Nasal, oral, or hypopharyngeal bleeding may contaminate the tracheobronchial tree, mimicking true hemoptysis. The clinician should closely inspect the nasopharynx and oral cavity to exclude this possibility. Gastric or proximal duodenal bleeding can similarly mimic hemoptysis, and differentiating a gastrointestinal (GI) source of bleeding is especially important because further evaluation and management of these two pathologies follow divergent pathways. In unclear cases, inspection and pH testing may help to distinguish GI from tracheobronchial hemorrhage. Unless an active, brisk upper GI hemorrhage is present, the acidification of blood in the stomach results in fragmentation and darkening, producing specks of brown or black material often referred to as *coffee-ground emesis*. Pulmonary blood appears bright red or as only slightly darker clots and is alkaline.

Inflammatory disorders that secondarily involve the lungs or pulmonary vasculature include Wegener's granulomatosis, Goodpasture syndrome, and SLE, and a history of these should be elicited. Any risk factors for platelet dysfunction, thrombocytopenia, and coagulopathy should be noted, as should any hypercoagulable states that might contribute to venous thromboembolic disease.

Primary or metastatic cancer can cause hemoptysis by erosion into pulmonary and bronchial vessels. Recent percutaneous or transbronchial procedures can cause immediate or delayed postprocedural bleeding, and any recent history of trauma should also be noted. A pertinent travel history to areas in which TB or pulmonary *paragonimiasis* is endemic is crucial.

A history of chronic alcoholism, cancer, and pulmonary fungal infections are other critical historical elements because these independently predict increased in-hospital mortality.[1]

Pivotal Findings

Symptoms

Although patient reports of bleeding severity can be inaccurate, an estimate of the rate, volume, and appearance of expectorated blood should be obtained. Additional pertinent history includes prior episodes of hemoptysis or parenchymal pulmonary disorders, including bronchiectasis, recurrent pneumonia, chronic obstructive pulmonary disease, bronchitis, TB, fungal infection, and travel history.

Signs

A targeted examination may suggest the location and cause of bleeding but does so in less than 50% of cases. Focal adventitious breath sounds in a febrile patient may indicate pneumonia or pulmonary abscess. A new heart murmur, especially in a febrile patient, may reflect endocarditis causing septic pulmonary emboli. A rash might hint at underlying rheumatologic disorders, such as SLE or vasculitis. Symptoms and signs of deep venous thrombosis suggest pulmonary embolism. Ecchymoses and petechiae can indicate coagulopathy and thrombocytopenia, respectively.

Ancillary Testing

In patients with massive hemoptysis, a diagnostic work-up should begin after resuscitation and stabilization. Initial laboratory studies include a complete blood count, coagulation tests, and a type and crossmatch for packed red blood cells. Renal function tests should be performed if vasculitis is suggested. Plain chest radiography plays a limited role in evaluating patients with minor hemoptysis. Although chest x-rays are easy to obtain and can screen for causes of hemoptysis (including infection and malignancy), their sensitivity is poor and often cannot identify the source of bleeding, a critical step in triage and management (see the Empirical Management section). Up to half of hemoptysis patients with a normal chest radiograph will have positive findings on chest computed tomography (CT).

When there is massive hemoptysis, plain films can localize the side of hemorrhage in approximately half of patients and suggest an etiology in only a third. High-resolution CT (HRCT) of the chest is the principle diagnostic test for investigating both bronchial and nonbronchial causes of massive hemoptysis and is able to determine the site and cause of bleeding in 70% to 80%.[2] Advantages of HRCT include highly detailed parenchymal images due to thin slices and no requirement for intravenous (IV) contrast given the high intrinsic contrast between air and lung tissue. When compared with bronchoscopy, HRCT is nearly twice as likely to determine the cause of bleeding.[3] A chest HRCT scan should be obtained in the high-risk patient (i.e., smokers, oncology

patients) or in any patient with moderate to severe bleeding, even if the initial chest radiograph is normal. HRCT localization of hemorrhage can expedite bronchoscopic evaluation and guide subsequent interventional procedures.

HRCT is diagnostically comparable to conventional angiography but less invasive and more rapidly available. Angiography is the first line study when the cause of the hemoptysis is known (e.g., malignancy), when bronchial artery hemorrhage is suspected, or when angiography-assisted embolization therapy is to be performed. Successful embolization rates are as high as 95%.

DIAGNOSTIC ALGORITHM

Critical Diagnoses

Box 20.2 shows critical and emergent diagnoses. Proper management hinges not only on standard resuscitative measures but also specific therapies, such as reversal of coagulopathy or emergent surgical intervention. For example, in patients with preexisting tracheostomies, new hemoptysis (especially within 3 to 4 weeks of surgery) often represents a tracheo-innominate artery fistula (TIF) for which the need for hemorrhage control is immediate and can often be accomplished in the ED.

BOX 20.2 Critical and Emergent Diagnoses in Patients Presenting With Hemoptysis

Critical Diagnoses
Disseminated intravascular coagulopathy (DIC)
Tracheo-innominate artery fistula (TIF)
Aortobronchial fistula
Iatrogenic (postprocedural) hemoptysis
Pulmonary embolism

Emergent Diagnoses
Trauma
Bronchiectasis
Pneumonia
Abscess/fungal infection
Oral anticoagulant overdose
Endocarditis

Congestive Heart Failure
Acute Pulmonary Edema

Although management decisions hinge on the volume and rate of bleeding, the initial diagnostic strategy is the same for all patients with hemoptysis (Fig. 20.1). Patients with trace hemoptysis or blood-tinged sputum only and a classic story for viral bronchitis may not require laboratory or radiology investigation of any type. In a recent single-center ED study of patients presenting with submassive hemoptysis, those with normal blood pressure, lack of a cancer history, and a single episode of blood-tinged sputum could safely be discharged after a normal chest x-ray.[1] For all others, the initial screening test obtained in the ED is a chest x-ray. Since the advent of HRCT, radiologic evaluation has had an integral role in the evaluation and treatment of patients with hemoptysis. Unless the initial chest radiograph is diagnostic or the patient is hemodynamically unstable, a chest HRCT should be obtained. Further management decisions should be guided by the HRCT results and made in conjunction with pulmonary and thoracic surgery consultants.

Bronchoscopy

Early bronchoscopy may be the right option because it facilitates both localization of bleeding and therapeutic intervention. HRCT may be diagnostically more accurate than bronchoscopy in locating bleeding peripheral vessels, not accessible by a flexible bronchoscope. HRCT of the chest can be used to identify the site of bleeding to determine whether angiography is indicated. There may be little added benefit of bronchoscopy before interventional angiography if the bleeding source has already been accurately identified on HRCT.

EMPIRICAL MANAGEMENT

Fig. 20.2 outlines the management algorithm for patients with hemoptysis. Although hemodynamic instability can occur as a result of hemorrhage, the most lethal sequela of massive hemoptysis is hypoxia,

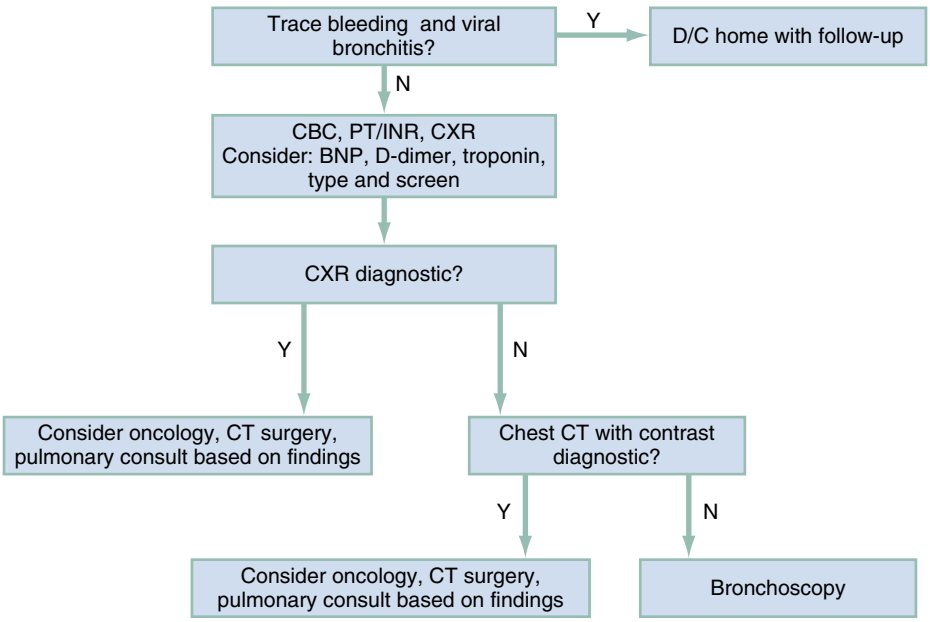

Fig. 20.1 The Emergency Department Diagnostic Approach to Hemoptysis. *BNP,* B-type natriuretic peptide; *CBC,* complete blood count; *CXR,* chest x-ray; *D/C,* discharge; *HRCT,* high-resolution computed tomography; *INR,* international normalized ratio; *PT,* prothrombin time.

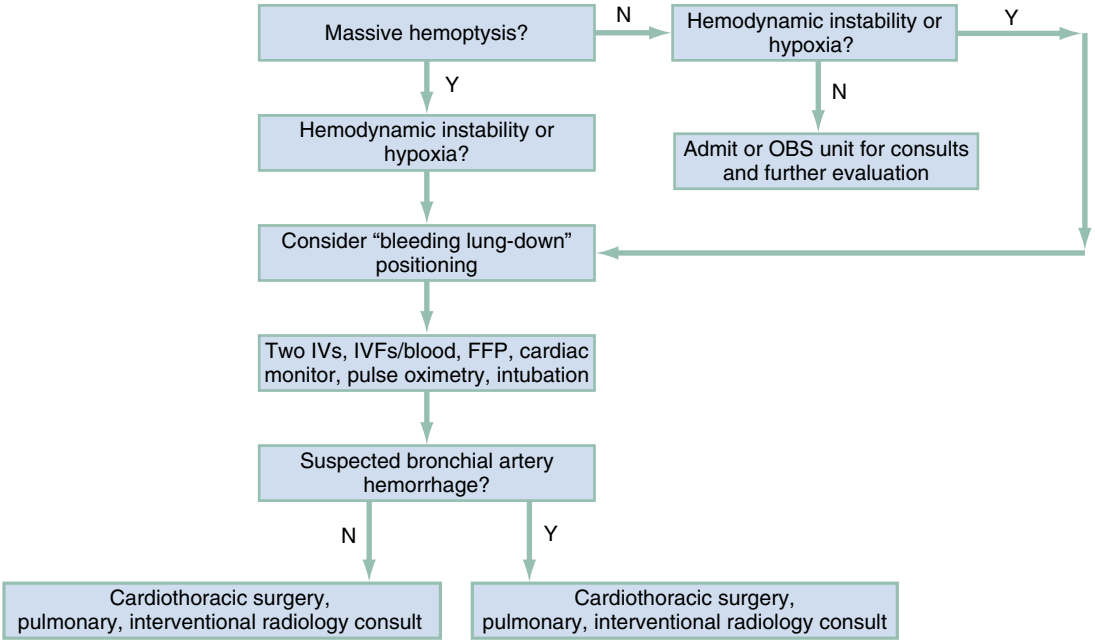

Fig. 20.2 The Emergency Department Management Approach to Hemoptysis. *IV,* Intravenous; *IVF,* intravenous fluid; *FFP,* fresh frozen plasma; *OBS,* observation.

which results from the ventilation-perfusion mismatch that follows submersion of the small airways and alveoli with blood.

All patients with massive hemoptysis should have multiple large-bore peripheral IV lines placed. Volume resuscitation should begin immediately for patients with ongoing bleeding or shock. Coagulopathy, in the setting of severe bleeding, should be reversed by infusing 2 to 4 units of fresh frozen plasma (FFP) and 10 mg of IV vitamin K. Prothrombin complex concentrates (PCCs) have been successful in reversing warfarin-induced intracranial hemorrhage, but there is no information to guide the use of PCC in patients with severe hemoptysis. In a recent single-center randomized controlled pilot study of patients presenting with submassive hemoptysis, tranexamic acid (TXA) reduced the severity of bleeding compared with placebo.[4] Case reports of bleeding cessation have been reported after use of inhaled, nebulized TXA.[5] Patients with thrombocytopenia should have a platelet transfusion with a goal platelet count of 50,000 to 60,000.

If a TIF is suspected, the emergency clinician should immediately attempt to overinflate the tracheostomy balloon in an effort to tamponade the bleeding. If this fails, the tracheostomy tube should be removed, the patient should be orally intubated, and the operator's index finger should be placed through the tracheostomy hole with pressure applied at the sight of bleeding (Fig. 20.3).

Aortobronchial artery fistulae are highly lethal, but if caught early, general resuscitative measures should be undertaken in addition to immediate consultation with or transfer to an endovascular surgeon. Pulmonary embolus is only rarely associated with massive hemoptysis. When trace hemoptysis accompanies pulmonary embolism, usual care with anticoagulation is standard treatment.

Hemoptysis as a complication of disseminated intravascular coagulation (DIC) should be treated following the general management guidelines for DIC. Treatment of DIC remains controversial; however, when bleeding is present with platelet counts less than 50,000, transfusion is indicated. FFP and cryoprecipitate have also been advocated to replace factors lost due to consumptive coagulopathy.

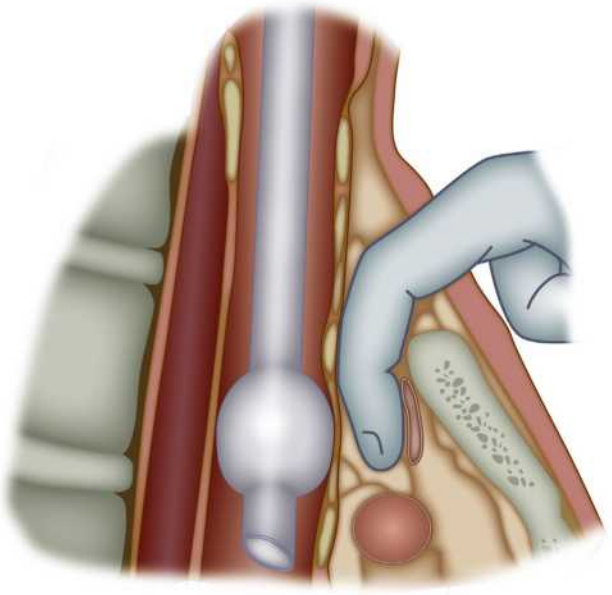

Fig. 20.3 Pressure placed by the clinician's finger through the tracheostomy hole occluding the tracheo-innominate artery.

Patients with a known or suspected lateralizing source of bleeding should be placed in the "bleeding lung-down" position such that the bleeding lung is more dependent, promoting continued protection and ventilation of the unaffected lung and improved oxygenation. If intubation is required, a large-diameter (8.0) endotracheal tube should be used to facilitate emergent flexible bronchoscopy.

If the patient has marginal hemodynamic status, the intubation should proceed with a "shock-sensitive" strategy focusing on preload maximization with isotonic fluids or blood, reduced dose induction agents, and peri-intubation pressors, such as norepinephrine (see Chapter 1). In selected cases of confirmed left-sided bleeding, a single-lumen right-mainstem intubation often can be successfully performed

through advancement of the tube in the neutral position or use of a 90-degree rotational technique, during which the tube is rotated 90 degrees in the direction of desired placement and advanced until resistance is met. Left-mainstem intubations are more difficult but may be attempted when the bleeding site is the right lung and simple lung-down positioning is not sufficient to stabilize the patient's airway and oxygenation.

When these measures fail or the hemoptysis is life threatening, anesthesia consultation is sought for consideration of placement of double-lumen endotracheal tubes for lung isolation. The correct positioning of blindly placed double-lumen tubes is difficult and requires confirmation by auscultation and fiberoptic bronchoscopy, both of which are severely impaired by massive hemoptysis. Complications of double-lumen tubes include unilateral and bilateral pneumothoraces, pneumomediastinum, carinal rupture, lobar collapse, and tube malposition.

Fiberoptic bronchoscopy, in addition to being one of the first diagnostic maneuvers, is a first line therapeutic option as well. Balloon and topical hemostatic tamponade, thermocoagulation, and injection of vasoactive agents can all effectively control arterial bleeding. Optimal timing for bronchoscopy remains conjectural. Although stable patients with mild to moderate bleeding may benefit from early bronchoscopy, in unstable patients or those with brisk hemorrhage, bronchoscopy may facilitate airway management but is less likely to control bleeding.

Bronchial arterial embolization is an effective first line therapy for massive hemoptysis and is the procedure of choice for patients either unable to tolerate surgery or in whom bronchoscopy has been unsuccessful. Hemostatic rates range from 85% to 98%, but as many as 20% to 50% of patients have early episodes of recurrent bleeding. The risk of bleeding may exist for up to 36 months. To guide therapy, initial localization of bleeding by bronchoscopy or HRCT is preferred. Rare complications include arterial perforation and dissection.

Emergency thoracotomy, in the operating room, is reserved for life-threatening hemoptysis that is uncontrolled by bronchoscopy and percutaneous embolization. Although lung resection for massive hemoptysis carries with it high morbidity and mortality, it is a permanent solution to ongoing life-threatening hemoptysis. Pulmonary arterial hemorrhage from tumor necrosis represents a surgical emergency.

Healthy patients with blood-streaked sputum or intermittent small-volume hemoptysis in the context of an acute or subacute respiratory infection with resolved hemoptysis and normal vital signs do not require imaging beyond plain chest radiography and can be discharged. High-risk patients (e.g., those with known lung cancer, pulmonary vascular abnormalities, or coagulopathy with minor hemoptysis) and all patients with moderate or large amounts of hemoptysis should undergo emergent HRCT scan. In these situations, there is little value in first obtaining a plain chest radiograph and a plain x-ray film should not be obtained if HRCT is planned regardless of the findings on the plain film. Brief hospitalization or admission to an observation unit for bronchoscopy should be considered. All patients with massive hemoptysis require admission to an ICU and expedited multidisciplinary treatment involving the emergency physician, pulmonologist, interventional radiologist, and thoracic surgeon.

CHAPTER 20: QUESTIONS AND ANSWERS

1. What is the most common cause of trace hemoptysis (blood-tinged sputum)?
   - **a.** Bronchiectasis
   - **b.** Bronchitis
   - **c.** Cancer
   - **d.** Congestive heart failure
   - **e.** Pulmonary embolism

Answer: b. The most common cause of small-volume hemoptysis is bronchitis.

2. Disruption of which of the following vessels is responsible for the vast majority of cases of massive hemoptysis?
   - **a.** Aorta
   - **b.** Bronchial arteries
   - **c.** Pulmonary arteries
   - **d.** Pulmonary veins
   - **e.** Tracheobronchial capillaries

Answer: b. Massive hemoptysis almost exclusively involves one of the two sets of vessels that constitute the lung's dual blood supply. Bronchial arteries, direct branches from the thoracic aorta, are responsible for supplying oxygenated blood to the lung parenchyma. Disruption of these vessels can result in sudden and profound hemorrhage. Although small in caliber, the bronchial circulation is a high-pressure system and the cause in nearly 90% of the cases of massive hemoptysis requiring embolization. Although they transmit large volumes of blood, pulmonary arteries are at much lower pressure and, unless affected at a very central location, are less likely to cause massive hemoptysis. Trace hemoptysis typically originates from tracheobronchial capillaries that become disrupted with vigorous coughing or minor bronchial infections.

3. Which of the following statements regarding the evaluation of hemoptysis is true?
   - **a.** Chest x-ray localizes the site of bleeding in nearly 90% of cases of patients with large volume hemoptysis.
   - **b.** Conventional angiography is the preferred diagnostic test to detect both bronchial and nonbronchial arterial causes of massive hemoptysis.
   - **c.** High-resolution CT, even with recent advances in technology, remains diagnostically inferior to angiography.
   - **d.** Patients with fever, cough, and blood-tinged sputum should receive a chest x-ray even if the vital signs are normal.

Answer: b. In patients with massive hemoptysis, plain films may localize the site of hemorrhage in approximately 50% of patients. However, high-resolution multidetector CT of the chest is the principal diagnostic test to detect both bronchial and nonbronchial arterial causes of massive hemoptysis. CT is diagnostically comparable with, but less invasive than, conventional angiography, which currently is done as a combined diagnostic/therapeutic modality. A chest CT scan should be obtained in high-risk patients (smokers and oncology patients) or in any patient with moderate-to-severe bleeding even if the initial chest radiograph is normal. CT localization of hemorrhage can expedite bronchoscopic evaluation or guide subsequent interventional procedures. Patients with "garden variety" bronchitis, normal oxygenation, and a normal exam do not require imaging in the emergency department.

4. A 50-year-old man presents after an episode of hemoptysis. He describes coughing up several large clots of dark blood. During his evaluation, he coughs and expectorates approximately 5 mL of clotted blood. The patient's vital signs are normal, and no abnormalities are noted on physical examination. His chest radiograph is normal. Which of the following is the most appropriate next step in the management of this patient?
   - **a.** Admission to an observation unit
   - **b.** Consultation for bronchoscopy
   - **c.** Consultation for percutaneous embolization
   - **d.** Discharge home with follow-up in 24 hours
   - **e.** Obtain chest high-resolution computed tomography (HRCT) scan

Answer: e. Since the advent of HRCT, radiologic evaluation has had an integral role in the evaluation and management of patients with hemoptysis. Unless the initial chest radiograph is diagnostic or the patient is hemodynamically unstable, an HRCT scan should be obtained in most cases. Further management strategy should occur in conjunction with pulmonary and thoracic surgery consultants, guided by the HRCT results.

5. A 58-year-old man with a single lung transplant presents to the emergency department (ED) with what appears to be large-volume hemoptysis. He was just discharged from the endoscopy suite, where he had a number of surveillance biopsies performed. He looks pale and diaphoretic with an initial oxygen saturation of 71%. After placement of an intravenous line and supplemental oxygen, the next most appropriate step is:
   - **a.** Blood transfusion
   - **b.** High-resolution computed tomography scan of the chest
   - **c.** Intubation
   - **d.** Thoracic surgery consultation

Answer: c. This patient is profoundly hypoxic and will need imaging outside of the ED and invasive procedures. The primary cause of mortality in patients with hemoptysis is asphyxiation. All resuscitative and procedural efforts will be futile without intubation and adequate oxygenation.

21

Dyspnea

Sabina A. Braithwaite and Amanda L. Wessel

KEY CONCEPTS

- Dyspnea results from a variety of conditions, ranging from nonurgent to life-threatening. Neither the clinical severity nor the patient's perception correlates well with the seriousness of underlying pathology.
- Dyspnea is subjective and the differential diagnosis can be divided into acute, acute on chronic, and chronic causes, of which the majority are cardiopulmonary. Other causes include metabolic, infectious, neuromuscular, traumatic, psychiatric, and hematologic conditions.
- Chronic or progressive dyspnea usually denotes primary cardiac or pulmonary disease. Acute dyspneic spells may result from asthma exacerbation, infection, pulmonary embolism, cardiac dysfunction, or psychogenic causes.
- All patients experiencing dyspnea, regardless of etiology, should be promptly evaluated. Bedside pulse oximetry readings should be obtained, and the patient placed on a cardiac monitor.
- If the pulse oximetry is less than 92% on room air, the patient should be placed on supplemental oxygen either by nasal cannula or mask, depending on the degree of desaturation.
- If altered level of consciousness, or hypoxia cannot be improved with suctioning, supplemental oxygen, or airway adjuncts then breathing should be assisted with manual or mechanical ventilation, either noninvasively for the short term, or with intubation for prolonged ventilation.
- Unstable patients or patients with critical diagnoses must be stabilized and may require an emergent procedure and admission to an intensive care unit. Urgent patients who improve with emergency department management may be admitted to an intermediate care unit. Patients diagnosed with urgent conditions in danger of deterioration without proper treatment or patients with severe comorbidities, such as diabetes, immunosuppression, or cancer, may also require admission for observation and treatment.

FOUNDATIONS

Dyspnea is the term applied to the uncomfortable sensation of breathlessness. It is described by patients in various ways, such as shortness of breath, chest tightness, or difficulty breathing. Dyspnea results from a variety of conditions, ranging from non-urgent to life-threatening. Neither the clinical severity nor the patient's perception correlates well with the seriousness of underlying pathology and may be affected by emotions, behavioral and cultural influences, and external stimuli.

The following terms may be used in the assessment of the dyspneic patient:

Tachypnea: Greater than normal respiratory rate. Normal rates range from 44 cycles/min in a newborn to 14 to 18 cycles/min in adults.

Hyperventilation: A minute ventilation that exceeds metabolic demand.

Dyspnea on exertion: Dyspnea provoked by physical effort. It often is quantified simply as the number of stairs or number of blocks tolerated before symptom onset.

Orthopnea: Dyspnea in a recumbent position. It is commonly described as the number of pillows the patient uses to rest comfortably in bed (e.g., two-pillow orthopnea).

Paroxysmal nocturnal dyspnea: Sudden onset of dyspnea occurring while reclining at night.

Epidemiology

Dyspnea is a very common presenting complaint among emergency department (ED) patients of every age. Causes vary widely, and range from benign, self-limited conditions to life-threatening events. The symptom of dyspnea itself is an independent predictor of mortality.[1] As chronic conditions become more prevalent, especially in the elderly, multiple etiologies may contribute to an individual's symptoms.[2,3]

Pathophysiology

Normal breathing is controlled both centrally by the respiratory control center in the medulla oblongata and peripherally by chemoreceptors located near the carotid bodies, but there are numerous sensory inputs that affect the feeling of dyspnea, including pulmonary stretch receptors and mechanoreceptors in the diaphragm and skeletal muscles. Imbalances among these inputs can be perceived as dyspnea and may manifest as increased work of breathing due to increased lung resistance, or decreased compliance in asthma or chronic obstructive pulmonary disease (COPD).[4]

DIAGNOSTIC APPROACH

Differential Diagnosis Considerations

The differential diagnosis for dyspnea can be divided into acute, acute on chronic, and chronic causes. It spans a wide range of systems including cardiac, metabolic, infectious, neuromuscular, traumatic, hematologic, and psychiatric conditions (Table 21.1).

Pivotal Findings

Symptoms

Patient descriptions of dyspnea vary significantly and frequently correlate poorly with the healthcare provider's perception of the patient's presentation.[5] One example is patients presenting with severe acute respiratory syndrome-2 coronavirus (COVID-19) who present with profound hypoxia without signs of respiratory distress (i.e., "the happy hypoxic") (see Chapter 119).

Quality of symptoms. The description of symptoms may provide clues to a diagnosis. For example, chest tightness is fairly specific to bronchoconstriction and the stimulation of airway receptors.[6]

Duration and onset of dyspnea. Chronic or progressive dyspnea usually denotes primary cardiac, pulmonary, or, less commonly, neuromuscular disease. Many of these processes such as COPD or heart failure are prone to acute exacerbations. Sudden onset of dyspnea should lead to consideration of pulmonary embolism (PE), spontaneous

TABLE 21.1 Differential Diagnoses for Acute Dyspnea

Organ System	Critical Diagnoses	Emergent Diagnoses	Nonemergent Diagnoses
Pulmonary	Airway obstruction	Spontaneous pneumothorax	Pleural effusion
	Pulmonary embolus	Asthma	Neoplasm
	Noncardiogenic pulmonary edema	Cor pulmonale	Pneumonia (CAP score ≤70)
	Anaphylaxis	Aspiration	COPD
	Ventilatory failure	Pneumonia (CAP score >70)	
Cardiac	Pulmonary edema	Pericarditis	Congenital heart disease
	Myocardial infarction		Valvular heart disease
	Cardiac tamponade		Cardiomyopathy
PRIMARILY ASSOCIATED WITH NORMAL OR INCREASED RESPIRATORY EFFORT			
Abdominal		Mechanical interference	Pregnancy
		Hypotension, sepsis from ruptured viscus, bowel obstruction, inflammatory or infectious process	Ascites, obesity
Psychogenic			Hyperventilation syndrome
			Somatization disorder
			Panic attack
Metabolic or endocrine	Toxic ingestion	Renal failure	Fever
	DKA	Electrolyte abnormalities	Thyroid disease
		Metabolic acidosis	
Infectious	Epiglottitis	Pneumonia (CAP score >70)	Pneumonia (CAP score ≤70)
Traumatic	Tension pneumothorax	Simple pneumothorax, hemothorax	Rib fractures
	Cardiac tamponade	Diaphragmatic rupture	
	Flail chest	Neurologic injury	
Hematologic	Carbon monoxide or cyanide poisoning	Anemia	
	Acute chest syndrome		
PRIMARILY ASSOCIATED WITH DECREASED RESPIRATORY EFFORT			
Neuromuscular	CVA, intracranial insult	Multiple sclerosis	ALS
	Organophosphate poisoning	Guillain-Barré syndrome	Polymyositis
		Tick paralysis	Porphyria

ALS, Amyotrophic lateral sclerosis; *CAP,* community-acquired pneumonia; *COPD,* chronic obstructive pulmonary disease; *CVA,* cerebrovascular accident; *DKA,* diabetic ketoacidosis.

pneumothorax, myocardial infarction, acute environmental exposure, or foreign body. Worsening of new symptoms over several days may indicate a more gradual process such as pneumonia.

***Positional changes.*.** Orthopnea can result from left-sided heart failure, COPD, or neuromuscular disorders.[4] It can be one of the earliest symptoms in patients with diaphragmatic weakness from neuromuscular disease. Paroxysmal nocturnal dyspnea is most common in patients with left-sided heart failure but also occurs in COPD. Exertional dyspnea is commonly associated with COPD but also can be seen with poor cardiac reserve and abdominal loading. Abdominal loading, caused by ascites, obesity, or pregnancy, leads to elevation of the diaphragm, resulting in less effective ventilation and dyspnea.[7]

***Associated symptoms.*.** Anxiety or overwhelming fear, particularly if it precedes the onset of dyspnea, may point to panic attack or psychogenic dyspnea. Organic causes should be considered first as the sensation of dyspnea can itself provoke anxiety, but it is also frequently noted with hypoxia or inadequate ventilation. PE or myocardial infarction may or may not be associated with chest pain, particularly pain that is constant, dull, or visceral. Pain that is sharp and worsened by deep breathing but not by movement may indicate pleural effusion, pleurisy, or pleural irritation from pneumonia or PE.

Signs

Physical signs in dyspneic patients may be consistent with specific illnesses (Table 21.2). For example, fever suggests an infectious cause, somnolence or obtundation may indicate hypercarbia, agitation can be associated with hypoxia, and trauma may produce dyspnea through various injuries. Drooling or a tripod position may indicate upper airway obstruction.[8] Physical findings found in specific diseases also can be grouped by presenting patterns (Table 21.3). Some findings have improved predictive value for specific pathologies when combined with laboratory testing in validated risk stratification tools.[9–11]

Ancillary Testing

Specific findings obtained from the history and physical examination should drive which ancillary studies are needed to focus the differential diagnosis (Table 21.4). Bedside oxygen saturation is useful in assessing the degree of hypoxia and typically correlates well with arterial blood gases (ABG), which are invasive and painful. Venous blood gas (VBG)

TABLE 21.2 Pivotal Findings in Physical Examination

Sign	Physical Finding	Diagnoses to Consider
Vital signs	Tachypnea	Pneumonia, pneumothorax, metabolic acidosis
	Hypopnea	Intracranial insult, drug or toxin ingestion
	Tachycardia	PE, traumatic chest injury, sepsis, anxiety
	Hypotension	Tension pneumothorax, cardiac tamponade, sepsis
	Fever	Pneumonia, PE
General appearance	Cachexia, weight loss	Malignancy, acquired immune disorder, mycobacterial infection, COPD
	Obesity	Hypoventilation, sleep apnea, PE
	Pregnancy	PE
	Barrel chest	COPD
	"Sniffing" position	Epiglottitis
	"Tripoding" position	COPD or asthma with severe exacerbation
	Traumatic injury	Pneumothorax (simple, tension), rib fractures, diaphragmatic injury, flail chest, hemothorax, pulmonary contusion
Skin and nails	Tobacco stains or odor	COPD, malignancy, infection
	Clubbing	Chronic hypoxia, intracardiac shunts, or pulmonary vascular anomalies
	Pallid skin or conjunctivae	Anemia
	Muscle wasting	Neuromuscular disease, malignancy, COPD
	Bruising	Chest wall: Rib fractures, pneumothorax
	Diffuse: Thrombocytopenia, chronic steroid use, anticoagulation	
	Subcutaneous emphysema	Rib fractures, pneumothorax, tracheobronchial disruption
	Hives, rash	Allergic reaction, infection, tick-borne illness
Neck	Stridor	Upper airway edema or infection, foreign body, traumatic injury, anaphylaxis, vocal cord dysfunction
	JVD	Tension pneumothorax, fluid overload or CHF, cardiac tamponade
Lung examination	Wheezes	bronchospasm due to asthma, COPD, or anaphylaxis; CHF
	Rales	CHF, pneumonia
	Unilateral decrease	Pneumothorax, pleural effusion, consolidation, rib fractures or contusion, pulmonary contusion
	Hemoptysis	Malignancy, infection, PE, bleeding disorder, CHF
	Sputum production	Infection (viral, bacterial), CHF
	Friction rub	Pleurisy
	Abnormal respiratory pattern (e.g., Cheyne-Stokes)	Intracranial insult
Chest examination	Pain on palpation	Rib or sternal fractures
	Subcutaneous emphysema or crepitus	Pneumothorax, tracheobronchial rupture
	Thoracoabdominal dyssynchrony	Diaphragmatic injury with herniation; cervical spinal cord trauma
	Flail segment	Flail chest, pulmonary contusion
Cardiac examination	Murmur	Valvular dysfunction/CHF
	S_3 or S_4 gallop	PE, CHF
	S_2 accentuation	PE
	Muffled heart sounds	Cardiac tamponade, pericardial effusion
Extremities	Unilateral edema or pain	VTE
	Bilateral Edema	CHF
Neurologic examination	Focal deficits (motor, sensory, cognitive)	Stroke, intracranial hemorrhage causing central abnormal respiratory drive; if long-standing, risk of aspiration pneumonia
	Symmetrical deficits	Neuromuscular disease
	Diffuse weakness	Metabolic or electrolyte abnormality (hypocalcemia, hypomagnesemia, hypophosphatemia), anemia
	Hyporeflexia	Hypermagnesemia
	Ascending weakness	Guillain-Barré syndrome

CHF, Congestive heart failure; *COPD,* chronic obstructive pulmonary disease; *JVD,* jugular venous distention; *PE,* pulmonary embolism.

TABLE 21.3 Diagnostic Table: Patterns of Diseases Often Resulting in Dyspnea

Disease	History (Dyspnea)	Associated Symptoms	Signs and Physical Findings	Tests
Pulmonary embolism	HPI: Abrupt onset, pleuritic pain, immobility (travel, recent surgery) PMH: Malignancy, DVT, PE, hypercoagulability, hormonal therapy, obesity, tobacco use, pregnancy	Pleuritic chest pain, unilateral lower extremity pain or swelling	Tachycardia, tachypnea, low-grade fever	Pulse oximetry, ABG (A-a gradient), D-dimer ECG (dysrhythmia, right-sided heart strain) CXR (Westermark sign, Hampton's hump), CTA, MRV Pulmonary angiogram Ultrasound positive for DVT
Pneumonia	Fever, productive cough, chest pain	Anorexia, chills, nausea, vomiting, cough	Fever, tachycardia, tachypnea, rales or decreased breath sounds	CXR, CBC, sputum and blood cultures
Bacterial	SH: Tobacco use			Pulse oximetry Waveform capnography if altered mental status; ABG if capnography unavailable and acid-base derangement or hypercarbia suspected
Viral	Exposure (e.g., influenza, varicella)			Viral polymerase chain reaction
Opportunistic	Immune disorder, chemotherapy			
Fungal or parasitic	Exposure (e.g., birds), indolent onset	Episodic fever, nonproductive cough		Fungal sputum culture
Pneumothorax	Abrupt onset: Trauma, chest pain, thin males more likely to have spontaneous pneumothorax	Localized chest pain	Decreased breath sounds, subcutaneous emphysema, chest wall wounds or instability	CXR: Pneumothorax, rib fractures, hemothorax Ultrasound: Pneumothorax, pleural effusion
Simple				Ultrasound positive for pneumothorax
Tension	Decompensation of simple pneumothorax	Diaphoresis, lightheadedness	JVD, tracheal deviation, muffled heart sounds, cardiovascular collapse due to obstructive shock	Clinical diagnosis: Requires immediate decompression. May verify via bedside ultrasound
COPD or asthma	Tobacco use, medication noncompliance, URI symptoms, sudden weather change PMH: Environmental allergies FH: Asthma	Air hunger, chest tightness	Retractions, accessory muscle use, tripoding, cyanosis "Shark fin" capnograph	CXR: Rule out infiltrate, pneumothorax, atelectasis (mucus plug) Ultrasound: Distinguish from heart failure Waveform capnography
Malignancy	Weight loss, tobacco, or other occupational exposure	Dysphagia, generalized weakness	Hemoptysis	CXR, chest CT: Mass, hilar adenopathy, focal atelectasis
Fluid overload	Gradual onset, dietary indiscretion or medication noncompliance, chest pain PMH: Recent MI, diabetes, CHF	Worsening orthopnea, PND	JVD, peripheral edema, S_3 or S_4 gallop, new cardiac dysrhythmia, hepatojugular reflux	CXR and/or ultrasound: Pleural effusion, interstitial edema, Kerley B lines, cardiomegaly ECG: Ischemia, dysrhythmia BNP
Anaphylaxis	Abrupt onset, exposure to allergen	Dysphagia, nausea/vomiting, abdominal pain, pruritis	Oral swelling, stridor, wheezing, hives	

A-a, Alveolar-arterial; *ABG,* arterial blood gas; *BNP,* B-type natriuretic peptide; *CBC,* complete blood count; *CHF,* congestive heart failure; *COPD,* chronic obstructive pulmonary disease; *CT,* computed tomography; *CTA,* CT angiography; *CXR,* chest x-ray examination; *DVT,* deep vein thrombosis; *ECG,* electrocardiogram; *FH,* family history; *HPI,* history of present illness; *JVD,* jugular venous distention; *MI,* myocardial infarction; *MRV,* magnetic resonance venography; *PE,* pulmonary embolism; *PMH,* past medical history; *PND,* paroxysmal nocturnal dyspnea; *SH,* social history; *URI,* upper respiratory infection.

TABLE 21.4 Ancillary Testing in the Dyspneic Patient

Category	Test	Findings and Potential Diagnoses
Laboratory	Pulse oximetry, VBG, selective ABG use	Hypoxia, hypercarbia, hyperventilation (muscular weakness, intracranial event)
	Waveform capnography	CO_2 retention (COPD, sleep apnea), obstructive or restrictive pulmonary pattern
		Metabolic versus respiratory acidosis (DKA, ingestions)
		A-a gradient (PE)
		Elevated carboxyhemoglobin (inhalation injury or CO poisoning)
	Complete blood count	WBC
		Increase: Infection, stress demargination, hematologic malignancy
		Decrease: Neutropenia, sepsis
		Hgb, Hct: Anemia, polycythemia
		Smear: Abnormal Hgb (i.e., sickling), inclusions
		Platelets: Thrombocytopenia (marrow toxicity)
		Electrolytes
		BUN, Cr: Acute or chronic renal failure
		K, Mg, PO_4: Low levels resulting in muscular weakness
		Glucose: DKA
		D-dimer: Abnormal clotting activity
		BNP: Heart failure, PE
		Troponin: Cardiac ischemia or infarct
Cardiac	ECG	Ischemia, dysrhythmia, $S_1Q_3T_3$ (PE), right-sided heart strain
	Echocardiogram	Pulmonary hypertension, valvular disorders
		Wall motion abnormalities related to ischemia, intracardiac shunts
Radiologic	Chest radiograph	Bony structures: Fractures, lytic lesions, pectus, kyphoscoliosis
		Mass: Malignancy, cavitary lesion, infiltrate, foreign body
		Diaphragm: Eventration, elevation of hemidiaphragm, bowel herniation
		Mediastinum: Adenopathy (infection, sarcoid), air
		Cardiac silhouette: Enlarged (cardiomyopathy, fluid overload)
		Soft tissue: Subcutaneous air
		Lung parenchyma: Blebs, pneumothorax, effusions (blood, infectious), interstitial edema, local consolidation, air bronchograms, Hampton's hump, Westermark sign
	Ventilation perfusion scan	PE
	Pulmonary angiogram	PE, intervention (thrombolysis)
	CTA	Mass lesion, adenopathy, trauma, PE
	MRI	PE, bony and soft tissue lesions, vascular abnormality
	Soft tissue neck radiograph	Epiglottitis, foreign body
	Ultrasound	Pneumothorax, pleural effusion, impaired cardiac function or pericardial effusion
Fiberoptic	Bronchoscopy	Mass lesion, foreign body
		Intervention (stenting, biopsy)
	Laryngoscopy	Mass lesion, edema, epiglottitis, foreign body

A-a, Alveolar-arterial; *ABG,* arterial blood gas; *BNP,* B-type natriuretic peptide; *BUN,* blood urea nitrogen; *CO,* carbon monoxide; *CO_2,* carbon dioxide; *COPD,* chronic obstructive pulmonary disease; *Cr,* creatinine; *CT,* computed tomography; *CTA,* CT angiography; *DKA,* diabetic ketoacidosis; *ECG,* electrocardiogram; *Hct,* hematocrit; *Hgb,* hemoglobin; *K,* potassium; *Mg,* magnesium; *MRI,* magnetic resonance imaging; *PE,* pulmonary embolism; Phos, phosphate; *VBG,* venous blood gas; *WBC,* white blood cell.

is a less painful alternative while still useful in determining pH and pCO_2.[12,13] An additional noninvasive resource for quickly assessing ventilatory status is waveform capnography. End-tidal carbon dioxide ($ETco_2$) measurement and waveform can be helpful in assessing the adequacy of ventilation, and also can provide clues to the underlying cause of dyspnea (see Chapter 5).[14–16] An electrocardiogram may be useful if history or physical examination findings suggest heart failure, ischemic cardiac disease, dysrhythmia, or right heart strain. Bedside ultrasound can quickly visualize pleural effusion, pulmonary edema, pneumothorax, and cardiovascular anomalies such as regional wall motion abnormalities or global dysfunction, right heart strain, pericardial effusion or tamponade, inferior vena cava size and collapsibility, and lower extremity deep venous thrombosis[17,18] (see Chapter e3) Procalcitonin correlates well with community acquired pneumonia pathogens in admitted patients, but its usefulness in EDs to guide antibiotic therapy has not yet been shown, therefore routine use is not recommended.[19,20]

Serum electrolytes may confirm metabolic acidosis or a less common cause, such as hypokalemia, hypophosphatemia, or hypocalcemia. A complete blood count may identify severe anemia or thrombocytopenia associated with sepsis. The white blood cell count is not sufficiently sensitive or specific to be of discriminatory value.

Expanded availability of specific blood biomarkers relevant to emergent evaluation of dyspnea provides improved immediate decision support, and in some situations, prognostication. These biomarkers include cardiac markers in cardiac ischemia and D-dimer assay in venous thromboembolic disease. B-type natriuretic peptide (BNP) analysis adds both diagnostic and prognostic value for several causes of dyspnea, including heart failure, PE, and ischemic cardiac disease.[21]

If venous thromboembolism is suspected, the use of D-dimer testing, chest computed tomographic angiography (CTA), duplex venous ultrasonography, or, rarely, ventilation-perfusion scanning, is performed on patients identified using clinical decision rules. If dyspnea is believed to be of upper airway origin, direct or fiberoptic laryngoscopy or a soft tissue lateral radiograph of the neck may be useful.

DIAGNOSTIC ALGORITHM

The range and diversity of pathophysiologic conditions that produce dyspnea render a simple algorithmic approach difficult. The primary branch point is the determination of acuity of illness. After initial assessment, stabilization, and symptom relief in critical patients, findings from the history, physical examination, and ancillary testing are collated to match illness scripts related to dyspnea.[22,23] Table 21.3 presents recognizable patterns of disease for common dyspnea-producing conditions, along with specific associated symptoms.

Critical Diagnoses

Several critical diagnoses should be promptly considered to determine the best treatment options for immediate stabilization. The presence of hypotension and dyspnea should raise suspicion for tension pneumothorax and cardiac tamponade, two immediately life-threatening causes of obstructive shock that can quickly be confirmed with bedside ultrasonography (see Chapter e3). Jugular venous distension may or may not be apparent and its absence does not rule out these conditions. Tension pneumothorax is differentiated by asymmetric breath sounds with signs of poor perfusion, and requires prompt decompression via needle thoracostomy. Dyspnea and stridor can indicate upper airway obstruction, which at its worst can require complex maneuvers including emergent consultation by anesthesia, or head and neck surgery, to secure a definitive airway. Complete obstruction by a foreign body warrants abdominal thrusts in adult patients until the obstruction is relieved or the patient is unconscious, followed rapidly by direct laryngoscopy for foreign body removal. ST elevation myocardial infarction requires prompt activation of a cardiac catheterization lab. Hypoxic or hypercarbic respiratory failure may require any of a range of interventions ranging from nasal cannula and non-rebreather mask to noninvasive positive pressure ventilation via mask or endotracheal intubation.[24] Significant dyspnea and wheezing in anaphylaxis requires immediate use of intramuscular epinephrine in addition to supportive airway measures. Bronchospastic exacerbations of asthma at any age may lead rapidly to respiratory failure and arrest and should receive continuous or frequent administration of a beta-agonist aerosol, early steroid and magnesium therapy, and in severe cases intramuscular epinephrine. Presumptive anticoagulation or even thrombolytics, even prior to diagnostic testing or confirmation, may be appropriate in patients presenting with severe symptoms consistent with PE.

Emergent Diagnoses

Asthma and COPD exacerbations can result in marked dyspnea with bronchospasm and decreased ventilatory volumes. Sudden onset of dyspnea with a decreased oxygen saturation on room air accompanied by sharp chest pain may represent PE or pneumothorax. Dyspnea associated with decreased respiratory effort and negative inspiratory force may represent progression of a neuromuscular process, such as multiple sclerosis, Guillain-Barré syndrome, or myasthenia gravis. Unilateral rales, cough, fever, and dyspnea usually indicate pneumonia.

Fig. 21.1 provides an algorithm for assessment and stabilization of a dyspneic patient. The initial division is based on the degree of breathing effort associated with the symptoms. The most critical diagnoses are considered first, and appropriate intervention undertaken.

All patients experiencing dyspnea, regardless of possible cause, should be promptly evaluated. Bedside pulse oximetry readings should be obtained, and the patient placed on a cardiac monitor. If the pulse oximetry is less than 92% on room air, supplemental oxygen either by nasal cannula or mask should be administered, depending on the degree of desaturation. In patients with somnolence or obtundation, hypercarbia and respiratory failure should be considered as possible etiologies and waveform capnography used for confirmation. Ventilation should be assisted manually or mechanically, either noninvasively for the short term, or with endotracheal intubation for prolonged ventilation.

Decreased mental alertness, inability to speak in full sentences, or certain types of body positioning (tripod) signal the presence of significant respiratory distress and the need for rapid intervention.

Empirical Management

The management algorithm for dyspnea (Fig. 21.2) outlines the approach to treatment for most identifiable diseases. Empiric treatments are typically directed at optimizing oxygenation, ventilation, and overall work of breathing. There are few other treatments directed at the symptom itself, rather than the underlying diagnosis. Opiate medications and sedatives help to relieve the sensation of air hunger and anxiety, but their use is generally reserved for the palliative care setting due to their respiratory depressant effects.

Unstable patients or patients with critical diagnoses must be stabilized and may require admission to an intensive care unit or an emergent procedure. Urgent patients who improve with ED management may be admitted to an intermediate care unit. Patients diagnosed with urgent conditions in danger of deterioration without proper treatment or patients with severe comorbidities, such as diabetes, immunosuppression, or cancer, may also require admission for observation and treatment.

Most patients in the nonurgent category can be treated as outpatients if medical follow-up can be arranged. If dyspnea persists despite therapy and no definitive cause has been delineated, the preferred course of action is hospitalization for observation and further evaluation. If no definitive diagnosis can be obtained and the symptoms have abated, the patient may be discharged with medical follow-up and instructions to return if symptoms recur.

CHAPTER 21: QUESTIONS AND ANSWERS

1. Orthopnea is best defined by which of the following?
- **a.** A respiratory rate greater than normal
- **b.** A tidal volume that exceeds metabolic demands
- **c.** Decreased end-tidal carbon dioxide levels
- **d.** Dyspnea in a recumbent position

Answer: d. Dyspnea in a recumbent position, commonly described as the number of pillows the patient uses to rest comfortably in bed (e.g., two-pillow orthopnea).

2. Stridor is most likely due to which of the following conditions?
- **a.** Bronchospasm
- **b.** Guillain-Barré syndrome
- **c.** Laryngeal edema
- **d.** Malignancy

Answer: c. Stridor is an upper airway noise caused by airway narrowing. Of the given options, stridor is most likely due to laryngeal edema.

3. A 34-year-old male was struck repeatedly with a pipe in the right chest. He becomes acutely more dyspneic during emergency medical services (EMS) transport and becomes clammy, hypotensive, and more tachycardic on arrival to the emergency department (ED). Examination reveals tachypnea, right chest crepitus, and decreased breath sounds. Which of the following actions should be done next?
- **a.** Needle chest decompression of the right chest
- **b.** Perform portable chest radiograph
- **c.** Provide supplemental oxygen by non-rebreather mask
- **d.** Rapid sequence intubation (RSI) and endotracheal intubation

Answer: a. Needle chest decompression is indicated for management of a likely tension pneumothorax. If ultrasound is immediately available, it can be used to confirm pneumothorax, but in this patient, who is in cardiovascular collapse, immediate intervention is necessary.

4. Which of the following causes of acute respiratory distress is most likely to be associated with decreased respiratory effort?
- **a.** Pleural effusion
- **b.** Tension pneumothorax
- **c.** Cyanide poisoning
- **d.** Multiple sclerosis

Answer: d. multiple sclerosis. Several different neuromuscular diseases are associated with decreased respiratory effort in acute distress due largely to inadequate ability to create sufficient negative inspiratory force and generate adequate tidal volume and minute ventilation.

CHAPTER 21: QUESTIONS AND ANSWERS—Cont'd

5. When assessing a patient with acute respiratory distress, a shark fin waveform on capnography suggests which of the following conditions?

a. Cardiac ischemia
b. Pneumothorax
c. Pulmonary embolism
d. Pneumonia
e. Bronchospasm

Answer: e. Bronchospasm. The classic "shark fin" indicates bronchospasm such as with significant asthma exacerbation. See Fig. 21.1 for assessment paradigm considerations.

22

Chest Pain

James E. Brown

KEY CONCEPTS

- Tension pneumothorax is a clinical diagnosis, treated with needle decompression, followed by tube thoracostomy.
- Patients with suspected acute coronary syndrome (ACS) are risk-stratified by history, electrocardiogram (ECG), and troponin levels. Those with ST segment elevation myocardial infarction (STEMI) undergo revascularization via fibrinolysis or percutaneous coronary intervention (PCI). Those with non–ST segment elevation myocardial infarction (NSTEMI) do not require immediate PCI. Those with a nondiagnostic ECG and troponin level are managed with observation.
- Thoracic dissection is diagnosed with CT angiography. The initial management of dissection is with urgent control of heart rate, followed by lowering of blood pressure. Further management, medical or surgical, depends on the location of the dissection.
- Pulmonary embolism is diagnosed using a combination of history, serum D-dimer measurement, and imaging, usually CT angiography. Patients with a low pretest probability and normal D-dimer level do not have pulmonary embolism as the cause of their chest pain presentation.
- Patients with pericardial effusions undergo echocardiography to evaluate for cardiac tamponade. Those with signs of shock may require emergent pericardiocentesis.

FOUNDATIONS

Approximately 7.5 million patients visit the emergency department (ED) each year with complaints of chest pain, constituting 5% of all patients seen in EDs in the United States.[1] Chest pain is a symptom caused by several life-threatening as well as non–life-threatening diseases and has a broad differential diagnosis. It is complicated by a frequent disassociation between the intensity of symptoms and signs and the seriousness of underlying pathology.

Epidemiology

The epidemiology of the critical diagnoses causing chest pain varies widely. Acute coronary syndrome (ACS), aortic dissection, pulmonary embolism (PE), pneumothorax, pericarditis with tamponade, and esophageal rupture are potentially catastrophic causes of chest pain. These are discussed in the relevant chapters in this text. Chest pain that is atypical or of unclear cause is a daily presentation in virtually every ED—large or small, academic or community, urban, suburban, or rural.

Pathophysiology

Afferent fibers from the heart, lungs, great vessels, and esophagus enter the same thoracic dorsal ganglia. Through these visceral fibers, each organ produces the same indistinct quality and location of pain. The quality of visceral chest pain varies widely and is described as "burning," "aching," "stabbing," or "pressure." Because dorsal segments overlap three segments above and below a level, disease of a thoracic origin can produce pain anywhere from the jaw to the epigastrium. Radiation of pain is caused by somatic afferent fibers synapsing in the same dorsal root ganglia as the thoracic viscera. This stimulation can confuse the patient's central nervous system into misperceiving that the pain originates in the arms, shoulders, or neck.

DIAGNOSTIC APPROACH

Differential Considerations

Because of the indistinct nature of visceral pain, the differential diagnosis of chest pain is broad and includes many of the most critical diagnoses in medicine and many nonemergent conditions (Table 22.1).

All patients, except those with obvious benign causes of chest pain, undergo electrocardiography as soon as possible after reporting their pain. The electrocardiogram (ECG) should be read for acute myocardial infarction (MI) by the emergency clinician promptly after it is completed.[2] Patients with positive electrocardiographic findings and those considered at high risk are triaged directly to the treatment area and monitored.

In clinical evaluation of the patient, the initial questions are "Should I intervene now?" and "What are the life-threatening possibilities in this patient?" The answers are usually apparent within the first few minutes after assessment of the patient's appearance, ECG, and vital signs. If a patient has unilateral chest pain, respiratory distress, shock, and unilateral reduction or absence of breath sounds, emergent intervention with needle or tube thoracostomy is required. In addition, patients with severe derangements in vital signs require stabilizing treatment during a search for the precipitating cause. Patients with respiratory distress require prompt intervention and lead the emergency clinician to consider a more serious cause of the pain (Fig. 22.1).

Symptomatic derangements in vital signs are addressed. If vital signs are stable, a focused history and physical examination are performed. Many patients also require a chest radiograph to evaluate the chest pain. If myocardial ischemia is suspected, aspirin and nitroglycerin may be appropriate. Patients with pain, findings suggestive of aortic dissection, and significant hypertension are candidates for immediate reduction of blood pressure (see Chapter 71). Patients with low voltage on the ECG, diffuse ST segment elevation, elevated jugular venous pressure on examination, and signs of shock should undergo prompt bedside cardiac ultrasound to evaluate for pericardial tamponade.[3]

Pivotal Findings

The broad and complex nature of chest pain defies application of a simple algorithm. An organized approach to a patient with chest pain is essential, however, to ensure that all causes are evaluated appropriately. The history and physical examination are key to diagnosis. Information pertinent to the differential diagnosis is obtained through the directed history, physical examination, and ECG in 80% to 90% of patients.

TABLE 22.1 Differential Diagnosis of Chest Pain

Organ System	Critical Diagnoses	Emergent Diagnoses	Nonemergent Diagnoses
Cardiovascular	Acute myocardial infarction	Unstable angina	Valvular heart disease
	Acute coronary ischemia	Coronary spasm	Aortic stenosis
	Aortic dissection	Prinzmetal angina	Mitral valve prolapse
	Cardiac tamponade	Cocaine-induced pericarditis or myocarditis	Hypertrophic cardiomyopathy
Pulmonary	Pulmonary embolus	Pneumothorax	Pneumonia
	Tension pneumothorax	Mediastinitis	Pleuritis, tumor, pneumomediastinum
Gastrointestinal	Esophageal rupture (Boerhaave syndrome)	Esophageal tear (Mallory-Weiss)	Esophageal spasm
		Cholecystitis	Esophageal reflux
		Pancreatitis	Peptic ulcer, biliary colic
Musculoskeletal			Muscle strain, rib fracture, arthritis, tumor, costochondritis, nonspecific chest wall pain
Neurologic			Spinal root compression, thoracic outlet, herpes zoster, postherpetic neuralgia
Other			Psychological, hyperventilation

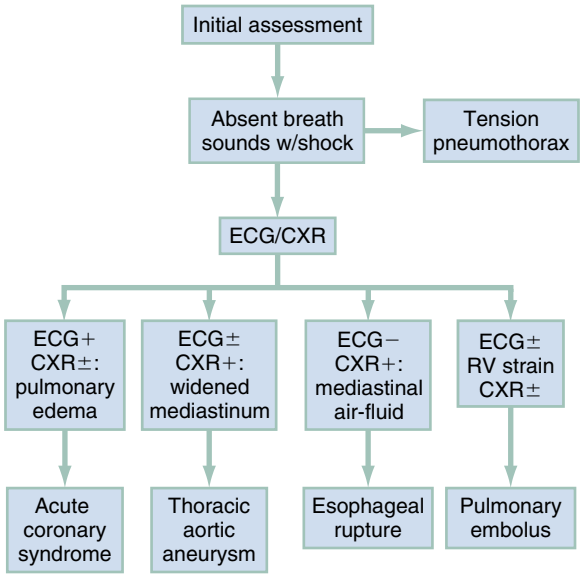

Fig. 22.1 Initial Assessment of Critical Diagnoses. *CXR,* Chest x-ray study; *ECG,* electrocardiogram; *RV,* right ventricular.

History

The patient is asked to describe the character of the pain or discomfort. Descriptions such as "squeezing," "crushing," or "pressure" lead the emergency clinician to suspect a cardiac ischemic syndrome, although cardiac ischemia can also be characterized by nonspecific discomfort, such as "bloating" or "indigestion." "Tearing" pain that may migrate from the front to back or back to front is the classic description in aortic dissection. "Sharp" or "stabbing" pain is seen more in pulmonary and musculoskeletal diagnoses. Patients reporting a "burning" or "indigestion" type of pain may initially be thought to have a gastrointestinal condition, but owing to the visceral nature of chest pain, patients with all causes of pain may report any of the preceding descriptions. Of note, descriptors may vary among ethnic groups; for example, "sharp" may mean "severe."

Additional history about the patient's activity at the onset of pain may be helpful. Pain occurring during exertion suggests an ischemic coronary syndrome, whereas progressive onset of pain at rest suggests an acute MI. Pain of sudden onset is more typical with aortic dissection, PE, or pneumothorax. Pain after meals is more indicative of a gastrointestinal cause.

The severity of pain is commonly quantified with a 1 to 10 pain scale. Alterations in pain severity are documented at times of onset, at peak, at present, and after intervention.

The location of the discomfort is described. Pain that is localized to a small area is more likely to be somatic versus visceral in origin. Pain localized at the periphery of the chest is more likely to have a pulmonary rather than cardiac cause. Lower chest or upper abdominal pain may be of cardiac or gastrointestinal origin.

Any description of radiation of pain should be noted. Transthoracic pain through to the back should suggest aortic dissection or gastrointestinal causes, especially pancreatitis, cholecystitis, or posterior ulcer. Inferoposterior myocardial ischemia may also manifest primarily as thoracic back pain. Radiation to the arms, neck, or jaw increases the likelihood of cardiac ischemia. Pain located primarily in the back, especially interscapular back pain that migrates to the base of the neck, suggests aortic dissection.

Duration of pain is another important historical factor. Pain that lasts a few seconds or minutes is rarely of cardiac origin. Pain that is exertional but abates with a few minutes of rest may be a manifestation of cardiac ischemia. Pain that is maximal at onset may be caused by aortic dissection.[4,5] Pain that is not severe and persists over the course of days is less likely to be of serious origin than pain that is severe or has a stuttering or fluctuating course.

The emergency clinician should consider aggravating or alleviating factors. Pain that worsens with exertion and improves with rest is more likely related to coronary ischemia. Pain related to meals is more suggestive of a gastrointestinal cause. Pain that worsens with respiration is seen more often with pulmonary, pulmonary vascular, pericardial, and musculoskeletal causes.

Other associated symptoms may suggest the visceral nature of the pain (Table 22.2). Diaphoresis is uncommonly associated with somatic pain unless it is severe, such as with rib fractures, so the presence of diaphoresis should prompt a search for a serious or visceral cause and points away from a chest wall origin. Hemoptysis, a classic PE sign, is rarely seen. Near-syncope and syncope suggest a higher likelihood of a cardiovascular cause or PE. Dyspnea is seen in cardiovascular and pulmonary disease. Nausea and vomiting may be seen in those with cardiovascular and gastrointestinal complaints.

TABLE 22.2 Significant Symptoms of Chest Pain

Symptom	Findings	Diagnosis
Pain	Severe, crushing, pressure, substernal, exertional, radiation to jaw, neck, shoulder, arm	Acute MI, coronary ischemia, unstable angina, coronary spasm
	Tearing, severe, radiating to or located in back, maximum at onset, may migrate to upper back or neck	Aortic dissection
	Pleuritic	Esophageal rupture, pneumothorax, cholecystitis, pericarditis, myocarditis
	Indigestion or burning	Acute MI, coronary ischemia, esophageal rupture, unstable angina, coronary spasm, esophageal tear, cholecystitis
Associated syncope or near-syncope		Aortic dissection, PE, acute MI, pericarditis, myocarditis
Associated dyspnea (SOB, DOE, PND, orthopnea)		Acute MI, coronary ischemia, PE, tension pneumothorax, pneumothorax, unstable angina, pericarditis
Associated hemoptysis		PE
Associated nausea, vomiting		Esophageal rupture, acute MI, coronary ischemia, unstable angina, coronary spasm, esophageal tear, cholecystitis

DOE, Dyspnea on exertion; *MI,* myocardial infarction; *PE,* pulmonary embolism; *PND,* paroxysmal nocturnal dyspnea; *SOB,* shortness of breath.

BOX 22.1 Risk Factors Associated With Potentially Catastrophic Causes of Chest Pain

Acute coronary syndromes
- Past or family history of coronary artery disease
- Age
  - Men >33 years
  - Women >40 years
- Diabetes mellitus
- Hypertension
- Cigarette use or possible passive exposure
- Elevated cholesterol (low-density lipoprotein [LDL]) or triglyceride levels
- Sedentary lifestyle
- Obesity
- Postmenopausal
- Left ventricular hypertrophy
- Cocaine abuse

Pulmonary embolism
- Malignancy
- Prolonged immobilization
- Surgery >30 min in last 3 months
- Prior deep vein thrombosis or pulmonary embolus
- Pregnancy or recent pregnancy
- Pelvic or lower extremity trauma
- Oral contraceptives with cigarette smoking
- Congestive heart failure
- Chronic obstructive pulmonary disease
- Obesity
- Past medical or family history of hypercoagulability

Aortic dissection
- Hypertension
- Congenital disease of the aorta or aortic valve
- Inflammatory aortic disease
- Connective tissue disease
- Pregnancy
- Arteriosclerosis
- Cigarette use

Pericarditis or myocarditis
- Infection
- Autoimmune disease (e.g., systemic lupus erythematosus)
- Acute rheumatic fever
- Recent myocardial infarction or cardiac surgery
- Malignancy
- Radiation therapy to mediastinum
- Uremia
- Drugs
- Prior pericarditis

Pneumothorax
- Prior pneumothorax
- Valsalva maneuver
- Chronic lung disease
- Cigarette use

A history of prior pain and diagnosis of that episode may facilitate the diagnostic process, but the emergency clinician should not allow the prior diagnosis to form an anchoring bias and be misled. A prior history of cardiac testing, such as stress testing, echocardiography, or angiography, may be useful in determining if the current episode is suggestive of cardiac disease. Similarly, patients with previous spontaneous pneumothorax or PE are at increased risk of recurrence.

The presence of risk factors for a particular disease is primarily of value as an epidemiological marker for large population studies (Box 22.1). In the ED, presence of risk factors in an individual patient without established disease has minimal or no effect on the clinical likelihood (pretest probability) of a specific disease process.

Physical Examination

Specific findings may be found with a variety of causes (Table 22.3).

Ultrasound

Point-of-care ultrasonography (POCUS) is an emerging, important tool in the evaluation of chest pain.[6,7] It is a quick, economical, noninvasive way to evaluate the patient with chest pain in whom the diagnosis is not readily apparent.[8] POCUS has improved sensitivity over chest

TABLE 22.3 Pivotal Findings in Physical Examination

Sign	Finding	Diagnoses
Appearance	Acute respiratory distress	PE, tension pneumothorax, acute MI, pneumothorax
	Diaphoresis	Acute MI, aortic dissection, coronary ischemia, PE, esophageal rupture, unstable angina, cholecystitis, perforated peptic ulcer
Vital signs	Hypotension	Tension pneumothorax, PE, acute MI, aortic dissection (late), coronary ischemia, esophageal rupture, pericarditis, myocarditis
	Tachycardia	Acute MI, PE, aortic dissection, coronary ischemia, tension pneumothorax, esophageal rupture, coronary spasm, pericarditis, myocarditis, mediastinitis, cholecystitis, esophageal tear (Mallory-Weiss)
	Bradycardia	Acute MI, coronary ischemia, unstable angina
	Hypertension	Acute MI, coronary ischemia, aortic dissection (early)
	Fever	PE, esophageal rupture, pericarditis, myocarditis, mediastinitis, cholecystitis
	Hypoxemia	PE, tension pneumothorax, pneumothorax
Cardiovascular examination	Significant difference in upper extremity blood pressures	Aortic dissection
	Narrow pulse pressure	Pericarditis (with effusion)
	New murmur	Acute MI, aortic dissection, coronary ischemia
	S3–S4 gallop	Acute MI, coronary ischemia
	Pericardial rub	Pericarditis
	Audible systolic "crunch" on cardiac auscultation (Hamman's sign)	Esophageal rupture, mediastinitis
	JVD	Acute MI, coronary ischemia, tension pneumothorax, PE, pericarditis
Pulmonary examination	Unilateral diminished or absent breath sounds	Tension pneumothorax, pneumothorax
	Pleural rub	PE
	Subcutaneous emphysema	Tension pneumothorax, esophageal rupture, pneumothorax, mediastinitis
	Rales	Acute MI, coronary ischemia, unstable angina
Abdominal examination	Epigastric tenderness	Esophageal rupture, esophageal tear, cholecystitis, pancreatitis
	Left upper quadrant tenderness	Pancreatitis
	Right upper quadrant tenderness	Cholecystitis
Extremity examination	Unilateral leg swelling, warmth, pain, tenderness, or erythema	PE
Neurologic examination	Focal findings	Aortic dissection
	Stroke	Acute MI
	Coronary ischemia	Aortic dissection, coronary spasm

JVD, Jugular venous distention; *MI,* myocardial infarction; *PE,* pulmonary embolism.

radiography in many important diagnoses with improved sensitivity over all of these except pneumonia. POCUS is useful in the evaluation of the following conditions: pericardial effusion/tamponade, pneumothorax, pleural effusion, pulmonary edema, acute coronary syndrome, and PE.[9] Should an intimal flap be identified, it is useful in the diagnosis of thoracic dissection.[10,11]

Ancillary Studies

The two most commonly performed studies in patients with chest pain are chest radiography and 12-lead electrocardiography (Table 22.4). Electrocardiography should be performed as quickly as feasible and ideally within 10 minutes of arrival in all patients with chest pain or potential angina equivalent in whom myocardial ischemia is a possibility.[2,12] This generally includes all patients who report pain from the umbilicus to the mandible, unless a noncardiac cause is readily apparent. Rapid acquisition of the ECG facilitates the diagnosis of acute MI and expedites the recommended door to treatment times for PCI or fibrinolytic therapy in acute MI. Patients with a new injury pattern on the ECG (Table 22.5) or new ischemic electrocardiographic changes should have appropriate therapy instituted at this point (Fig. 22.2; see also Chapter 64). An ECG showing right ventricular strain pattern, in the appropriate setting, should raise the clinical suspicion for PE.[13,14] Diffuse ST segment elevation helps confirm the diagnosis of pericarditis.[15]

Chest radiography is performed for patients with a possibly serious cause of chest pain. Pneumothorax, pneumonia, empyema, and pleural effusion are definitively diagnosed at this point. A wide mediastinum or ill-defined aortic knob increases the clinical suspicion for acute aortic dissection. Pleural effusion, subcutaneous air, or mediastinal air-fluid level may be seen in esophageal rupture.[16] An increased cardiac silhouette may indicate pericarditis or cardiomyopathy. Pneumomediastinum is seen with esophageal rupture and mediastinitis.[16]

A serum D-dimer assay may help discriminate patients with PE from those with a possible gastrointestinal cause. A low serum D-dimer level in a patient without a high pretest probability of PE effectively excludes the diagnosis.[13,17,18] Patients with a low pretest probability who meet certain defined criteria do not require further testing (see Chapter 74).

Patients at high pretest probability for PE should undergo diagnostic imaging. High pretest probability warrants initiation of anticoagulation

TABLE 22.4 Ancillary Testing of Patients With Chest Pain

Test	Finding	Diagnosis
ECG	New injury	Acute MI, aortic dissection
	New ischemia	Coronary ischemia, coronary spasm
	RV strain	PE
	Diffuse ST segment elevation/Electrical Alternans	Pericarditis
CXR	Pneumothorax with mediastinal shift	Tension pneumothorax
	Wide mediastinum	Aortic dissection
	Pneumothorax	Esophageal rupture, pneumothorax
	Effusion	Esophageal rupture
	Increased cardiac silhouette	Pericarditis
	Pneumomediastinum	Esophageal rupture, mediastinitis
ABG	Hypoxemia, A-a gradient	PE
CT with contrast	Intimal tear in aorta	Aortic dissection
	Clot in pulmonary artery	Pulmonary embolism
	Esophageal wall edema, pneumomediastinum, periesophageal fluid, pleural effusion	Esophageal rupture
Bedside ultrasound	Pericardial fluid	Pericarditis/tamponade
	Loss of lung sliding	Pneumothorax
scan	High probability or any positive in patient with high clinical suspicion	PE

A-a, Alveolar-arterial; *ABG,* arterial blood gas; *CT,* computed tomography; *CXR,* chest x-ray examination; *ECG,* electrocardiography; *MI,* myocardial infarction; *PE,* pulmonary embolism; *RV,* right ventricular; , ventilation-perfusion.

TABLE 22.5 Electrocardiographic Findings in Ischemic Chest Pain

	Findings
Classic myocardial infarction	ST segment elevation (>1 mm) in contiguous leads; new LBBB
	Q waves > 0.04-s duration
Subendocardial infarction	T wave inversion or ST segment depression in concordant leads
Unstable angina	Most often normal or nonspecific changes; may see T wave inversion
Pericarditis	Diffuse ST segment elevation; PR segment depression

LBBB, left bundle branch block.

(e.g., with heparin or low-molecular-weight heparin, DOAC [rivaroxaban or apixaban]) therapy in the ED before the imaging study in the absence of a contraindication.[13]

Patients with suspected thoracic aortic dissection may be evaluated by computed tomography (CT) angiography, transesophageal echocardiography, or magnetic resonance imaging. Selection of the imaging modality depends on the patient's clinical status and availability of the test modality.[5]

A high-resolution (>64 slice) CT scanner can be used to rule out all the life-threatening causes of chest pain. Although ACS, PE, and thoracic dissection (the so-called triple rule-out) are the causes most commonly discussed, pneumothorax, mediastinitis, and pericardial effusions are also diagnosed with CT.

Laboratory testing is useful in the evaluation of ACS. An elevated troponin level in the correct clinical setting is synonymous with acute MI and is embedded in the universal definition of MI.[19] Troponins (I and T), when elevated, identify patients with ACS who have the highest risk for an adverse outcome. Sensitivity for acute MI at 4 hours is approximately 50%, rising to nearly 100% by 12 hours. Creatine kinase (CK) and CK-MB are used only if determination of the troponin level is unavailable. [19]

DIAGNOSTIC ALGORITHM

After the patient is stabilized and assessment is completed, the findings are matched to the classical and atypical patterns of the seven potentially critical diseases causing chest pain. This matching process is continuous while the patient is evaluated and the response to therapy is monitored. Any inconsistency in findings with the primary working diagnoses necessitates a rapid review of the pivotal findings and the potential diagnoses (Table 22.6).

EMPIRICAL MANAGEMENT

The management of ACS is discussed in Chapter 64. Fig. 22.3 outlines the approach to treatment of critical noncardiac diagnoses. Patients with critical diagnoses generally are admitted to the intensive care unit. Patients with emergent diagnoses typically are admitted to the hospital, most often on telemetry units. Patients with nonemergent diagnoses are usually treated as outpatients. Hospitalization is required in certain cases, particularly when patients have other comorbid conditions.

Frequently, no definitive diagnosis is established. Any patient with almost any type of chest pain may be having coronary ischemia, PE, or aortic dissection. When a clear pattern does not emerge to allow the emergency clinician to make an alternative diagnosis confidently, or if the pattern of symptoms clearly is not compatible with a serious disorder, such as coronary ischemia, continued evaluation, hospitalization, or observation admission may be the best course.

TABLE 22.6 Causes and Differentiation of Potentially Catastrophic Illness Manifesting With Central Chest Pain or Discomfort

	Pain History	Associated Symptoms	Supporting History	Prevalence in Emergency Department	Physical Examination	Useful Tests	Atypical or Additional Aspects
Myocardial infarction	Discomfort is usually moderately severe to severe and rapid in onset. May be more "pressure" than pain. Usually retrosternal, may radiate to neck, jaw, both arms, upper back, epigastrium, and sides of chest (left more than right). Lasts more than 15–30 min and is unrelieved by NTG.	Diaphoresis, nausea, vomiting, dyspnea.	May be precipitated by emotional stress or exertion. Often comes on at rest. May come on in early awakening period. Prodromal pain pattern often elicited. Previous history of MI or angina. Age >40 years, positive risk factors, and male sex increase possibility.	Common.	Patients are anxious and uncomfortable. Blood pressure usually is elevated, but normotension and hypotension are seen. The heart rate is usually mildly increased, but bradycardia can be seen. Patients may be diaphoretic and show peripheral poor perfusion. There are no diagnostic examination findings for MI, although S3 and S4 heart sounds and new murmur are supportive.	ECG changes (new Q waves or ST segment–T wave changes) occur in 80% of patients. CK-MB and troponins are helpful if elevated, but may be normal.	Pain may be reported as "indigestion" or "unable to describe." Other atypical presentations include altered mental status, stroke, angina pattern without extended pain, severe fatigue, syncope. Elderly may have weakness, congestive heart failure, or chest tightness. 25% of nonfatal MIs are unrecognized by patient. The pain may have resolved by the time of evaluation.
Unstable angina	Changes in pattern of preexisting angina with more severe, prolonged, or frequent pain (crescendo angina). Pain usually lasts >10 min. Angina at rest lasting 15–20 min or new-onset angina (duration <2 months) with minimal exertion. Pattern of pain change important in gauging risk for AMI. Unpredictable responses to NTG and rest.	Often minimal. May have mild diaphoresis, nausea, dyspnea with pain. Increasing pattern of dyspnea on exertion.	Not clearly related to precipitating factors. May be a decrease in amount of physical activity that initiates pain. Previous history of MI or angina. Older than 40 years, presence of risk factors, and male sex increase probability.	Common.	Nonspecific findings of a transient nature; may have similar cardiac findings as in MI, especially intermittent diaphoresis.	Often no ECG or enzyme changes. Variant angina (Prinzmetal) has episodic pain, at rest, often severe, with prominent ST segment elevation.	May be pain-free at presentation. Full history is essential. Fewer than 15% of patients hospitalized for unstable angina go on to acute MI. May respond to NTG. May manifest similarly to non–Q wave infarction.
Aortic dissection	90% of patients have rapid-onset severe chest pain that is maximal at beginning. Radiates anteriorly in chest to the back interscapular area or into abdomen. Pain often has a "tearing" sensation and may migrate.	Neurologic complications of stroke, peripheral neuropathy, paresis or paraplegia, abdominal and extremity ischemia possible.	Median age, 59 years. History of hypertension in 70%–90% of patients. 3:1 ratio, males to females. Marfan syndrome and congenital bicuspid aortic valves have increased incidence.	Rare.	Often poorly perfused peripherally but with elevated BP. In 50%–60% of cases, there is asymmetric decrease or absence of peripheral pulses; 50% of proximal dissections cause aortic insufficiency. Other vascular occlusions—coronary (1%–2%), mesentery, renal, spinal cord. New-onset pericardial friction rub or aortic insufficiency murmur supportive of diagnosis.	ECG usually shows left ventricular hypertrophy, nonspecific changes. Chest film shows abnormal aortic silhouette (90%). Aortic angiography has diagnostic accuracy of 95%–99%. Transesophageal echocardiogram, CT, MRI most useful in screening.	Rare for patient to be pain-free. May have neurologic complications. Physical examination findings may be minimal. Dissection into coronary arteries can mimic MI. Ascending aortic aneurysms are more often approached surgically. Descending are generally managed medically.

Continued

TABLE 22.6 Causes and Differentiation of Potentially Catastrophic Illness Manifesting With Central Chest Pain or Discomfort—cont'd

	Pain History	Associated Symptoms	Supporting History	Prevalence in Emergency Department	Physical Examination	Useful Tests	Atypical or Additional Aspects
Pulmonary embolism	Pain is more often lateral pleuritic. Central pain is more consistent with massive embolus. Abrupt in onset and maximal at beginning. May be episodic or intermittent.	Dyspnea and apprehension play a prominent role, often more than pain. Cough accompanies about 50% of cases. Hemoptysis occurs in < 20%. Angina-like pain may occur in 5%.	Often some period of immobilization has occurred (e.g., postoperative). Pregnancy, oral contraceptives, heart disease, and cancer are all risk factors. Previous DVT or PE is the greatest risk factor.	Uncommon in ambulatory patients but common in departments with high volumes of older or medically complex patients.	Patients are anxious and often have respiratory rate >16 breaths/min. Tachycardia, inspiratory rales, and an increased pulmonic second sound are common. Fever, phlebitis, and diaphoresis are seen in 30%–40% of patients. Wheezes and peripheral cyanosis are less common.	Arterial blood gases show Po2 <80 mm Hg in 90%. Widened A-a gradient is helpful. Chest film is usually normal, although 40% show some volume loss, oligemia, or signs of consolidation caused by pulmonary infarction. Lung perfusion scan rules out, if truly negative.	Patients may have dyspnea, with or without bronchospasm. Acute mortality rate is 10%. Emboli usually from lower extremities above knee, prostate or pelvis venous plexus, right side of heart. May be subtle cause of COPD exacerbation.
Pneumothorax	Pain is usually acute and maximal at onset. Most often lateral pleuritic, but central pain can occur in large pneumothorax.	Dyspnea has a prominent role. Hypotension and altered mental states occur in tension pneumothorax.	Chest trauma, previous episode, or asthenic body type.	Infrequent.	Decreased breath sounds, increased resonance on percussion. Elevated pressure in neck veins occurs in tension pneumothorax.	Chest film definitive. Inspiratory and expiratory films may enhance contrast between air and lung parenchyma. Tension pneumothorax should be diagnosed on physical examination.	May be subtle in COPD, asthma, cystic fibrosis. Can be complicated by pneumomediastinum.
Esophageal rupture	Pain usually is preceded by vomiting and is abrupt in onset. Pain is persistent and unrelieved, localized along the esophagus, and increased by swallowing and neck flexion.	Diaphoresis, dyspnea (late), shock.	Older individual with known gastrointestinal problems. History of violent emesis, foreign body, caustic ingestion, blunt trauma, alcoholism, esophageal disease.	Rare.	Signs of lung consolidation, subcutaneous emphysema may be present.	Chest film usually has mediastinal air, a left-sided pleural effusion, pneumothorax, or a widened mediastinum. pH of pleural effusion <6.0. Diagnosis supported by water-soluble contrast esophagram or esophagoscopy.	Patient may be in shock state. This entity often considered late in differential diagnostic process.
Pericarditis	Dull, aching recurrent pain unrelated to exercises or meals, or it may be a sharp, stabbing, pleuritic-type pain that does not change with chest wall motion. May be severe. Not relieved by NTG.	Dyspnea, diaphoresis.	Pain is often worse when supine but improves sitting up. Often preceded by viral illness or underlying disease (SLE or uremia).	Rare. Tamponade even more rare complication.	Friction rub may be heard, often fleeting, position-dependent (50% of patients).	ECG pattern typical for ST segment elevation across the precordial leads. Erythrocyte sedimentation rate may be elevated.	More common in 20- to 50-year-olds. May have associated tachycardias, ventricular dysrhythmias. Idiopathic most common (80%). Treated with aspirin, NSAIDs.

CHAPTER 22: QUESTIONS AND ANSWERS

1. A 25-year-old man presents with the sudden onset of unilateral chest pain, followed almost immediately by respiratory distress. He is noted to have a blood pressure of 75/45 mm Hg, pulse of 130 beats/min, and decreased breath sounds on the right side of his chest. What is the most appropriate initial step in the management of this patient?

a. Administer intravenous (IV) antibiotics.
b. Infuse a 2-L bolus of normal saline.
c. Obtain a chest radiograph.
d. Perform a tube thoracostomy.

Answer: d. Tension pneumothorax is a critical diagnosis that must be made and remedied, if present, in the first few moments of the rapid stabilization and assessment phase of any patient encounter. If a patient presents with chest pain, respiratory distress, shock, and unilateral reduction or absence of breath sounds, immediate intervention with needle or tube thoracostomy is required.

2. A 65-year-old man with a past medical history of prostate cancer presents with chest pain. His blood pressure is 60/40 mm Hg, and his pulse is 145 beats/min. The ECG shows diffuse ST segment elevation, and cardiomegaly is seen on his chest radiograph. What is the most appropriate first step in the management of this patient?

a. Administration of dobutamine
b. Thrombolysis
c. Cardiac catheterization
d. Cardiac ultrasonography

Answer: d. Prompt bedside cardiac ultrasonography would be the most appropriate next step in the management of this patient, who presents with symptoms and signs of pericardial effusion with tamponade. If confirmed by ultrasonography, immediate pericardiocentesis would logically follow in an effort to reverse the signs of shock in this patient. Other signs that could accompany the presentation are low voltage on the ECG and elevated jugular venous pressure on examination.

3. A "tearing" sensation is classically described for which of the following causes of chest pain?

a. Aortic dissection
b. Esophageal rupture
c. Mallory-Weiss tear
d. Pneumothorax

Answer: a. "Tearing" pain that may migrate from the front to back or back to front is classically described in aortic dissection. Descriptions such as "squeezing," "crushing," or "pressure" lead to the suspicion of a cardiac ischemic syndrome, although cardiac ischemia can be characterized by nonspecific discomfort, such as "bloating" or "indigestion." "Sharp" or "stabbing" pain is seen more in pulmonary and musculoskeletal diagnoses. Patients complaining of a burning- or indigestion-type of pain may initially be suspected of having a gastrointestinal cause; however, because of the visceral nature of chest pain, all causes of pain may present with any of the preceding descriptions.

4. Uremia is a risk factor associated with which of the following causes of chest pain?

a. Acute coronary syndrome
b. Aortic dissection
c. Pericarditis
d. Pneumothorax
e. Pulmonary embolism

Answer: c. Uremia is a risk factor for the development of pericarditis. Other risk factors associated with the development of pericarditis include infection, autoimmune disease, acute rheumatic fever, recent myocardial infarction or cardiac surgery, malignancy, radiation therapy to the mediastinum, and prior pericarditis.

5. A narrow pulse pressure is more closely associated with which of the following diagnoses?

a. Acute myocardial infarction
b. Aortic dissection
c. Pericarditis with effusion
d. Pulmonary embolism

Answer: c. A narrow pulse pressure is a pivotal finding in the diagnosis of pericarditis with associated pericardial effusion. Other characteristic, but less specific, potential findings in the patient with pericarditis include hypotension, tachycardia, fever, and jugular venous distention (JVD). The more specific finding of pericardial rub is also heard in some patients with pericarditis.

6. The finding of Hamman's sign is most consistent with which of the following?

a. Cholecystitis
b. Mediastinitis

c. Pericarditis
d. Pulmonary embolus

Answer: b. Hamman's sign is an audible systolic "crunch" heard on cardiac auscultation that is produced by the heart moving against air in the mediastinum. This can be heard in conditions such as esophageal rupture, mediastinitis, and pneumomediastinum.

7. Right ventricular strain on the ECG of a patient complaining of chest pain would be most consistent with which of the following diagnoses?
a. Acute myocardial infarction
b. Coronary ischemia
c. Coronary spasm
d. Pulmonary embolus

Answer: d. In the setting of chest pain, right ventricular strain as evidenced on the ECG is highly suspicious for pulmonary embolus.

8. The ECG finding of PR segment depression would be more commonly found in which of the following causes of chest pain?
a. Pericarditis
b. Pulmonary embolus
c. ST segment elevation myocardial infarction (STEMI)
d. Subendocardial infarction
e. Unstable angina

Answer: a. The electrocardiographic findings most commonly associated with pericarditis are diffuse ST segment elevation and PR segment depression. The ECG in patients with unstable angina is most often normal or nonspecific. T wave inversion may be seen in these patients. The characteristic ECG findings with subendocardial infarction are T wave inversion and/or ST segment depression in concordant leads. Classic STEMI is manifested electrocardiographically by ST segment elevation (>1 mm) in contiguous leads, a new left bundle branch block (LBBB), or Q waves 0.04 second or more in duration. Many possible electrocardiographic findings are associated with pulmonary embolus, usually manifestations of right ventricular strain.

23

Abdominal Pain

Joseph P. Martinez

KEY CONCEPTS

- While the etiology of abdominal pain is frequently benign, requiring little work-up or intervention, abdominal pain can also be the presenting symptom of catastrophic illness, requiring life-saving interventions to be implemented within minutes to hours (see Table 23.1).
- Patients who are pregnant, of advanced age, or immunocompromised are at higher risk for acute pathology and require expeditious evaluation, which generally includes imaging studies.
- Patients with prior surgery, especially bariatric surgery, have unique anatomic features that put them at risk for pathology not seen in patients that have never had abdominal surgery.
- Patients with hemodynamic instability require resuscitation in conjunction with diagnostic evaluation, and often surgical (or gynecologic) consultation. Bedside ultrasonography can be helpful in these patients.
- Pain medication while evaluating stable patients is appropriate and generally should not be withheld. We recommend the administration of IV morphine at a dose of 0.05 to 0.10 mg/kg (usually 2 to 5 mg in adults) every 15 to 20 minutes until pain is controlled (pain score <4).
- Intra-abdominal infections are often polymicrobial and require broad spectrum antibiotic coverage with regimens such as: piperacillin/tazobactam 3.375 g IV, ciprofloxacin 400 mg IV + metronidazole 500 mg IV, or cefepime 2 g IV + metronidazole 500 mg IV.
- Stable patients with unrevealing evaluations whose symptoms improve may be considered for disposition to home with close follow-up. High-risk patients without a clear diagnosis may require in-hospital observation.

FOUNDATIONS

Epidemiology

Abdominal pain is one of the most common emergency department (ED) presentations. Both the absolute number of patients and the overall percentage of patients presenting to U.S. EDs with abdominal pain is increasing.[1] Laboratory tests and imaging studies are being performed at high rates, but many patients ultimately are discharged home without a specific diagnosis.

The etiology of abdominal pain is frequently benign, requiring little work-up or intervention. However, abdominal pain can also be the presenting symptom of catastrophic illness, requiring life-saving interventions to be implemented within minutes to hours. Certain patient populations have a higher likelihood of acute pathology when they present with abdominal pain (Box 23.1). Patients with advanced age, pregnant women, and immunocompromised patients are high-risk populations. Adhesions from previous surgeries are the leading cause of small bowel obstruction in the U.S. Patients who have had bariatric surgery are also at high risk for internal hernias, anastomotic site breakdown, and bleeding. Elders have a higher prevalence of deadly conditions such as abdominal aortic aneurysm (AAA) or acute mesenteric ischemia (AMI). They often present atypically, even with conditions such as appendicitis, where they account for a disproportionate number of deaths.[2] Older patients with benign causes for their symptoms still often receive higher rates of testing compared to younger cohorts, as clinicians are appropriately cautious of being falsely reassured by stable appearance in this age group. Pregnant women with abdominal pain can have symptoms either related or unrelated to their pregnancy. Ruptured ectopic pregnancy can be rapidly fatal if not diagnosed and treated emergently. With increasing rates of assisted reproductive technology, heterotopic pregnancy (simultaneous intrauterine and extrauterine pregnancy) is being seen more frequently,[3] although still often underrecognized. Patients with immunosuppression have variable and often subtle presentations with laboratory values that may confound the clinical picture, such as derangements in liver function, or false elevations (or depressions) of white blood cell (WBC) counts.

Pathophysiology

The most common etiology of abdominal pain is pathology of the gastrointestinal tract, genitourinary tract, or reproductive organs (Fig. 23.1). However, abdominal pain may also be a manifestation of extra-abdominal causes, such as thoracic or spinal pathology, and may also be a symptom of systemic disease, such as diabetic ketoacidosis or Addisonian crisis. Abdominal pain can be perceived as visceral or somatic and may also be referred to a location distinct from its origin (Fig. 23.2).

Visceral pain results from stimulation of autonomic nerves in the walls of hollow organs or the capsules of solid organs. Visceral pain fibers enter the spinal cord bilaterally. The pain is usually poorly characterized, difficult to localize, and located in the midline of the abdominal region correlated to its embryonic development.

- Foregut structures (stomach, duodenum, liver, gallbladder, and pancreas) are associated with upper abdominal pain.
- Midgut derivatives (small bowel, proximal colon, and appendix) are associated with periumbilical pain.
- Hindgut structures (distal colon and genitourinary tract) are associated with lower abdominal pain.

Somatic pain arises from irritation of the parietal peritoneum. Stimuli are transmitted to the dorsal root ganglia ipsilaterally; therefore pain is often sharper and more well localized. The classic example of visceral followed by somatic pain is appendicitis. The typical periumbilical, dull, aching pain reflects visceral pain which classically then becomes a sharper, more well localized right lower quadrant pain as the inflammation of the appendix irritates the overlying parietal peritoneum.

Abdominal pain can also be referred to distant sites through shared central pathways for afferent neurons from disparate sites. Classic examples of referred pain include epigastric pain associated with an inferior myocardial infarction, shoulder pain associated with free peritoneal blood irritating the diaphragm from ruptured spleen or liver, or lower lobe pneumonia causing upper abdominal pain.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis of abdominal pain is divided into abdominopelvic (intraperitoneal, retroperitoneal, pelvic) causes (e.g., appendicitis, cholecystitis, pancreatitis) and non-abdominopelvic processes (e.g., pneumonia, myocardial infarction, ketoacidosis, and toxicologic causes). Table 23.1 lists potentially life-threatening nontraumatic causes of abdominal pain, representing most major causative disorders likely to be associated with hemodynamic compromise and for which early therapeutic intervention is critical. More common emergent conditions that lead to abdominal pain are listed in Table 23.2.

BOX 23.1 Populations at Higher Risk When Presenting With Abdominal Pain

- Age greater than 60 years
- Pregnant women
- Patients with previous abdominal surgeries, particularly bariatric surgery
- Recent instrumentation of the gastrointestinal tract
- Immunocompromised patients, including low-dose steroid therapy or immune modulator use
- Patients with known vascular disease
- Patients with known abdominal/pelvic malignancy

Pivotal Findings

Symptoms

A careful and focused history is central to determining the source of abdominal pain. Language or cultural differences may influence accurate communication and mutual understanding; therefore, use of a medical interpreter is a key component of evaluation when the clinician doesn't speak the patient's language.

Abrupt onset, severe pain, especially if accompanied by nausea, vomiting, or diaphoresis, suggest a serious underlying cause. While dividing the abdomen into four quadrants and thinking anatomically about causes for pain is a useful starting point, it is helpful to remember that pain can be referred and that anatomic variations or changes due to pregnancy, weight loss, or previous surgery may alter both the site

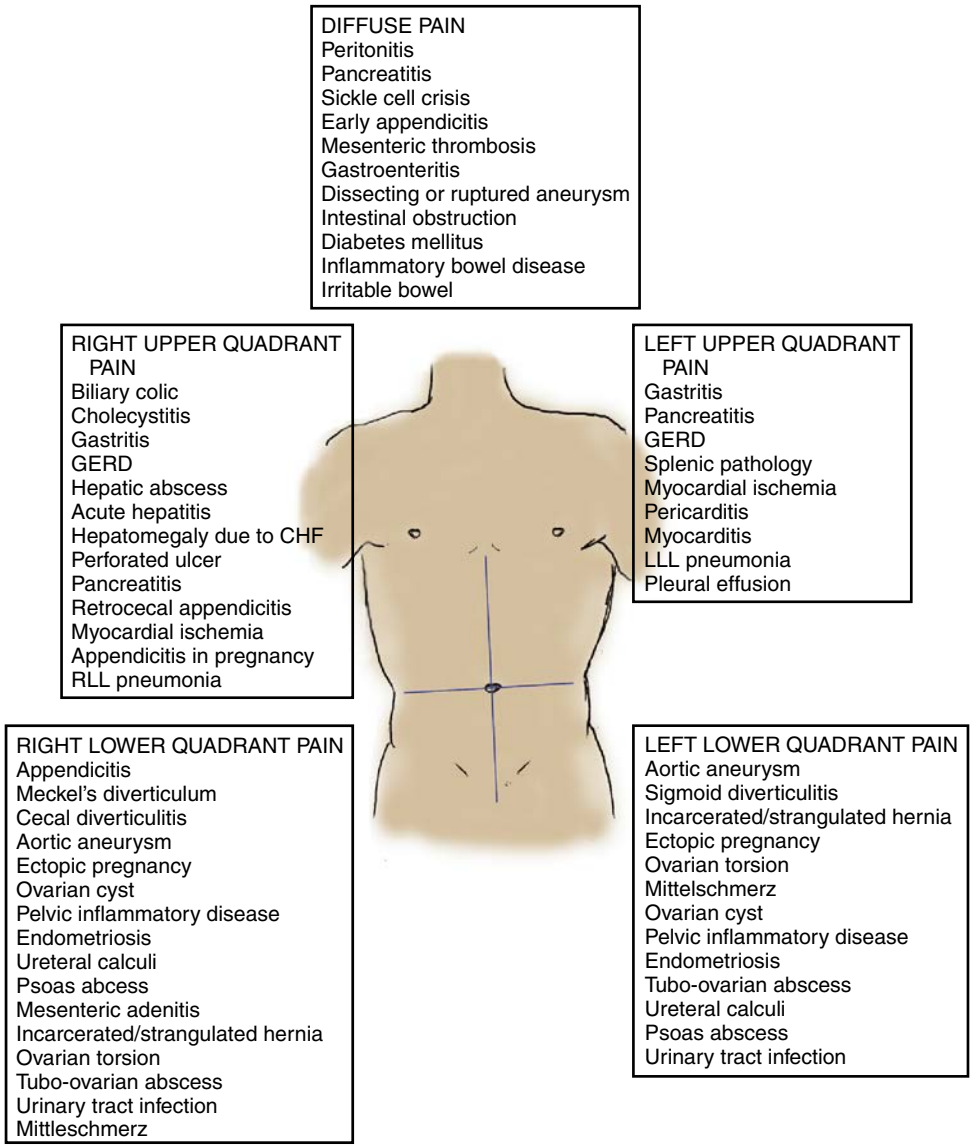

Fig. 23.1 Differential Diagnosis of Acute Abdominal Pain by Location. *CHF,* Congestive heart failure; *GERD,* gastroesophageal reflux disease; *LLL,* left lower lobe; *RLL,* right lower lobe.

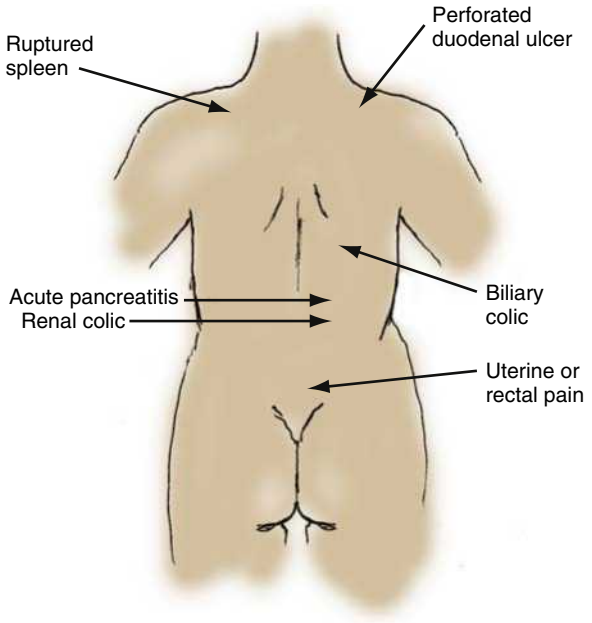

Fig. 23.2 Common Locations of Referred Pain from an Abdominal Cause.

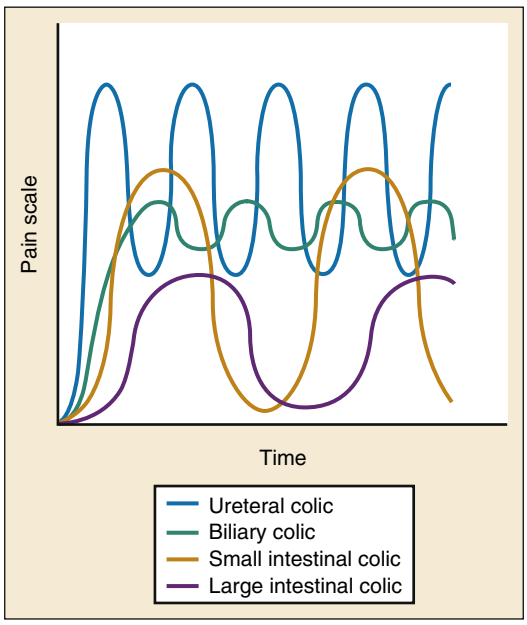

Fig. 23.3 The Characteristics of Colicky Abdominal Pain.

of organs and how their pain is perceived. Provoking factors such as movement or eating should be noted. Diffuse pain, particularly crampy pain that migrates and has periods of minimal or no symptoms, generally is nonsurgical, especially if the pain does not worsen during serial evaluations. Poorly localized pain may represent the early visceral component of a surgical process, however, so monitoring for progression of symptoms is important. Colicky pain is indicative of hollow viscus distention, and duration and timing of colic may give clues to the identity of the culprit organ (Fig. 23.3).

Character of pain is highly subjective, but certain patterns and descriptions emerge:

- The diffuse, severe, colicky pain, occurring at regular ("timeable") intervals associated with severe nausea in small bowel obstruction
- The "pain out of proportion to examination" (i.e., severe pain that is not readily reproduced with palpation) observed in patients with mesenteric ischemia
- The radiation of pain from the epigastrium straight through to the midback, almost invariably accompanied by nausea and vomiting, associated with acute pancreatitis
- The radiation of pain to the left shoulder, or independent pain in the left shoulder, associated with splenic pathology, diaphragmatic irritation, or free intraperitoneal fluid
- The onset of pain associated with syncope seen in ruptured aortic aneurysm or ruptured ectopic pregnancy

The patient's medical and surgical history is crucial, especially as many of the truly emergent conditions are vascular related. Medications can both cause or mask pathology in the abdomen. Social history, especially with respect to tobacco, alcohol, and illicit substance usage is important. Conditions such as perforated peptic ulcers and chronic mesenteric ischemia are much more common in smokers. Alcohol use can lead to gastritis, peptic ulcer disease, pancreatitis, and liver disease. Illicit substances such as cocaine can lead to vascular pathology or peptic ulcer disease, while opioids can lead to severe constipation. Family history of gastrointestinal diseases such as inflammatory bowel disease or colon cancer may also be helpful.

Signs

Physical examination begins with the patient's general appearance and vital signs. Position of the patient in bed and response to movement may point toward peritonitis. Pallor or jaundice may be appreciated. Mental status changes may accompany abdominal pathology, especially in elders. Examination of the patient's vital signs may show derangements consistent with severe hypovolemia or sepsis. Tachypnea may be a marker of metabolic acidosis from intra-abdominal pathology, sepsis, diabetic ketoacidosis, or simply from pain itself. While abnormal vital signs are important, seemingly normal vitals are not uniformly reassuring. Elders may not mount a fever even with a surgical cause of abdominal pain. Similarly, tachycardic response may be blunted, particularly by medications such as beta-adrenergic blockers. Paradoxical bradycardia resulting from reflex, parasympathetically-mediated vasomotor disturbance in response to peritoneal irritation is well described in cases of ruptured ectopic pregnancy.[4]

Head and neck examination may show pallor or scleral icterus. Pulmonary examination may reveal abnormalities such as lower lobe rales pointing to pneumonia or pulmonary edema with concomitant hepatic congestion. Cardiovascular examination may reveal signs of volume depletion or sepsis; show atrial fibrillation, pointing toward AMI; or offer signs of peripheral vascular disease, increasing the likelihood of either AMI or ruptured AAA.

A thorough abdominal examination is an essential component of evaluating abdominal pain. Inspection of the abdomen may reveal ecchymosis, visible peristalsis, or surgical scars. Auscultation has more limited utility though may reveal findings such as the pathognomonic "tinkles and rushes" of an early small bowel obstruction, the hypoactive bowel sounds of an ileus, or a constant bruit which may be the only clue to an aortocaval fistula. Palpation begins with asking the patient to identify the area of maximal tenderness then examining the remainder of the abdomen first, using initially soft then more firm pressure. Gentle shaking of the abdomen may elicit pain in patients with peritonitis. Tenderness in one quadrant often corresponds with the location of the diseased organ, which will direct the evaluation. Some disease processes may manifest with pain that is not exclusively within one specific quadrant, such as the suprapubic pain of a urinary tract infection or the midepigastric pain of a gastric ulcer. Although many patients with appendicitis have right lower quadrant abdominal tenderness, this may

be absent in elders, immunocompromised patients, or women with advanced pregnancy.

A tender, rigid abdomen indicates the presence of diffuse peritonitis. Localized peritoneal irritation is often revealed by the presence of rebound tenderness, where pressure sufficient to indent the peritoneum is applied to the abdomen, then abruptly withdrawn. Discomfort with releasing the peritoneum is visually noted, rather than asking the patient if their symptoms were worse with pressure or with release of pressure. A gentler method of eliciting the presence of peritoneal irritation is having patients perform maneuvers that cause the abdominal parietal and visceral peritoneal surfaces to rub against each other, such as coughing or having them drop their heels to the ground after standing on their toes. Studies of all tests used to elicit rebound tenderness show them to have limited sensitivity and specificity.

Rectal examination is of limited utility unless there are concerns for prostatitis, anorectal pathology, rectal foreign body, or fecal impaction. Pelvic examination in females may help differentiate pelvic source from abdominal source. This may change initial imaging strategy as pelvic organs are generally better imaged with ultrasound, while intraabdominal disorders are better evaluated with abdominal computerized tomography (CT). Findings in acute appendicitis and right adnexal or ovarian pathology can overlap and may require the use of both imaging modalities. Testicular pathology should be assessed for in male patients. Inguinal or femoral hernias can also cause abdominal symptoms. Fournier's gangrene is a time-sensitive entity that may be missed without a thorough physical examination of the perineum.

In view of the evolving nature of abdominal pain, documented serial examinations are useful. This is common practice with respect to suspected appendicitis and serves to improve the diagnostic accuracy in patients with atypical presentations.

Ancillary Testing

Laboratory Tests

Urinalysis and testing for pregnancy are perhaps the most time- and cost-effective laboratory tests available to evaluate acute abdominal pain. Urinalysis results should be interpreted within the context of the patient's clinical picture. Pyuria, with or without bacteriuria, often may confirm the diagnosis of urinary tract infection, but also is present in a variety of other conditions, such as appendicitis or pelvic inflammatory disease. Similarly, hematuria is present in the vast majority of patients with nephrolithiasis but also may be seen in conditions ranging from benign cystitis to ruptured AAA. Pregnancy testing, especially when performed as a point-of-care (POC) test, has the ability to rapidly alter a patient's evaluation and disposition. A POC fingerstick glucose can be helpful in pointing clinicians toward diabetic ketoacidosis as a cause for abdominal pain.

The utility of other laboratory tests is less clear. Although many clinicians will send a broad panel of laboratory studies in patients with undifferentiated abdominal pain, rarely do blood tests confirm or exclude diagnoses with sufficient sensitivity or specificity. The complete blood count and evaluation of the WBC count has been studied extensively with mixed results. The WBC count can be falsely normal, especially in patient populations that are already high risk, such as elders or immunocompromised patients. It may be falsely elevated in any acutely ill patient owing to stress demargination. Serum electrolytes and measurements of renal function are prudent in patients suspected of being significantly volume depleted. Serum lipase is useful when there is suspicion for acute pancreatitis and is preferred over serum amylase for its greater specificity. Lactate levels may be elevated in AMI. While this is the best laboratory test readily available, early in the course of the disease, serum lactate may be normal. Serial levels showing rising lactate or failure to clear despite fluid resuscitation is suspicious for mesenteric ischemia.

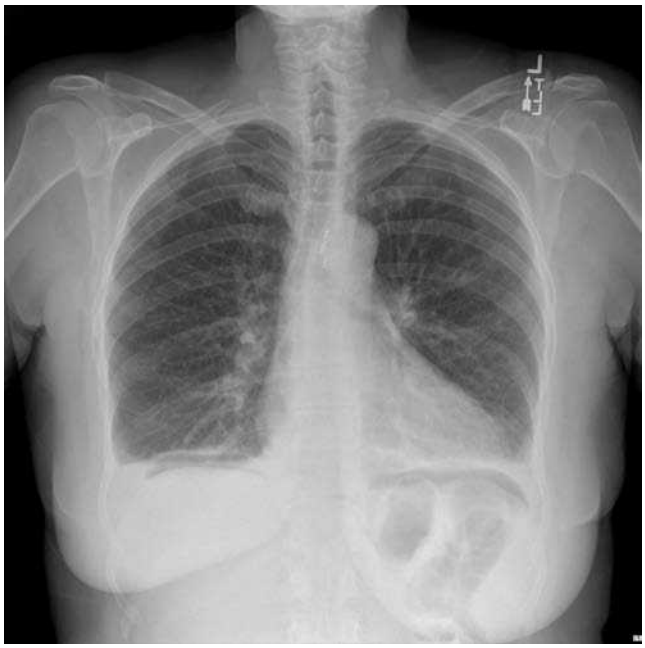

Fig. 23.4 Upright chest radiograph showing free intraperitoneal air under both hemidiaphragms.

Imaging Studies

Plain radiographs of the abdomen have limited utility and are generally only useful if there is clinical suspicion for bowel obstruction, perforation, or foreign body ingestion or rectal insertion. Chest radiographs may reveal a pulmonary cause or may show free air under the diaphragm in cases of perforated viscus (Fig. 23.4).

Ultrasonography can be performed at the bedside and may expeditiously reveal biliary pathology, small bowel obstruction, ovarian/testicular pathology, ectopic pregnancy, or AAA. Patients that are hemodynamically unstable and found to have free intraperitoneal fluid on ultrasound should be considered for emergent surgical (or gynecologic) consultation.

Abdominal CT has become the test of choice for undifferentiated abdominal pain when the clinician determines that advanced imaging is warranted. It has a high degree of accuracy, and has been shown to improve clinician confidence in both diagnosis and disposition. After many years of increased CT utilization, CT imaging has decreased in adults[1] and plateaued in children.[5] The utility of CT imaging in elders is well established and has been shown to change management or disposition in a significant number of patients.[6] Technologic advances have improved both image acquisition and resolution. With new generation CT scanners, the need for oral contrast has been greatly reduced.[7] Reducing the use of oral contrast can help decrease turnaround and throughput times, and improve patient satisfaction, without sacrificing diagnostic accuracy. Computed tomography angiography (CT-A) has also advanced to the point that it is the test of choice in most EDs when AMI is suspected. Institution-specific protocols should be developed accounting for the quality of the scanner and the comfort level of the radiologist. Individual patient presentations that fall outside of the usual protocols merit discussion with the interpreting radiologist to ensure that the optimal imaging protocol is performed.

Magnetic resonance imaging is rarely utilized in the evaluation of acute abdominal pain. Emerging evidence suggests that it has utility in pregnant patients, particularly when the specific clinical question relates to the possibility of acute appendicitis.[8,9]

DIAGNOSTIC ALGORITHM

Critical Diagnoses

The list of diagnoses that lead to abdominal pain is extensive and includes numerous conditions that may be rapidly fatal (see Table 23.1). These diagnoses should be entertained early in the evaluation of any patient with abdominal pain, especially if there is overt hemodynamic instability or a toxic appearance. A diagnostic algorithm for initial assessment is shown in Fig.23.5.

Rapid history, physical examination, and other initial diagnostic evaluations occur concurrently with resuscitative efforts. Intravenous (IV) access and fluid administration, as well as bedside tests such as electrocardiogram, POC laboratory sampling, or bedside ultrasound should be considered. Women of reproductive age with a positive pregnancy test and

TABLE 23.1 Critical Causes of Abdominal Pain

Cause	Epidemiology	Etiology	Presentation	Physical Examination	Useful Tool(S)	Pearls/Pitfalls
Ruptured ectopic pregnancy	Occurs in females of childbearing age. No method of contraception prevents ectopic pregnancy. Approximately 1 in every 100 pregnancies. Heterotopic pregnancy seen increasingly with ART.	Risk factors include nonwhite race, older gestational age, prior history of sexually transmitted diseases (STD) or pelvic inflammatory disease (PID), infertility treatment (ART), intrauterine contraceptive device (IUD) placed within the past year, tubal sterilization, or previous ectopic pregnancy.	Severe, sharp, constant pain often localized to the affected side. More diffuse abdominal pain with intraperitoneal hemorrhage. Signs of shock may be present.	Shock or evidence of peritonitis may be present. Lateralized abdominal tenderness. Localized adnexal tenderness or cervical motion tenderness increases the likelihood of ectopic pregnancy. Vaginal bleeding does not have to be present.	β-hCG testing should be considered in all females of childbearing age or reproductive capacity (10–55 years old); Pelvic ultrasonography is a critical diagnostic tool in evaluation. FAST examination is useful in evaluating for free fluid in patients with shock or peritonitis.	ART patients should not be considered to have an ectopic pregnancy ruled-out when intrauterine pregnancy is found given incidence of multiple gestations with ART.
Ruptured abdominal aortic aneurysm	Incidence increases with advancing age. More frequent in men. Risk factors include HTN, DM, smoking, COPD, and CAD.	Exact cause is undetermined. Contributing factors include atherosclerosis, genetic predisposition, HTN, connective tissue disease, trauma, or infection.	Patient is often asymptomatic until rupture. Acute epigastric and back pain is often associated with, or followed by, syncope or signs of shock. Pain may radiate to back, groin, or testes.	Vital signs may be normal (in 70%) to severely abnormal. Palpation of a pulsatile mass is possible in aneurysms 5 cm or greater. The physical examination may be nonspecific. Bruits or inequality of femoral pulses may be evident.	Abdominal plain films are abnormal in 80% of cases. Ultrasound can define diameter and length but can be limited by obesity or bowel gas. FAST examination can be helpful in evaluating for leak by looking for free fluid. CT-A test of choice in stable patients.	Endovascular repair possible, even in some complex cases. Permissive hypotension allowable.
Acute mesenteric ischemia	Occurs most commonly in elders with CV disease, CHF, cardiac dysrhythmias, DM, sepsis, dialysis, or dehydration. Mortality is 70%. MVT is associated with hypercoagulable states, hematologic inflammation, or trauma. MVT often presents less acute and in younger patients.	20%–30% of lesions are nonocclusive. The causes of ischemia are multifactorial, including transient hypotension in the presence of preexisting atherosclerotic lesion. The arterial occlusive causes (65%) are secondary to emboli (75%) or acute arterial thrombosis (25%).	Pain can be severe and colicky starting in the periumbilical region and then becomes diffuse. Often associated with vomiting and diarrhea. May be preceded by months of postprandial pain or "intestinal angina."	Early examination results can be remarkably benign in the presence of severe ischemia. Bowel sounds are often still present.	Often a pronounced leukocytosis is present. Metabolic acidosis caused by lactic acidemia is often seen with infarction. CT-A is now test of choice, but traditional angiography allows for therapy as well.	Needs multidisciplinary approach in most cases (general surgery, vascular surgery, interventional radiology, critical care). Interventional approaches can usually be pursued first, unless frank peritonitis.

Continued

TABLE 23.1 Critical Causes of Abdominal Pain—cont'd

Cause	Epidemiology	Etiology	Presentation	Physical Examination	Useful Tool(S)	Pearls/Pitfalls
Perforated viscus	Incidence increases with advancing age. History of peptic ulcer disease or diverticular disease common.	More often a duodenal ulcer that erodes through the serosa. Colonic diverticula, large bowel, and gallbladder perforations are rare. Spillage of bowel contents causes peritonitis.	Acute onset of epigastric pain is common. Vomiting in 50%. Fever may develop later. Pain may localize with omental walling off of peritonitis. Shock may be present with bleeding or sepsis.	Fever, usually of low grade, is common; worsens over time. Tachycardia is common. Abdominal examination reveals diffuse guarding and rebound. "Board-like" abdomen in later stages. Bowel sounds are decreased.	WBC count is usually elevated owing to peritonitis. Amylase may be elevated; LFT results are variable. The upright radiographic view reveals free air in 70%–80% of cases with perforated ulcers.	Elderly rarely have rigidity (absent in almost 90% of cases).
Massive gastrointestinal bleeding	More common in adults ages 40–70.	History of peptic ulcer disease, gastritis, or liver disease; prior GI bleeding history	Nausea and vomiting typically occur with upper GI bleeding with hallmark coffee-ground or hematemesis; slow transit can lead to melena; lower GI bleeds associated with poorly localized discomfort and bright red blood per rectum.	Non-focal abdominal tenderness; large bleeds may result in tachycardia or hypotension with significant blood loss. Hemoglobin/hematocrit may be falsely reassuring in acute, massive bleeding.	Stool guaiac if there is a question of bleeding; massive bleeds may require emergent consultation by gastroenterology, interventional radiology, or surgery to intervene.	Stigmata of liver disease should prompt consideration of esophageal varices.
Acute myocardial infarction	Elderly women in particular may present with GI symptoms.	Plaque rupture leads to coronary vessel occlusion.	Nausea, vomiting, or epigastric discomfort may be the sole presenting symptoms, particularly in inferior events or in elderly females.	Nonspecific. Bradycardia often seen with inferior myocardial infarction.	Rapid electrocardiogram in evaluation of abdominal pain if possibility of coronary ischemia is suspected.	Mortality increases with delays in care.

ART, Assisted reproductive technologies; *β-hCG*, beta-human chorionic gonadotropin; *CAD*, coronary artery disease; *CHF*, congestive heart failure; *COPD*, chronic obstructive pulmonary disease; *CT-A*, computed tomography angiography; *CV*, cardiovascular; *DM*, diabetes mellitus; *FAST*, focused assessment by sonography in trauma; *GI*, gastrointestinal; *HTN*, hypertension; *LFT*, liver function test; *MVT*, mesenteric venous thrombosis; *WBC*, white blood cell.

hemodynamic instability, especially if free intraperitoneal fluid is found on ultrasound, should be assumed to have a ruptured ectopic pregnancy. Gynecologic consultation should be obtained, and preparations made for operative intervention. Patients suspected of ruptured AAA, based on physical examination or ultrasound, should similarly have emergent surgical consultation pursued, often contemporaneously with further imaging. ST elevation myocardial infarction necessitates expeditious reperfusion. Patients with frank peritonitis on examination should receive early surgical consultation, even if the etiology is not initially apparent. Patients suspected of AMI should have emergent CT-angiography performed, and appropriate consultations initiated, as mortality decreases dramatically if reperfusion is accomplished before the onset of peritonitis. Patients with overt gastrointestinal bleeding, especially if known or suspected to have cirrhosis, should be considered for blood product administration and emergent gastroenterology consultation if upper source is suspected, with interventional radiology or surgery consultation if hemodynamically significant lower gastrointestinal bleeding is suspected.

Emergent Diagnoses

Common emergent diagnoses of abdominal pain are listed in Table 23.2. Despite the limitations, the approach to the differential diagnosis of abdominal pain generally is based on the location of maximum tenderness. Patients should have ancillary testing performed after initial evaluation, with the goal of identifying serious or life-threatening causes. Serial examinations should be performed. Deterioration should prompt surgical (or gynecologic) consultation.

Despite the significant variety of tests available, nearly half of the patients presenting to the ED with acute abdominal pain will have no conclusive diagnosis. Prior to arriving at the diagnosis of nonspecific abdominal pain, clinicians should pause to consider extra-abdominal or life-threatening causes, especially in elders or immunocompromised patients.

EMPIRIC MANAGEMENT

The main therapeutic goals in managing acute abdominal pain include physiologic stabilization, mitigation of symptoms (e.g., nausea or pain), and expeditious diagnosis to the extent feasible, with consultation if required. An algorithm for management is presented in Fig. 23.6. Analgesia should not be withheld from patients while they are undergoing further evaluation or awaiting consultation. There is no evidence that administration of

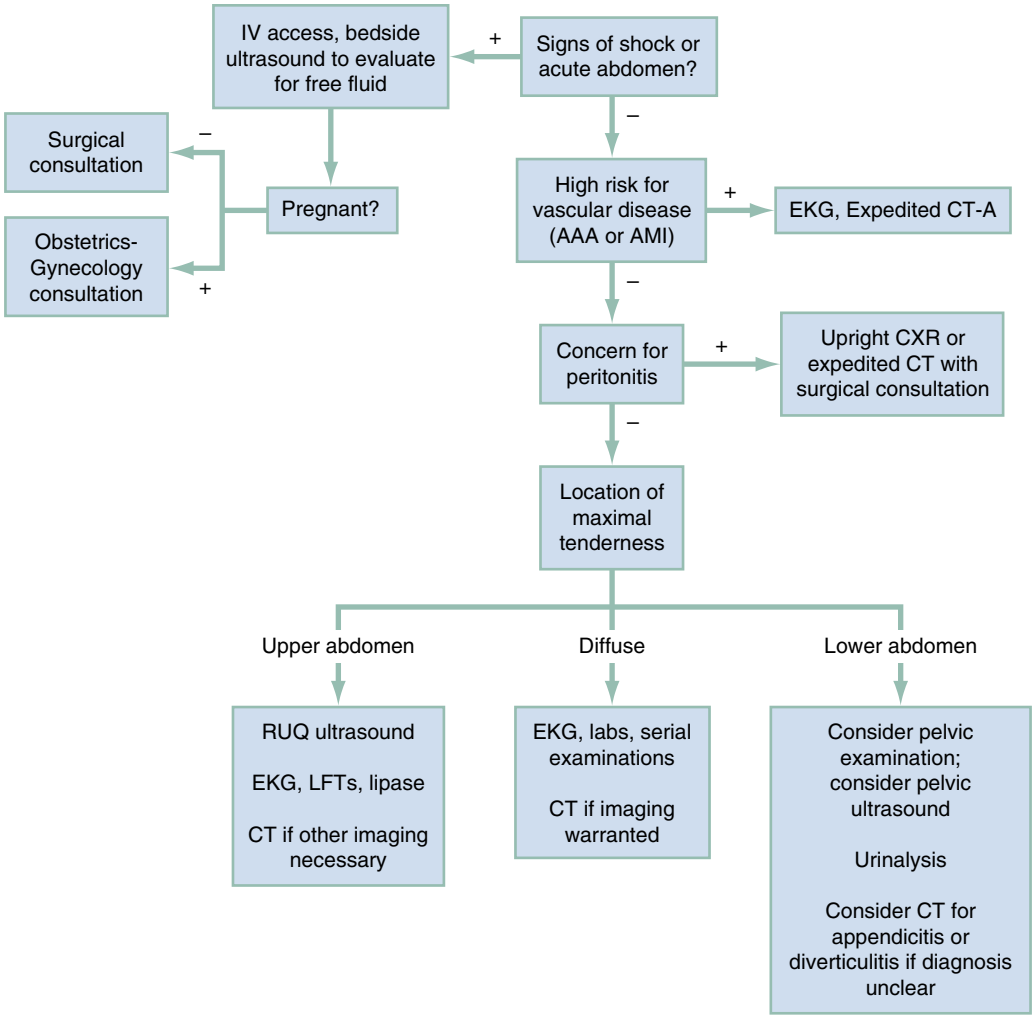

Fig. 23.5 Diagnostic Algorithm for Abdominal Pain. *AAA*, Abdominal aortic aneurysm; *AMI*, acute mesenteric ischemia; *CT*, computed tomography; *CT-A*, Computed tomography angiography; *CXR*, chest x-ray; *EKG*, electrocardiogram; *IV*, intravenous; *LFTs*, liver function tests; *RUQ*, right upper quadrant.

analgesia leads to an increase in diagnostic errors.[10] We recommend the administration of IV morphine at a dose of 0.05 to 0.10 mg/kg (usually 2 to 5 mg in adults) every 15 to 20 minutes until pain is controlled (pain score <4). Morphine is not preferred in patients with renal dysfunction. In the setting of renal insufficiency, fentanyl or hydromorphone are the preferred IV opioid analgesics. Patients with opioid dependence and those taking narcotics for chronic pain may require larger doses. The patient's mental and respiratory status should be monitored during treatment.

Other medications that may be commonly administered include antiemetics such as ondansetron, 4 or 8 mg, either IV or as an orally disintegrating tablet, or liquid antacids. Liquid antacids are most effective when the pain is suspected to arise from the esophageal or gastric mucosa. There are no scientific studies that show increased efficacy of a "GI cocktail" (which typically includes an antacid, an anesthetic agent such as viscous lidocaine, and an anticholinergic agent), when compared to liquid antacid alone.

If intra-abdominal infection is suspected, antibiotic therapy should be initiated promptly. Abdominal infections are often polymicrobial, and coverage for enteric gram-negative, gram-positive, and anaerobic bacteria is indicated. Considerations for antimicrobial selection include:

- Unless local antibiotic resistance dictates otherwise, in low-risk patients who have not recently been hospitalized, single agent therapy includes piperacillin-tazobactam 3.375 g IV or ertapenem 1 g IV. Combination therapy includes metronidazole 500 mg IV along with a cephalosporin, such as cefazolin 2 g IV, ceftriaxone 2 g IV, or cefotaxime 2 g IV, piperacillin-tazobactam 3.375g to 4.5g IV, or a quinolone such as ciprofloxacin 400 mg IV.
- Higher-risk patients (advanced age, significant comorbidities, immunosuppression, or evidence of severe disease) should be treated with meropenem 1g IV, or higher-dose piperacillin-tazobactam 4.5 g IV as single agent, or receive combination therapy with cefepime 2 g IV plus metronidazole 500 mg IV.
- It is unusual to require empiric antifungal therapy in the ED, but it may be considered in critically ill patients with immunosuppression.

For patients who do not have a clear diagnosis following ED evaluation, some may require observation or admission for continued evaluation, especially if they have high-risk features such as the following:

- Immunosuppression or advanced age[11, 12]
- Worsening abdominal examination or continued pain requiring potent analgesia
- Inability to tolerate oral hydration
- Unstable living situation with poor access to follow-up care

TABLE 23.2 Emergent Causes of Abdominal Pain

Causative Disorder or Condition	Epidemiology	Etiology	Presentation	Physical Examination	Useful Test(s)
Gastric, esophageal, or duodenal inflammation	Occurs in all age groups.	Caused by imbalance between digestive enzymes and mucoprotective barriers, infection, or exogenous sources.	Pain is epigastric, radiating or localized, associated with certain foods. Pain may be burning. In some cases, exacerbation in supine position.	Epigastric tenderness without rebound or guarding. Perforation or bleeding leads to more profound clinical findings.	Uncomplicated cases are treated with antacids or histamine H_2 blockers before invasive studies are contemplated. Gastroduodenoscopy is valuable in diagnosis and biopsy. Testing for *Helicobacter pylori* with blood or biopsy specimens. If perforation is suspected, an upright chest radiograph is obtained early to rule out free air. CT may be beneficial.
Acute appendicitis	Peak age in adolescence and young adulthood; less common in children and elders. Higher perforation rate in women, children, and elders, or in pregnancy. Mortality rate is 0.1% but increases to approximately 2% with perforation.[11]	Appendiceal lumen obstruction leads to swelling, ischemia, infection, and perforation.	Epigastric or periumbilical pain migrates (+LR 1.8 child/3.2 adult) to RLQ over 8–12 hours. RLQ pain common (+LR 1.4 in child/7.3–8.5 in adult).[12] Later presentations associated with higher perforation rates. Pain, low-grade fever (+LR 1.2 in child/1.9 in adult), and anorexia (80%) common; vomiting less common (50%–70%).	Mean temperature 38°C (100.5°F). Higher temperature associated with perforation. RLQ tenderness (90%–95%) with rebound (40%–70%) in majority of cases. Rectal tenderness in 30%.	Leukocyte count is nonspecific and may be normal or elevated. If elevated, may or may not show left shift. Urinalysis may show sterile pyuria. CT is sensitive and specific. US may have use in those with non-obese body habitus, women, pregnancy, and children with RLQ pain. MRI has excellent diagnostic accuracy in pregnant women.
Biliary tract disease	Peak age 35–60 years old; unlikely in patients younger than 20. Female-to-male ratio of 3:1. Risk factors include multiparity, obesity, alcohol intake, and use of birth control pills.	Presence of gallstones may cause biliary colic. Impaction of a stone in cystic duct or common duct may lead to cholecystitis or cholangitis, respectively.	Crampy RUQ pain radiates to right subscapular area. Prior history of pain is common. May have nausea or postprandial pain. Longer duration of pain favors diagnosis of cholecystitis or cholangitis.	Temperature is normal in biliary colic, may be elevated in cholecystitis or cholangitis. RUQ tenderness, rebound, or jaundice (less common) may be present.	WBC may be elevated in cholecystitis and cholangitis. US may demonstrate wall thickening, pericholecystic fluid, stones, or duct dilatation. Hepatobiliary scintigraphy (HIDA scan) evaluates gallbladder function.
Ureteral colic	Average age for first episode is 30–40 years, primarily in men. Prior history or family history of kidney stones is common.	Family history, gout, *Proteus* infection. Renal tubular acidosis or cystinuria lead to stone formation.	Acute onset of flank pain radiating to groin. Nausea, vomiting, and pallor are common. Patients are usually restless and unable to find position of comfort.	Vital signs are usually normal. Tenderness on CVA percussion with benign abdominal examination.	Urinalysis usually shows hematuria. Noncontrast CT is sensitive and specific. Ultrasound to evaluate for hydronephrosis may be sufficient if diagnosis previously established.
Diverticulitis	Incidence increases with advancing age, affects males more often than females. Recurrences are common.	Colonic diverticula may become infected, perforate, or cause local colitis. Obstruction, peritonitis, abscesses, fistulae result from infection or swelling.	Change in stool frequency or consistency commonly reported. LLQ pain is common. Associated with fever, nausea, and vomiting; rectal bleeding may be seen.	Fever usually low grade. LLQ pain without rebound is common. Stool may be heme positive.	Results on most tests usually normal. Plain radiographs not indicated. CT is diagnostic, but diagnosis can also be made clinically, without imaging, in selected lower-risk patients.

Continued

TABLE 23.2 Emergent Causes of Abdominal Pain—cont'd

Causative Disorder or Condition	Epidemiology	Etiology	Presentation	Physical Examination	Useful Test(s)
Acute gastroenteritis	Seasonal. Most common misdiagnosis of appendicitis and of acute mesenteric ischemia. May be seen in multiple family members. History of travel or immunocompromise. Most common GI disease in the United States.	Usually viral. Consider invasive bacterial or parasitic cause in prolonged cases, in travelers, or immunocompromised patients.	Pain usually poorly localized, intermittent, crampy, and diffuse. Diarrhea is key element in diagnosis; usually large volume, watery. Nausea and vomiting usually begin before pain.	Abdominal examination usually nonspecific without peritoneal signs. Watery diarrhea or no stool noted on rectal examination. Fever may be present.	Usually symptomatic care with antiemetics and volume repletion. Heme-positive stools may be a clue to invasive pathogens. Also consider more serious causes prior to concluding on diagnosis of acute gastroenteritis.
Constipation and obstipation	More common in females, elders, the very young, and patients on narcotics.	Idiopathic, or bowel hypokinesis secondary to disease states (low motility) or exogenous sources (diet, medications).	Abdominal pain; change in bowel habits.	Variable, nonspecific without peritoneal signs. Rectal examination may reveal hard stool or impaction.	Radiographs may show large amounts of stool. Constipation or obstipation are diagnoses of exclusion.
Intestinal obstruction	Peaks in infancy and in the elderly. More common with history of previous abdominal surgery.	Adhesions, carcinoma, hernias, abscesses, volvulus, or infarction. Obstruction leads to vomiting, extravascular fluid accumulation; strangulation and necrosis of bowel may occur.	Crampy diffuse abdominal pain associated with vomiting.	Vital signs are usually normal unless dehydration or bowel strangulation has occurred. Abdominal distention, hyperactive bowel sounds, and diffuse tenderness. Local peritoneal signs may indicate strangulation.	Elevated WBC count may suggest advanced disease or strangulation. Volume depletion may be severe. Electrolytes may be abnormal if associated with vomiting or prolonged symptoms. Abdominal radiographs, CT, and ultrasound are useful in diagnosis.
Acute pancreatitis	Peak age is adulthood; rare in children. Male preponderance. Alcohol abuse and biliary tract disease are risk factors.	Alcohol, gallstones, hyperlipidemia, hypercalcemia, or endoscopic retrograde pancreatography causing pancreatic damage, saponification, or necrosis. ARDS, sepsis, hemorrhage, or renal failure may be secondary complications.	Acute onset of epigastric pain radiating to the mid-back. Nausea and vomiting are common. Pain disproportionate to physical findings. Adequate volume repletion is important in the initial therapy.	Low-grade fever is common. Patient may be hypotensive or tachypneic. Some epigastric tenderness is usually present. Because the pancreas is a retroperitoneal organ, guarding or rebound not present unless condition is severe. Flank or periumbilical ecchymosis may be seen with hemorrhagic pancreatitis.	Serum lipase is the test of choice. Ultrasound examination may show edema, pseudocyst, or biliary tract disease. CT scan may show abscesses, necrosis, hemorrhage, or pseudocysts. Ultrasound is recommended to assess for gallstones while CT is recommended if severe acute pancreatitis is suspected.

ARDS, Acute respiratory distress syndrome; *CT*, computed tomography; *CVA*, costovertebral angle; *HIDA*, hepatobiliary scintigraphy; *LLQ*, left lower quadrant; *LR*, likelihood ratio; *RLQ*, right lower quadrant; *RUQ*, right upper quadrant; *US*, ultrasound; *WBC*, white blood cell.

Clinically stable patients may be discharged from the ED with appropriate follow-up care, which may include close follow-up for repeated physical examination, or additional diagnostic imaging if indicated. Clear discharge instructions should be provided, including specific symptoms that should prompt return to the ED, precise instructions regarding timing of follow-up, and an acknowledgment that the etiology of the patient's symptoms is unclear, and may declare itself in time. It is helpful to document a repeat abdominal examination around the time of discharge showing stability or improvement, as well as the ability to tolerate oral hydration.

CHAPTER 23: QUESTIONS AND ANSWERS

1. A 65-year-old man presents with acute abdominal pain. He has a history of hypertension, diabetes, and an abdominal aortic aneurysm. On examination, he is hypotensive and tachycardic with a distended, rigid abdomen. Which of the following is the best method for diagnosis?

a. Computed tomography
b. Exploratory laparotomy
c. Plain radiograph
d. Right upper quadrant ultrasound

Answer: b. Exploratory laparotomy. Patients with known abdominal aortic aneurysm (AAA) and unstable vital signs must be assumed to have ruptured AAA and should be brought to the operating room without delay. If the patient were stable, CT would be indicated. Plain radiograph is not indicated in this patient, nor would right upper quadrant ultrasound be warranted.

2. A 25-year-old woman presents with abdominal pain. She has stable vitals. On pelvic examination, she has tenderness in the right adnexal region. Which of the following is the most appropriate initial imaging study?

a. Computed tomography
b. Magnetic resonance imaging
c. Plain radiograph
d. Pelvic ultrasound

Answer: d. Pelvic ultrasound. Women of child-bearing age with lower abdominal pain and adnexal tenderness on examination are best imaged with pelvic ultrasound. CT may be warranted if the ultrasound is inconclusive or suggestive of, but not diagnostic of, appendicitis. Plain radiographs are not helpful in undifferentiated lower abdominal pain. MRI could be a consideration if the patient were pregnant and there was concern for appendicitis.

3. A 70-year-old man presents with abdominal pain associated with one loose bowel movement and an episode of non-bloody emesis. He has a history of hypertension, diabetes, cigarette smoking, and atrial fibrillation. He rates his pain as "10/10." On examination, he has stable vitals. His abdomen is soft and nontender without signs of peritonitis. Which of the following is the most appropriate imaging study to confirm the suspected diagnosis?

a. Computed tomography angiography
b. Magnetic resonance imaging
c. Plain radiograph
d. Right upper quadrant ultrasound

Answer: a. Computed tomography angiography. The patient presents with "pain out of proportion" to examination, multiple vascular risk factors, and atrial fibrillation, which increases his risk for mesenteric ischemia. Computed tomography angiography would be the best screening test. Magnetic resonance imaging would be too time-consuming, plain radiographs have limited utility, and right upper quadrant ultrasound is not warranted in this patient with diffuse, non-localized symptoms.

4. A 30-year-old man presents with abdominal pain and fever. Which of the following would place him at higher risk for life-threatening pathology?

a. Drinking from a mountain spring
b. Prednisone therapy for systemic juvenile idiopathic arthritis
c. Recent cruise with norovirus outbreak
d. Use of metoprolol for essential hypertension

Answer: b. Prednisone therapy for systemic juvenile idiopathic arthritis. Low-dose steroid therapy places patients at higher risk when they present with abdominal pain. Drinking from a mountain spring increases risk for giardia. Neither this nor exposure to norovirus place the patient at increased risk for life-threatening pathology. Hypertension increases risk for vascular conditions such as abdominal aortic aneurysm, but this would be unlikely in a young patient controlled on metoprolol.

5. What is a characteristic of visceral abdominal pain?

a. Easily described
b. Midline
c. Sharp in nature
d. Well-localized

Answer: b. Midline. Visceral pain is classically midline, poorly localized, and less easily described than somatic pain, which is often referred to as "sharp."

Jaundice

Michael J. Zdradzinski and Todd Andrew Taylor

KEY CONCEPTS

- Jaundice is the clinical manifestation of elevated serum bilirubin, which arises through the metabolism of hemoglobin. Elevated bilirubin occurs when: (1) increased bilirubin is produced due to hemolysis, (2) liver dysfunction prevents conjugation of bilirubin, (3) an obstruction prevents secretion of bilirubin into the intestines.
- Jaundice is usually not evident on physical examination until the total serum bilirubin concentration rises above 2.5 mg/dL. Jaundice is first apparent in the conjunctiva, sublingually, or on the hard palate.
- Unconjugated bilirubin that is not bound to albumin can cross the blood-brain barrier, causing adverse neurologic effects; conjugated bilirubin is not neurotoxic.
- New-onset painless jaundice is the classic presentation for a neoplasm involving the head of the pancreas.
- In cases of unexplained hepatocellular injury, a quantitative acetaminophen level may be helpful.
- If the etiology of ascites is unknown, serum ascites albumin gradient (SAAG) determination will aid in distinguishing the cause as well as the presence of portal hypertension.
- Ultrasonography is the preferred initial imaging modality in evaluating for biliary obstruction, whereas CT is preferred if malignant obstruction is suspected or the full abdomen needs to be evaluated.
- Elevated direct bilirubin with transaminase elevation is indicative of hepatocellular inflammation or injury.
- Diagnosis of spontaneous bacterial peritonitis (SBP) is made by a peritoneal fluid neutrophil count of greater than 250. Treatment typically consists of cefotaxime 2 g IV and albumin 1.5 g/kg.

EPIDEMIOLOGY

Bilirubin is conjugated in the liver and secreted in the biliary system. If bilirubin cannot be processed adequately by the liver or secreted properly in the biliary system, it is deposited in the skin leading to jaundice. Therefore, many patients with jaundice will have a primary hepatic or biliary etiology. Jaundice can be caused by a variety of hepatic disorders including cirrhosis, hepatitis, toxin exposure, or infiltrative liver disease. Obstruction or infection of the biliary system can cause inadequate secretion of bilirubin. Recently, hepatitis A and B immunizations have significantly decreased the prevalence of these forms of hepatitis, and thus have altered the epidemiology of jaundice.

PATHOPHYSIOLOGY

Normal Bilirubin Metabolism

Bilirubin is generated from heme products, primarily red blood cells. A small portion is derived from myoglobin and maturing erythroid cells. Within the reticuloendothelial system, heme is oxidized to biliverdin, which is then converted to bilirubin. Unconjugated (i.e., indirect) bilirubin is passively taken into hepatocytes, where it undergoes glucuronidation and becomes conjugated (i.e., direct) bilirubin. This conjugated fraction is secreted into the biliary system and emptied into the gut. Colonic bacteria metabolize the majority of bilirubin to urobilinogen and stercobilin. Urobilinogen is reabsorbed and excreted in the urine and stercobilin is excreted in the stool, causing stool to turn brown. The remaining conjugated bilirubin is deconjugated and reenters the portal circulation to be taken up again by hepatocytes (enterohepatic circulation).

Abnormalities in Bilirubin Metabolism

Clinical jaundice is typically not evident until the total serum bilirubin concentration rises above 2.5 mg/dL. It is observed in tissues with high albumin concentrations including the skin and eyes. The physiology of bile metabolism may be altered in three principal areas: (1) overproduction of heme products, as occurs in hemolysis; (2) failure of the hepatocyte to take up, conjugate, and secrete bilirubin, as occurs in hepatocellular dysfunction; or (3) obstruction of biliary secretion into the intestine. The differential diagnosis of jaundice is broad, and understanding these components of bilirubin metabolism and excretion aids in narrowing the differential and streamlining the evaluation.

Unconjugated bilirubin that is not bound to albumin can cross the blood-brain barrier, potentially leading to adverse neurologic effects ranging from subtle developmental abnormalities to encephalopathy or death. Conditions that favor the unbound fraction of unconjugated bilirubin, including hemolysis, hypoalbuminemia, acidemia, or drugs that bind competitively to albumin, increase the risk of neurotoxicity. Conjugated bilirubin is not neurotoxic.

Diagnostic Approach

Differential Considerations

The three major diagnostic categories to consider in the patient with jaundice include:

1. Disorders of hemolysis (increased breakdown of heme products).
2. Liver injury, dysfunction, or cholestasis (failure to uptake, conjugate, or secrete bilirubin).
3. Biliary obstructive disorders.

Figs. 24.1 and 24.2 outline an approach to differentiating among these three broad categories.

Pivotal Findings

The pivotal findings related to history, physical examination, and ancillary testing are listed in Fig. 24.1.

Symptoms

Patients may be asymptomatic at presentation or have nonspecific symptoms, such as pruritus, malaise, or nausea. There are a few symptoms that can help narrow the differential diagnosis. Jaundice with

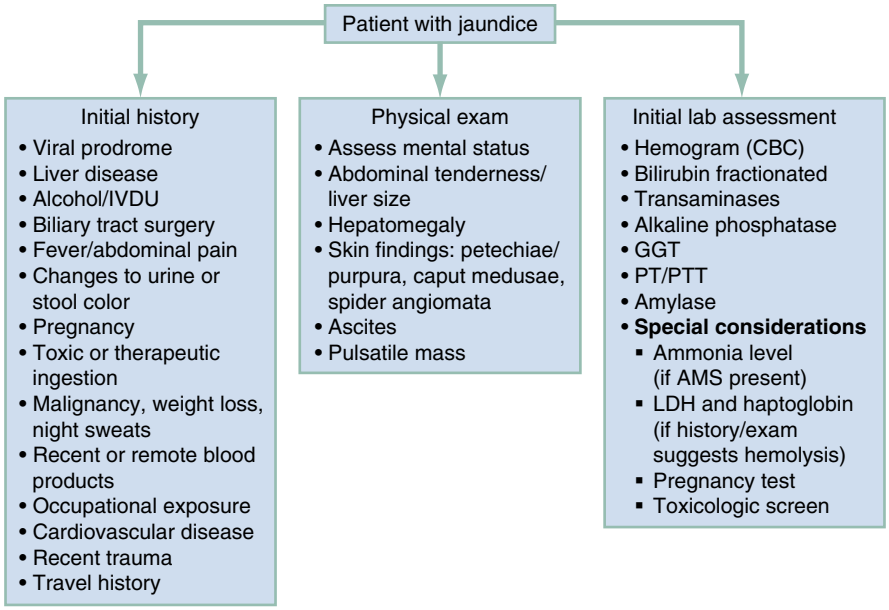

Fig. 24.1 Initial Approach to the Patient With Jaundice. *AMS,* Altered mental status; *CBC,* complete blood count; *GGT,* gamma-glutamyl transferase; *IVDU,* intravenous drug use; *LDH,* lactate dehydrogenase; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

abdominal pain suggests biliary obstruction or significant hepatic inflammation. New-onset painless jaundice is the classic presentation for a neoplasm involving the head of the pancreas. These patients may complain of weight loss or increasing abdominal girth related to ascites. Patients with hepatic encephalopathy may present with subtle mental status changes, increasing confusion, or frank altered mental status.

Signs

Pertinent physical examination findings are summarized in Fig. 24.1. Examination of the skin and the abdomen is particularly helpful in narrowing the differential diagnosis.

Skin findings can point to acute or chronic liver disease. Jaundice is first apparent sublingually, in the conjunctiva, or on the hard palate. From there, it spreads caudally; however, the extent of cephalocaudal progression does not correlate with rising serum bilirubin levels. Cutaneous findings of chronic liver disease include angiomas, excoriations from pruritus, or caput medusae.

The abdominal examination should begin with a thorough visual inspection. A distended or protuberant abdomen can indicate the presence of ascites. On palpation, an enlarged, tender liver suggests hepatic inflammation or engorgement caused by biliary obstruction. An enlarged nontender liver is concerning for malignant infiltration. A nonpalpable liver can indicate fibrosis caused by cirrhosis. A palpable gallbladder, a rare finding, suggests chronic cholestasis or malignancy. The presence of splenomegaly suggests hemolysis, malignancy, or portal hypertension.

Neurologic examination of the jaundiced patient may show depressed mental status. In patients with jaundice, mental status changes can be caused by neurotoxic effects of unconjugated bilirubin, or in the setting of other conditions that may be associated with jaundice such as hepatic encephalopathy. In hepatic encephalopathy, mental status changes are not caused by bilirubin itself, but rather from other impacts of liver dysfunction such as elevated serum ammonia levels. Asterixis is a specific finding of hepatic encephalopathy. Table 24.1 addresses the clinical stages of hepatic encephalopathy.

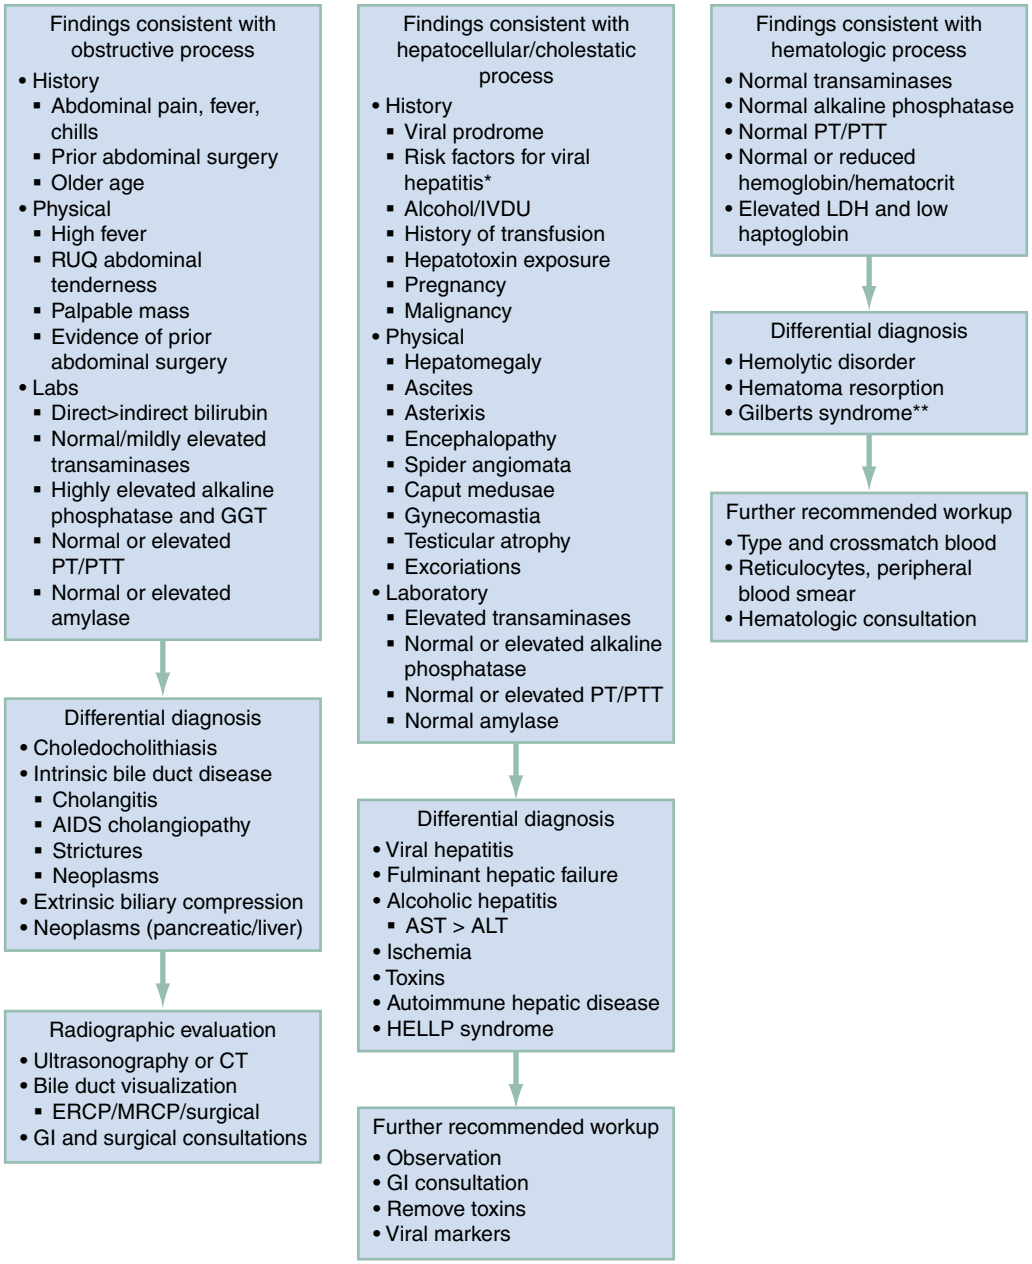
Laboratory Tests

Fig. 24.1 lists the laboratory tests that are helpful in the evaluation of a patient with jaundice.[1] Although there is some overlap, laboratory testing can be categorized in relation to presumed underlying etiology (hemolysis, liver dysfunction, or biliary obstructive disorders).

In hemolysis disorders, the most helpful laboratory tests include a reticulocyte count, evaluation of peripheral blood smear, haptoglobin, and lactate dehydrogenase (LDH). When the etiology is thought to be a primary liver dysfunction or cholestasis, the most helpful laboratory tests are serum gamma-glutamyl transpeptidase (GGT), hepatitis serologies, liver function tests (aspartate aminotransferase [AST], alanine aminotransferase [ALT], alkaline phosphatase, international normalized ratio [INR]), amylase, and an acetaminophen level in unexplained cases. Serum GGT rises in parallel with alkaline phosphatase in the setting of liver disease.[1] Although alkaline phosphatase also can be elevated in diseases affecting bone or placenta, the concomitant increase in serum GGT confirms a hepatic source. The evaluation for suspected biliary obstructive disorders includes testing for primary liver dysfunction with the addition of a lipase level.

Additional tests may be helpful in select patients. Both glucose and ammonia metabolism can be altered in the presence of hepatocellular injury, thus laboratory testing for blood glucose or ammonia levels may be important in the setting of altered mental status. The degree of elevation in serum ammonia does not correlate directly with the level of hepatic encephalopathy. Gastrointestinal bleeding can also cause an elevated ammonia level, secondary to the conversion of excess nitrogen load from blood into ammonia by intestinal bacteria, thus fecal guaiac testing may be helpful in select patients.

Ascitic fluid analysis should be considered in patients with new-onset ascites, or in those with established ascites but new complaints such as fever, worsening abdominal pain, gastrointestinal bleeding, hepatic encephalopathy, hypotension, or renal failure. Cell count and differential, as well as ascitic fluid albumin and total protein concentration, are typically sufficient initial screening tests. Gram stain and culture of ascitic fluid should be performed if spontaneous bacterial peritonitis (SBP) is suspected. The presence of more than 250 polymorphonuclear (PMN) cells per cubic millimeter of ascitic fluid is



* Risk factors for viral hepatitis include history of IVDU or intranasal drug use, tattoos, body piercings, blood transfusions, high risk sexual conduct or men who have sex with men, birth in HBV endemic area, known human immunodeficiency virus infection, birth between 1945 and 1965 (hepatitis C), dialysis patients (hepatitis B), recent travel (hepatitis A). (Kwo, 2017)

** A benign hereditary condition characterized by hyperbilirubinemia and jaundice due to inadequate hepatic conjugation of bilirubin.

diagnostic for SBP. A negative ascitic fluid Gram stain is insufficiently sensitive to exclude SBP; treatment should be continued until ascitic fluid cultures result. If SBP is suspected, blood cultures should be considered. If the etiology of the ascites is unknown, determining the serum ascites albumin gradient (SAAG) may be helpful. The SAAG value is obtained by subtracting the albumin level of ascitic fluid from the serum albumin level. A SAAG value ≥1.1 g/dL, corresponding to relatively low albumin level in ascitic fluid and therefore transudative fluid, is often found in patients with portal hypertension. There are many causes of portal hypertension, including cirrhosis, liver failure, and heart failure. A SAAG value of less than 1.1 g/dL, corresponding to a comparatively higher albumin level in ascitic fluid and therefore

TABLE 24.1 Clinical Stages of Hepatic Encephalopathy

Clinical Stage	Intellectual Function	Neuromuscular Function
Subclinical	Normal examination findings, but work or driving may be impaired	Subtle changes in psychometric testing
Stage 1	Impaired attention, irritability, depression, or personality changes	Tremor, incoordination, apraxia
Stage 2	Drowsiness, behavioral changes, poor memory, disturbed sleep	Asterixis, slowed or slurred speech, ataxia
Stage 3	Confusion, disorientation, somnolence, amnesia	Hypoactive reflexes, nystagmus, clonus, muscular rigidity
Stage 4	Stupor and coma	Dilated pupils and decerebrate posturing; oculocephalic reflex

exudative fluid, may be found in patients with conditions such as lupus or pancreatitis. Thus SAAG can assist in rapidly narrowing the differential diagnosis.

Imaging

When indicated, abdominal imaging can help narrow the differential diagnosis of jaundice, especially in patients for whom biliary obstruction is a concern. The primary role of imaging is in the characterization of obstructive biliary disease. The first choice of study depends on the clinical presentation. Ultrasonography is generally superior for visualization of the gallbladder and biliary ducts, and both ultrasonography and computed tomography (CT) are highly sensitive in diagnosing obstruction.[2] The choice of imaging modality depends on the pretest probability for biliary obstruction, and whether the obstruction may be malignant. For patients with painless, progressive jaundice without suspicion for hepatocellular injury, CT is the preferred imaging test. Unlike ultrasound, CT with IV contrast can evaluate for malignant obstruction by locating the site of the obstruction and can aid in determining resectability and assessing for disseminated disease. Patients with a high likelihood of non-malignant biliary disease and biliary obstruction are best screened initially with ultrasound. Ultrasonography is less expensive and less invasive than either magnetic resonance cholangiography or endoscopic ultrasound but has a lower sensitivity in identifying common bile duct stones. Ultrasonography with Doppler flow can detect obstruction in the hepatic, portal, and splenic veins. In patients with low or intermediate clinical likelihood of mechanical obstruction, ultrasonography is the preferred initial modality secondary to its low cost and absence of radiation exposure. CT is preferred if the entire abdomen needs to be evaluated.

Diagnostic Algorithm

The differential diagnostic considerations for jaundice are broad. There are critical and emergent causes that should be considered in the emergency department (ED) setting (Table 24.2). Particularly worrisome features are patients with jaundice and any of the following features: altered level of consciousness, hypotension, fever with abdominal pain, or active bleeding.

Further characterization of the cause of jaundice involves analysis of laboratory studies (see Fig. 24.2). Indirect bilirubinemia points to a hematologic cause, whereas direct bilirubinemia indicates hepatobiliary pathology. Elevated direct bilirubin with transaminase elevation is indicative of hepatocellular inflammation or injury. Prolongation of prothrombin time (PT) may indicate significant hepatocellular dysfunction. If hepatic dysfunction progresses, partial thromboplastin time (PTT) can also become elevated. Elevated alkaline phosphatase with elevated direct bilirubin suggests extrinsic biliary obstruction. As alkaline phosphatase elevation is not specific to liver disease, we recommend utilizing GGT as confirmatory biomarker evidence of biliary obstruction.[1]

Patients with suspected biliary obstruction should undergo ultrasonography or CT with IV contrast in the ED to determine the cause and site of the obstruction. Magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), or endoscopic ultrasound may be required to further characterize the obstruction, although these studies are usually performed following admission.[2] The most common causes of biliary obstruction are biliary stones and benign or malignant stenoses.

The identification of critical or emergent causes of jaundice is based on patterns of signs, symptoms, and ancillary testing. For instance, the triad of jaundice, encephalopathy, and coagulopathy (INR > 1.5) is usually indicative of acute hepatic failure. Fever, right upper quadrant abdominal pain, and jaundice can indicate biliary obstruction with infection (e.g., cholangitis, cholecystitis, or hepatitis). Ascites with abdominal tenderness raises suspicion for SBP. Rapid onset of hepatomegaly and ascites suggests portal vein thrombosis (Budd-Chiari syndrome). Mild or moderate transaminase elevations (up to 15× upper limit of normal) are often caused by viral hepatitis, alcoholic and nonalcoholic fatty liver disease, autoimmune hepatitis, or drug/supplement related injury. Severe elevations of transaminases (>15× upper limit of normal, or AST >1000 IU/L) are suggestive of acetaminophen toxicity or ischemic hepatopathy in particular.[1]

Empirical Management

Both general supportive and specific therapies are guided by the presumptive cause of jaundice (see Fig. 24.2). If coagulopathy is suspected or identified, compressible sites and ultrasound guidance should be considered for central venous access. Coagulopathy in the context of acute hemorrhage can be treated with fresh frozen plasma along with blood volume repletion with packed red blood cells.

In cases of SBP, the empirical antibiotic of choice is an IV third-generation cephalosporin (e.g., cefotaxime 2 g IV, ceftriaxone 2 g IV). Patients with SBP should receive an albumin infusion (initial dose 25% 1.5g/kg IV), as it has been shown to reduce the risk for mortality and hepatorenal syndrome.[3] Nonselective beta blocker use in patients with a history of cirrhosis should be discontinued, as beta-adrenergic blockers have been shown to increase mortality in patients with SBP.[3,4]

Jaundice and transaminitis out of proportion to the level of alkaline phosphatase elevation is consistent with a hepatocellular injury pattern. Patients with fulminant hepatic failure should be considered for admission to the intensive care setting. Strong consideration should be given to the possibility of transfer of acute hepatic failure patients to a facility with expertise in severe liver disease, when feasible.

Acetaminophen toxicity and indications for *N*-acetylcysteine (NAC) therapy are discussed in Chapter 138. There is evidence suggesting NAC offers a mortality benefit in non-acetaminophen induced acute liver failure, though the evidence is evolving and clear guidelines do not yet exist. Given the relative safety of NAC and the high morbidity of this disease, we recommend initiation of NAC therapy or discussion of NAC initiation with a hepatologist, depending on local practice patterns.[5,6]

In the absence of liver failure, patients with encephalopathy, coagulopathy, or unstable vital signs should be considered for admission.

TABLE 24.2 Jaundice: Differential Diagnosis of Critical and Emergent Diagnoses

System	Critical	Emergent	Nonemergent
Hepatic	Fulminant hepatic failure (toxin, virus, alcohol, ischemic insult, Reye syndrome)	Hepatitis of any cause with confusion, bleeding, or coagulopathy	Hepatitis with normal mental status, normal vital signs, and no active bleeding
		Wilson disease	
		Primary biliary cirrhosis	
		Autoimmune hepatitis	
		Liver transplant rejection	
		Infiltrative liver disease	
		Drug induced (isoniazid, phenytoin, acetaminophen, ritonavir, halothane, sulfonamides)	
		Toxin ingestion or exposure	
Biliary	Cholangitis	Bile duct obstruction (stone, inflammation, stricture, neoplasm)	
Systemic	Sepsis	Sarcoidosis	Post-traumatic hematoma resorption
	Heatstroke	Amyloidosis	Total parenteral nutrition
		Graft-versus-host disease	
Cardiovascular	Obstructing AAA	Right-sided congestive heart failure	
	Budd-Chiari syndrome	Veno-occlusive disease	
	Severe congestive heart failure		
Hematologic-oncologic	Transfusion reaction	Hemolytic anemia	Gilbert syndrome
		Massive malignant infiltration	Physiologic neonatal jaundice
		Inborn error of metabolism	
		Pancreatic head tumor	
		Metastatic disease	
Reproductive	Preeclampsia or HELLP syndrome	Hyperemesis gravidarum	
	Acute fatty liver of pregnancy		Cholestasis of pregnancy

AAA, Abdominal aortic aneurysm; *HELLP,* hemolysis, elevated liver enzymes, low platelets.

There are no comprehensive guidelines to indicate what level of hepatic or biliary dysfunction requires inpatient management. However, guidelines recommend consideration of immediate transfer to a liver specialist in cases of acute hepatitis with elevated INR or encephalopathy.[1] In addition, we recommend consideration of hospitalization for patients with new-onset jaundice and transaminase levels approaching 1000 IU/L, bilirubin approaching 10 mg/dL, or any evidence of coagulopathy, as these laboratory abnormalities suggest significant hepatic dysfunction. Patients with hepatitis or cholestatic jaundice may be managed in the outpatient setting, particularly patients with normal mental status, stable vital signs, ability to take oral fluids, no evidence of acute bleeding or significant coagulopathy, no complicating infectious process, and the ability to access follow-up care. Intravenous fluids and antiemetics may be necessary in the ED. Alcohol or medications with potential hepatotoxicity, particularly acetaminophen, should be avoided. In the setting of large volume paracentesis characterized by greater than 5 L of ascitic fluid removed, IV albumin repletion should be considered to prevent circulatory compromise with 6 to 8 g albumin administered IV for each liter of ascitic fluid removed.[3]

Management of biliary stone disease is discussed in Chapter 76. In general, patients with uncomplicated cholecystitis should receive intravenous fluids, antibiotics, parenteral analgesics, and antiemetics as needed, with subsequent hospitalization.[7] Ultrasound or CT with IV contrast, as well as consultation with a surgeon, should be considered.

Patients with confirmed or suspected choledocholithiasis, gallstones in the common bile duct, require admission for possible ERCP or cholecystectomy.[8] Neither CT nor ultrasonography is 100% sensitive in identifying a common bile duct stone, but they are reasonably sensitive in identifying a dilated common bile duct, which is highly suggestive of obstruction.

Fever, abdominal pain, and obstructive jaundice suggest ascending cholangitis (Fig. 24.3). Patients should receive antibiotics and intravenous fluids (see Chapter 76). As biliary excretion of most antibiotics is compromised in the setting of obstruction, patients often require biliary drainage.[8] This generally should be accomplished urgently but may be deferred 24 to 48 hours in stable patients. Drainage can be accomplished by endoscopic, percutaneous, or open surgical approaches. Prompt consultation with general surgery or gastroenterology, depending on local resources, is necessary to determine optimal timing and approach.

Patients with extrahepatic obstructive jaundice without cholangitis should also be considered for admission and drainage. ERCP is therapeutic for benign obstructions, such as gallstones or strictures. Patients with obstructive jaundice caused by malignancy may also benefit from biliary decompression, whether operative or endoscopic. Malignancy with jaundice heralds more advanced disease with increased morbidity and mortality.

In patients with anemia and jaundice, the management is based largely on the underlying etiology. Hematology consultation is often necessary to guide further management.

CHAPTER 24: QUESTIONS AND ANSWERS

1. A 56-year-old male presents with fever and abdominal distention. Bedside ultrasound reveals ascites and the results of paracentesis indicate possible spontaneous bacterial peritonitis (SBP). What daily medication should be stopped upon admission?

a. Amlodipine
b. Crestor
c. Lactulose
d. Nadolol

Answer: d. Beta blocker use in patients with cirrhosis with SBP should be discontinued as they have been shown to increase mortality.

2. A 43-year-old female presents with 1 month of painless abdominal swelling. On examination she has a diffusely swollen abdomen with a fluid wave. To help determine the etiology, you obtain the serum ascites albumin gradient (SAAG). Which value is consistent with cirrhosis?

a. 0.25 g/dL
b. 0.5 g/dL
c. 1 g/dL
d. 1.5 g/dL

Answer: d. A (SAAG) value of greater than or equal to 1.1 g/dL is found in patients with portal hypertension. There are many causes of portal hypertension, including cirrhosis, liver failure, or heart failure. A SAAG value of less than 1.1 g/dL may be found in patients with conditions such as lupus or pancreatitis.

3. A 48-year-old male with a history of cirrhosis presents with 3 days of abdominal pain and fever. Abdominal paracentesis suggests spontaneous bacterial peritonitis (SBP). Which of the following initial treatments is most appropriate?

a. Cefotaxime, albumin, and discontinue beta blockade
b. Ceftriaxone and dexamethasone
c. Ceftriaxone alone
d. Ciprofloxacin and metronidazole

Answer: a. The empirical antibiotic of choice is a third-generation cephalosporin (e.g., cefotaxime). Albumin administration has been shown to reduce risk for mortality and hepatorenal syndrome. If the patient has a history of cirrhosis and is taking a nonselective beta blocker, it should be discontinued because it has been shown to increase mortality in patients with SBP.

4. A 41-year-old male with a history of cirrhosis presents with fever, abdominal distension, and confusion. A paracentesis is performed in the evaluation of spontaneous bacterial peritonitis (SBP). What are the diagnostic criteria found in the ascitic fluid that confirms SBP?

a. Ascitic fluid neutrophil count >100
b. Ascitic fluid neutrophil count >250
c. Ascitic fluid total WBC count >100
d. Ascitic fluid total WBC >250

Answer: b. The presence of more than 250 polymorphonuclear cells per cubic millimeter of ascitic fluid is diagnostic for SBP.

5. A 55-year-old female presents with 1 month of diffuse abdominal swelling and pain. She reports a long history of alcohol use. In evaluating this patient for jaundice, at what bilirubin level does jaundice typically become clinically apparent?

a. 1 mg/dL
b. 2 mg/dL
c. 2.5 mg/dL
d. 4 mg/dL

Answer: d. Clinical jaundice is usually not evident until the total serum bilirubin concentration rises above 2.5 mg/dL. Jaundice is first apparent sublingually, in the conjunctiva or on the hard palate.

Nausea and Vomiting

Joshua Guttman

KEY CONCEPTS

- Nausea and vomiting can result from a primary problem in the gastrointestinal (GI) tract but can also result from problems in the neurological, vestibular, urogenital, cardiac, or other systems.
- In the acutely vomiting patient, associated symptoms and medication history are most helpful in narrowing the differential diagnosis.
- Laboratory studies are not necessary for all patients with vomiting. In patients with severe or protracted vomiting, consider checking electrolytes and renal function, particularly when intravenous (IV) rehydration is initiated.
- In patients with undifferentiated nausea or vomiting or vomiting due to non-obstructive GI disease, ondansetron is the first-line antiemetic due to its low side effect profile. However, no definitive evidence exists for the superiority of one antiemetic agent over others.
- Although evidence is limited, metoclopramide is the antiemetic of choice in hyperemesis gravidarum and vomiting associated with headache, and ondansetron is the drug of choice in chemotherapy-induced vomiting.
- Ondansetron is the first-line agent for children with vomiting due to acute gastroenteritis.
- Consider cannabinoid hyperemesis syndrome (CHS) in all patients with protracted vomiting. Emergency department (ED) treatment of CHS includes the use of capsaicin cream as well as haloperidol or lorazepam.

FOUNDATIONS

Epidemiology

The most common causes of nausea and vomiting are GI disorders. Nausea and vomiting may also represent disorders outside the GI tract, such as hyperemesis gravidarum, intracranial lesions and infections, myocardial infarction, diabetic ketoacidosis, and drug toxicities. With heightened access to marijuana, there has been an increased prevalence of cannabinoid hyperemesis syndrome (CHS). A cross-sectional study in the United States noted a near doubling of presentations for cyclical vomiting associated with marijuana use after legalization in one state.[1]

Pathophysiology

The act of vomiting occurs in three phases: nausea, retching, and actual vomiting. Nausea may occur without retching or vomiting, and retching may occur without vomiting. Similar pathways mediate them. In the *nausea* phase, increased tone in the musculature of the duodenum and jejunum, combined with a concomitant decrease in gastric tone, leads to the reflux of intestinal contents into the stomach. There is often associated hypersalivation, repetitive swallowing, and tachycardia.

Retching is the rhythmic, synchronous contraction of the diaphragm, abdominal muscles, and intercostal muscles against a closed glottis without the expulsion of gastric contents.

Vomiting is the forceful expulsion of gastric contents through the mouth. Contraction of the external oblique and abdominal rectus muscles, combined with relaxation of the hiatal portion of the diaphragm, increases the pressure in the abdominal and thoracic compartments. Simultaneously, there is relaxation of the gastric fundus, cardia, and upper esophageal sphincter as the vomitus is brought up and out of the mouth. The glottis closes to prevent aspiration.

Rumination may be confused with vomiting. Ruminating is when stomach contents dribble out of the mouth non-forcefully, which may be voluntary and is not associated with muscle contraction. Patients may swallow ruminated contents.

The complex act of vomiting is coordinated by the *vomiting center* located in the medulla. The vomiting center contains muscarinic receptors, which, when stimulated, trigger the vomiting reflex. The efferent pathways from the vomiting center are mainly through the vagus, phrenic, and spinal nerves (Fig. 25.1). These pathways are responsible for the integrated response of the diaphragm, intercostal muscles, abdominal muscles, stomach, and esophagus. The vomiting center is activated by afferent stimuli from a variety of sources. These include (1) visceral afferent impulses directly from the GI tract; (2) visceral afferent impulses from outside the GI tract, including the biliary system, peritoneum, pharynx, genitalia, and heart; (3) extramedullary central nervous system (CNS) afferents, including the vestibular system, thalamus, and cerebral cortex; and (4) the chemoreceptor trigger zone (CTZ) (Fig. 25.2), which is located in the area postrema in the floor of the fourth ventricle. Part of the CTZ is located outside of the blood-brain barrier, enabling it to respond to endogenous and exogenous substances that activate vomiting (see Fig. 25.2).

The discovery of various neurotransmitters and their receptor sites within the medulla has improved the understanding and development of therapeutic agents. The CTZ area is rich in dopamine D_2 and serotonin receptors, and the lateral vestibular nucleus is rich with cholinergic and histamine receptors. Serotonin receptors are also widely found in the GI tract. These receptor sites are targets for the various medications used to treat nausea and vomiting.

The pathophysiology of cannabinoid hyperemesis syndrome remains unknown, although downregulation of the cannabinoid receptor CB1 is speculated. While cannabinoid receptors typically inhibit vomiting, chronic cannabis use downregulates the receptors, predisposing to CHS. Other purported mechanisms include the pro-emetic properties of cannabis at higher and more sustained doses, as well as decreased gastric motility induced by cannabis.[2]

DIAGNOSTIC APPROACH

Differential Diagnosis Considerations

The differential diagnosis for nausea and vomiting is broad in scope; almost any organ system can be involved. *Acute* vomiting begins abruptly, generally lasts less than 1 week before presentation, and is

frequently associated with acute conditions. *Chronic* vomiting generally occurs longer than 1 month, is frequently associated with motility disorders, effects of systemic treatments (such as for cancer), neuropsychiatric conditions (e.g., bulimia), or neurologic conditions. *Persistent* vomiting has varying definitions and is not well defined in the literature.[3] *Cyclic* vomiting occurs in discrete episodes with intervening asymptomatic periods. Common causes of nausea and vomiting are outlined in Table 25.1, and a differential diagnosis is presented in Tables 25.2 and 25.3.

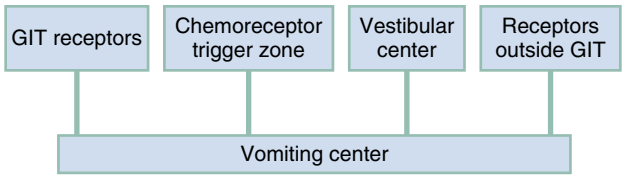

Fig. 25.1 Vomiting Process. *GIT,* Gastrointestinal tract.

Pivotal Findings

Symptoms

A thorough history, including past medical history, medications, and drug use, will generally elicit suspected etiologies of vomiting. The content and color of the vomitus may help determine its cause (Table 25.4). Although coffee ground emesis suggests a slower bleeding rate than bright red blood, this distinction is variable. The history is directed at assessing for both the causes of vomiting and its sequelae.

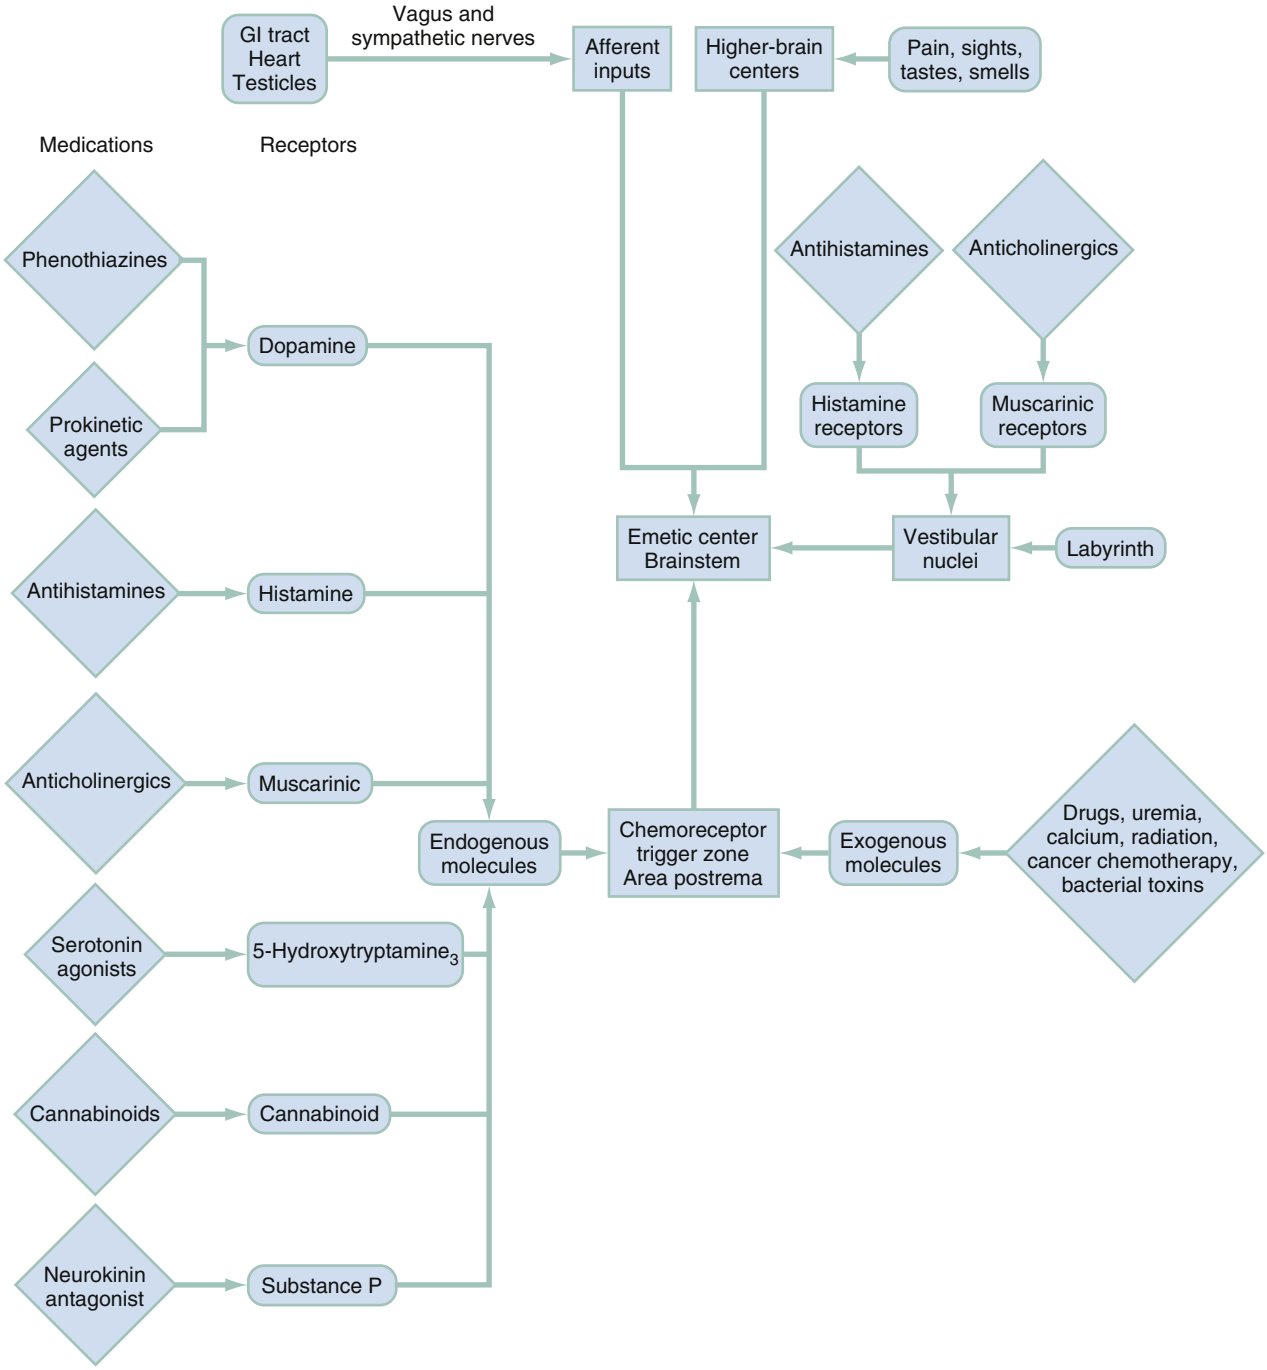

Fig. 25.2 Pathophysiology of Nausea and Vomiting. *GI,* Gastrointestinal.

TABLE 25.1 Disorders Commonly Associated With Vomiting.

Disorder	Class	History	Prevalence	Physical Examination	Useful Tests	Comments
Nausea and vomiting of pregnancy (NVP)	Acute	Vomiting may occur in the morning or throughout the day. Associated breast tenderness. NVP typically starts in weeks 4–7, peaks in weeks 10–16, and disappears by week 20. Vomiting that begins after week 12 or continues past week 20 should prompt a search for another cause.	Very common Affects 75% of all pregnancies	Benign abdomen	Urine pregnancy test Serum electrolytes, urine ketones to exclude hyperemesis gravidarum	Consider NVP in all females of childbearing capacity. Prognosis for mother and infant is excellent. NVP is associated with a decreased risk of miscarriage, fetal growth retardation, and fetal mortality.
Hyperemesis gravidarum	Acute	Severe, protracted form of NVP. No universally accepted definition of the disease. Generally accepted hallmarks include 5% weight loss, ketonuria, and electrolyte disturbance. Hyperemesis is associated with multiple gestation, molar pregnancy.	Affects 0.3%–3% of pregnancies	Signs of dehydration Benign abdomen	β-hCG Urinalysis for ketones (65% of patients) Serum electrolytes Ultrasound examination to exclude molar pregnancy or multiple gestations (if not already performed in current pregnancy)	Studies are conflicting on fetal outcomes. There may be an association with low fetal birth weight and maternal weight loss.
Gastroenteritis	Acute	Fever, diarrhea, and crampy abdominal pain. Vomiting and pain occur early, usually followed by diarrhea within 24 h.	Very common	Benign abdomen	Usually not necessary	Early gastroenteritis, when only vomiting and periumbilical pain are present, may be confused with early appendicitis. Diarrhea is usually in the diagnosis of gastroenteritis.
Gastritis	Acute	Epigastric pain, belching, bloating, fullness, heartburn, and food intolerance. Use of NSAIDs or alcohol is common.	Very common	Mild epigastric tenderness may be present.	Lipase, LFTs, and pregnancy test may be necessary to exclude other diagnoses	Removal of inciting agent along with antacid therapy will resolve symptoms in majority of patients.
Peptic ulcer disease (PUD)	Acute Chronic	Epigastric pain present in 90% of cases. Presence of severe pain should raise suspicion of perforation.	Very common	Mild epigastric tenderness	Hemoglobin and hemoccult testing if bleeding is suspected Upright chest film or CT scan if perforation is suspected	Three major causes of PUD are NSAIDs, *Helicobacter pylori* infection, and hypersecretory states.
Biliary disease		Abdominal pain may be midepigastric or RUQ. Onset frequently after a fatty meal. May have history of similar episodes in the past.	Very common	RUQ tenderness present in most cases. If instructed to breathe deeply during alpation in the RUQ, the patient experiences heightened tenderness and inspiratory arrest (Murphy sign).	WBCs Lipase Serum bilirubin LFTs RUQ ultrasound examination	Normal temperature, WBCs, and spontaneous resolution of symptoms suggest biliary colic. Fever, Murphy sign, elevated WBCs, and suggestive ultrasound indicate cholecystitis.
Myocardial infarction (MI)	Acute	Patients typically have substernal chest pain. Vomiting may be an associated symptom.	Common	Patients often are anxious and in distress from pain. No diagnostic examination findings.	ECG (new Q waves, ST segment changes, or T wave inversions) troponin	Not all patients have chest pain. Some patients, particularly women and diabetic patients, may not have chest pain. Consider an ECG and troponins for this subset of patients and patients with cardiac risk factors and isolated vomiting or vomiting with epigastric pain.

Continued

TABLE 25.1 Disorders Commonly Associated with Vomiting—cont'd.

Disorder	Class	History	Prevalence	Physical Examination	Useful Tests	Comments
Diabetic ketoacidosis (DKA)	Acute	Polydipsia and polyuria occur early. Without treatment, altered mental status and coma may develop. .	Common	"Fruity" breath odor results from serum acetone. Tachypnea Signs of dehydration may be present. Severe cases often manifest with altered mental status or coma.	Serum glucose Electrolytes serum beta hydroxybutyrate VBG	Any protracted vomiting, especially in children, should prompt measurement of a fingerstick glucose test.
Pancreatitis	Acute Chronic	Presenting symptom is epigastric pain, which often radiates to the back. Most cases are caused by gallstones or alcoholism.	Common	Epigastric tenderness is present. Associated paralytic ileus may cause abdominal distention and decreased bowel sounds. Frank shock may be present in severe cases.	Lipase WBC Serum glucose LDH AST Hematocrit BUN Calcium VBG	Early aggressive intravenous hydration is especially important in pancreatitis patients with severe vomiting.
Appendicitis	Acute	Abdominal pain classically begins in periumbilical region and later moves to right lower quadrant. Anorexia is common.	Common	Localized tenderness over right lower quadrant. Low-grade fever may be present.	WBC Ultrasound Abdominal CT	Early appendicitis can be a difficult diagnosis to make.
Bowel obstruction	Acute Chronic	Abdominal pain, vomiting, obstipation and constipation. Typically, patients will have a surgical history.	Common	Abdominal distention, mild diffuse tenderness, and high-pitched "tinkling" bowel sounds may be present. Thorough search for hernias should be performed.	Electrolytes Lactate POCUS Abdominal CT	Adhesions, hernias, and tumors account for 90% of bowel obstructions. NG tube placement can relieve the vomiting of obstructed gastrointestinal contents.
Carbon monoxide (CO) poisoning	Acute	Headache is usually present. CO poisoning often occurs during winter months when furnaces are turned on. Family members (or pets) may have similar symptoms if they also have been exposed.	Uncommon	No reliable signs of early CO poisoning.	CO level	Because CO is a tasteless, odorless gas, patients may not realize they have been exposed.
Boerhaave syndrome	Acute	Patients may have neck, chest, or epigastric pain. Forceful, protracted vomiting usually causes the tear. Most cases follow a bout of heavy eating and drinking. Other reported causes include childbirth, defecation, seizures, and heavy lifting.	Uncommon	Tachypnea, tachycardia, and hypotension may be present. Escaped air from the esophagus may produce subcutaneous emphysema. Air in the mediastinum produces a "crunching" sound as the heart beats (Hamman sign).	CXR showing mediastinal air is suggestive but CT is more sensitive. Esophagogram with water-soluble contrast is definitive.	The classic presentation includes forceful vomiting, severe chest pain, subcutaneous emphysema, and multiple CXR findings. There is a growing body of evidence that most cases do not have this "classic" picture. In more subtle presentations, the diagnosis can be difficult to make.
Cannabinoid hyperemesis syndrome	Cyclic	Severe retching and vomiting in the context of daily marijuana use. Relieved with hot showers.	Increasing	Severe distress from vomiting, dehydration. Occasional epigastric tenderness.	Electrolytes and renal function	Ask about marijuana use in all patients with intractable, recurrent, or episodic vomiting.

BPPV, Benign paroxysmal peripheral vertigo; *CNS,* central nervous system; *DKA,* diabetic ketoacidosis; *IBD,* inflammatory bowel disease; *IBS,* inflammatory bowel syndrome; *ICP,* intracranial pressure; *PUD,* peptic ulcer disease.

The timing and duration of the vomiting may be important. Symptoms occurring primarily in the morning may suggest increased intracranial pressure. Vomiting occurring more than 1 hour after eating suggests gastric outlet obstruction or gastroparesis. Vomiting of material eaten more than 12 hours previously is pathognomonic for outlet obstruction.

Associated symptoms are helpful: Vomiting with diarrhea is generally due to infectious gastroenteritis but may also be present in mesenteric ischemia or other GI surgical emergencies. Vomiting associated with abdominal pain is generally caused by diseases of the GI system. Chronic headaches with nausea and vomiting should raise suspicion of elevated intracranial pressure. Vomiting without preceding nausea is also suspicious for CNS pathology.

The *social history* should include alcohol or other substance use. The *past medical history* should include GI diseases or prior surgery. Finally, a thorough *medication list,* including over-the-counter drugs and supplements, should be elicited.

A history of *similar episodes* should be elicited. A history of severe episodes of nausea and vomiting lasting hours to days with symptom-free

BOX 25.1 Rome IV Criteria for Cannabinoid Hyperemesis Syndrome.

Must include all of the following:

1. Stereotypical episodic vomiting resembling cyclical vomiting syndrome in terms of onset, duration, and frequency
2. Presentation after prolonged, excessive cannabis use
3. Relief of vomiting episodes by sustained cessation of cannabis use

Criteria fulfilled for the last 3 months, with symptom onset at least 6 months before diagnosis

Supportive remarks:

May be associated with pathologic bathing behaviors (prolonged hot baths or showers)

Rome IV criteria[5]

intervals may lead to a diagnosis of cyclical vomiting syndrome (CVS). In patients with a history of cyclical vomiting, chronic use of cannabis is essential to elicit, as it may lead to a diagnosis of cannabis hyperemesis syndrome.[1] Symptoms are similar to CVS, though patients will often note temporary relief with a hot shower.[1] The onset of the syndrome may occur following years of chronic marijuana use but can also occur with daily marijuana use of less than 1-year duration.[4] The Rome IV diagnostic criteria for CHS can be found in Box 25.1.[5]

Signs

The examination begins with an overall assessment of the patient's clinical status, including an assessment for volume depletion. The history will direct the examination to the appropriate organ systems (Table 25.5). The eye examination may reveal nystagmus, which may indicate cerebellar pathology, peripheral vertigo, or drug intoxication. Oral examination may reveal loss of dental enamel seen with bulimia or dry mucus membranes from dehydration. Abdominal examination may

TABLE 25.5 Physical Examination of the Patient with Nausea and Vomiting.

Organ System	Finding	Suggested Diagnoses
General	Poor skin turgor Dry mucous membranes	Dehydration
Vital signs	Fever	Gastroenteritis, cholecystitis, appendicitis, hepatitis Bowel perforation
	Tachycardia, orthostatic changes	Dehydration
HEENT	Nystagmus	Labyrinthitis Vertebrobasilar insufficiency Cerebellar infarct or bleed CPA tumor
	Papilledema	Increased ICP from CNS tumor or bleeding
Neck	Goiter	Thyroid disease
Lungs	Rales	Pneumonia
Heart	Arrhythmia Murmur	Acute myocardial infarction or other cardiac pathology
Abdomen	Abdominal distention Peristaltic waves High-pitched bowel sounds Decreased bowel sounds Hernias or surgical scars Peritoneal signs	Bowel obstruction, gastroparesis Gastric outlet obstruction Bowel obstruction Ileus Possible bowel obstruction Appendicitis, cholecystitis Perforated viscus
Neurologic	Abnormal mental status Cerebellar findings Cranial nerve findings	CNS pathology

CNS, Central nervous system; *CPA,* cerebellopontine angle; *HEENT,* head, eyes, ears, nose, throat; *ICP,* intracranial pressure.

reveal ascites, distention, hernias, abdominal tenderness and masses, hyperactive or hypoactive bowel sounds. Neurological examination (including funduscopic) is essential when considering a central cause. Provocative testing in patients with suspected benign paroxysmal positional vertigo may elicit vomiting or nystagmus (see Chapter 15). Symptoms of depression or anxiety may suggest a psychiatric origin, although this is a diagnosis of exclusion and rarely is made in the ED.

Ancillary Studies

The history and physical examination direct testing:

- Serum electrolytes and renal function: Measurement of serum electrolytes and renal function is not routinely required. It should be considered in patients with a history of prolonged or severe vomiting or clinical evidence of dehydration requiring volume replacement to assess for hypokalemia, hypochloremia, hypo- or hypernatremia, or contraction alkalosis. In the context of vomiting, acute renal dysfunction typically results from pre-renal azotemia.
- Serum lipase: Lipase determination is prudent in cases of suspected pancreatitis.
- Liver function and ammonia tests: Liver function tests are indicated in cases of suspected hepatic or biliary disease. Ammonia testing is appropriate when liver failure is suspected.
- Serum drug levels: Serum drug levels may be necessary for determining the cause of nausea and vomiting in patients on digoxin, salicylates, acetaminophen, valproic acid, carbamazepine, or phenobarbital,

especially in elders with cognitive or visual impairment who are taking medications without supervision. Specific serum drug levels are obtained when knowledge of the drug level would alter a patient's management.

- Serum betahydroxybutyrate or venous blood gas: These tests are obtained when diabetic ketoacidosis is suspected.
- Urine tests: A urine pregnancy test (or serum pregnancy test) should be performed in all women of childbearing capacity with nausea or vomiting. A urinalysis may show leukocyte esterase, nitrites, or bacteria as evidence of a urinary tract infection. Ketones support a diagnosis of diabetic ketoacidosis or prolonged starvation state. Hematuria indicates a possible renal calculus.
- Ultrasound: A point-of-care ultrasound (POCUS) or comprehensive abdominal ultrasound evaluates for cholelithiasis, cholecystitis, renal colic, or gonadal torsion. POCUS can also assess for small bowel obstruction (SBO). Additionally, a POCUS assessment of the inferior vena cava may help monitor patients with suspected dehydration. In pregnant patients, an ultrasound should be performed to confirm an intrauterine pregnancy. In pediatric patients, POCUS or comprehensive ultrasound can assess for appendicitis or intussusception.
- Abdominal computed tomography (CT): Abdominal CT scan is indicated in patients with a suspected SBO or surgical cause, such as appendicitis, when not diagnosed by ultrasound.
- Neuroimaging: Head CT evaluates intracranial etiologies of nausea and vomiting, while MRI is preferred for posterior fossa pathologies, such as cerebellar infarction.
- Chest imaging: A chest x-ray may reveal subdiaphragmatic air in a patient with a perforated viscus, but abdominal CT is far superior when perforation or other serious intra-abdominal pathologies are suspected. For patients with suspected Boerhaave syndrome, a chest radiograph can assess for a pneumomediastinum, though CT is the preferred modality.

DIAGNOSTIC ALGORITHM

Patients presenting with acute vomiting are rapidly assessed for critical conditions (see Table 25.4). A diagnostic algorithm is shown in Fig. 25.3. Vomiting may result in serious sequelae (Table 25.6).

If the patient is unstable or seriously ill, oxygenation is provided as needed, IV access and cardiac monitoring are established, and vital sign disturbances are addressed. A brief history and directed physical examination are performed concomitantly to determine the most likely causes, with evaluation and management prioritized to those causes.

If the patient is stable, a more thorough history and physical examination are performed. The history and physical examination direct ancillary testing and empiric therapy. Serum electrolyte and renal function determination is prudent in patients with significant volume depletion requiring IV replacement. IV analgesics and antiemetics are reasonable in patients with severe abdominal pain and vomiting, as are liver function tests and lipase. A serum lactate level can be helpful when evaluating possible sepsis. Many patients with severe pain and tenderness will require abdominal imaging. Patients with a history of abdominal surgery and decreased stool output are evaluated for SBO. Patients with severe headache or neurological deficits not thought to be due to a primary headache disorder should have neuroimaging performed, and patients with suspected myocardial infarction need an electrocardiogram (ECG) and troponin testing. Acetaminophen and aspirin levels, as well as the measurement of other serum drug levels, should be considered in patients with suspected medication overdose or drug toxicity.

If an emergent cause of nausea and vomiting is highly suspected or confirmed based on the initial evaluation and ancillary testing, then appropriate management is initiated to treat the underlying cause. Patients who are generally well-appearing and have a low likelihood of severe disease, whose symptoms are controllable, but for whom the diagnosis is still unclear, should have follow-up arranged within 24 to 48 hours for reevaluation if symptoms persist, or more urgently if symptoms worsen or a new, concerning symptom, such as blood in the stool or vomit, fever, or localized pain develops.

Patients who have a suspected or confirmed nonemergent diagnosis are treated with antiemetic medications, with specific management directed at the underlying cause. Patients with cyclical or recurrent vomiting syndromes do not generally require diagnostic testing in the ED and are managed in consultation with the patient's primary care physician. However, care should be taken to avoid anchoring on a previous diagnosis of CVS. Corroborative information from the patient, the medical record, family members, or the primary care physician can help ensure that the pattern of the presentation fits the patient's syndrome.

EMPIRICAL MANAGEMENT

Management is directed at simultaneous symptom relief and identification of the underlying cause. Symptomatic relief should proceed regardless, as the underlying cause may not be identified during the ED course. Decreased oral intake with concomitant fluid loss by vomiting or diarrhea causes dehydration. If the patient is mildly or moderately dehydrated and can take oral liquids, a solution containing sodium, carbohydrate, and water is administered. Many sports drinks contain the proper balance of these elements. Patients who are severely dehydrated or in whom intake of oral fluids is not feasible or contraindicated should receive an IV crystalloid solution, including the correction of electrolyte abnormalities as needed. Placement of a nasogastric tube is rarely indicated, except in patients with severe bowel obstruction.

The need for antiemetics and the response to therapy may be measured with scales similar to those used for pain assessment, such as a visual analog scale and the verbal categorical scale.

Patients presenting to the ED with nausea or vomiting may have a known etiology with specific treatment aimed toward treating the underlying cause. These are discussed in the Specific Situations section.

Adults

For the adult patient with non-obstructive GI causes or undifferentiated nausea and vomiting, there is limited evidence to support the use of one antiemetic agent over another. A 2015 Cochrane review did not demonstrate the superiority of any agent over placebo, other than droperidol, which demonstrated superiority in a single study.[6] Table 25.7 lists medications commonly used to treat nausea and vomiting, and My recommendations are shown in Fig. 25.4.

Pharmacologic therapies include serotonin antagonists, histamine antagonists, muscarinic antagonists, and dopamine antagonists.

The serotonin antagonists, particularly ondansetron, are considered first-line therapies for most cases of nausea and vomiting in the ED. The initial dose of ondansetron is 4 to 8 mg PO/IV. A single dose of up to 16 mg is considered safe in the non-elderly population. In elders, the initial dose should not exceed 8 mg infused over at least 15 minutes. For most patients, there are few or no side effects of the serotonin receptor antagonists and, if they occur, are mild. Ondansetron is known to cause QT prolongation with the resultant risk of Torsade de pointes. Patients at risk for having a prolonged QT should have an ECG before administration of ondansetron. QT prolongation occurs in a dose-dependent manner, with the risk occurring as the dose increases. The FDA recommends the correction of electrolytes, particularly potassium and magnesium, before administration.[7] Ondansetron has also been associated with serotonin toxicity when given concurrently with other serotonergic agents.

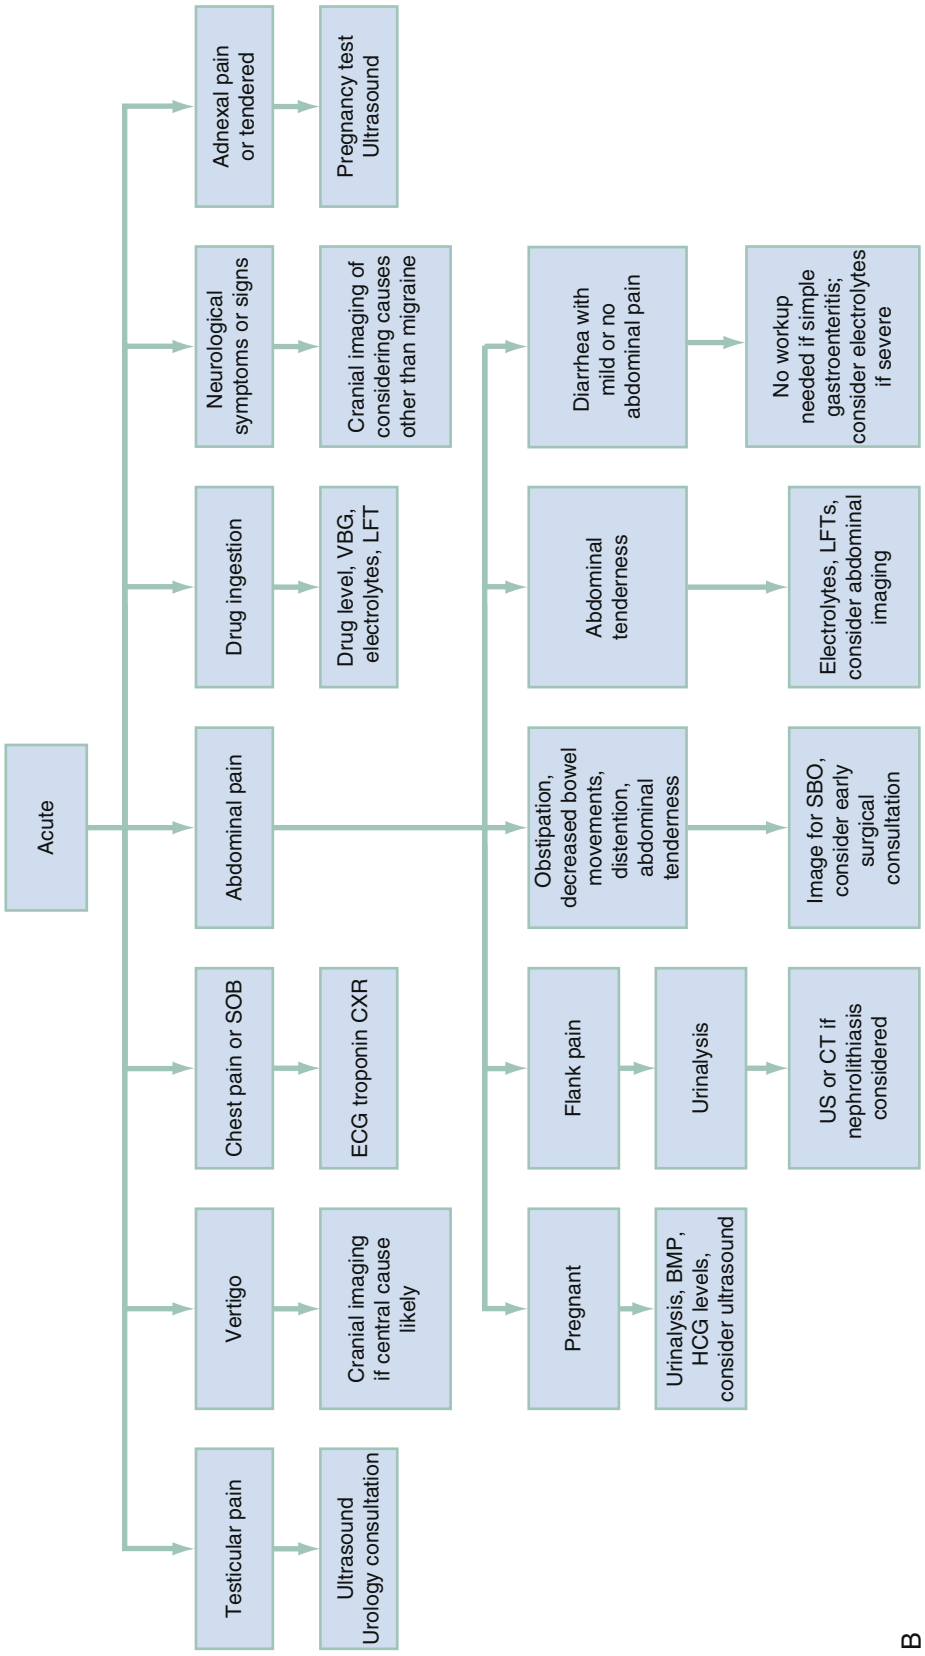
Continued



B

Fig. 25.3 cont'd.

Metoclopramide (Reglan) is another first-line agent for use in the ED as a general-purpose antiemetic. As a prokinetic agent, it is useful in patients with gastroparesis and other dysmotility syndromes. The initial dose of metoclopramide is 10 to 20 mg IV or intramuscular (IM).

The phenothiazines, prochlorperazine (Compazine, Stemetil) and promethazine (Phenergan), have historically been first-line agents and are still widely used as general-purpose antiemetics. Although both agents are sedating, promethazine is more sedating and is associated with more extrapyramidal effects. Due to increased side effects, these medications are considered third-line in the ED.

The antipsychotic medication, droperidol, is also considered useful in the treatment of nausea and vomiting. Droperidol had generally fallen out of favor due to the FDA black box warning regarding QT prolongation. Of note, none of the adverse events reviewed by the FDA were for the typical antiemetic doses of less than 2.5 mg. An ECG should be performed before administration to check for QT prolongation. A dose of 1.25 mg IV is sufficient in most patients. The dose may be repeated in 60 minutes if needed. Haloperidol, which is structurally similar to droperidol, may have similar antiemetic effects but has not been formally studied in patients with undifferentiated vomiting. It has no FDA black box warning and thus presents an alternative to droperidol, though similar precautions regarding QT prolongation remain.

Ondansetron 4 mg IV is an excellent first-line choice for patients with undifferentiated nausea and vomiting. It is inexpensive and generally well tolerated. IV crystalloid should also be given if the vomiting is severe. If needed, a repeat 4-mg IV dose can be given in 15 to 30 minutes. If there is an inadequate response, then metoclopramide 10 mg IV should be given, with a repeat dose of metoclopramide after 30 minutes, if needed. An inadequate response to these antiemetics should prompt the clinician to consider the possibility of an underlying mechanical GI obstruction.

If ondansetron and metoclopramide have not been effective and a mechanical obstruction is unlikely, consider using droperidol or haloperidol in a patient at a low risk of adverse effects. Begin with droperidol 1.25 mg IV or haloperidol 5 mg IV, with repeated dosing after 30 minutes, if needed.

If droperidol or haloperidol is not considered safe, then the next drug to consider is prochlorperazine 10 mg IV. If sedation is desired, promethazine may be given prior to trying prochlorperazine. For most patients, begin with promethazine 12.5 mg IM or IV, which may be repeated in 30 minutes if tolerated. If IV promethazine is used, it should be diluted in 10 to 20 mL 0.9% NaCl and administered over 10 to 15 minutes. Promethazine extravasation may cause severe tissue injury; thus, deep IM injection is preferred to the IV route. If the IV route is desired, then the IV should be confirmed to be patent and functioning appropriately prior to administration. In patients who may not tolerate sedation, such as elders, those with underlying respiratory diseases, or those using other sedating medications, begin at 6.25 mg IV or IM, then incrementally increase the dose as tolerated. Dimenhydrinate may be used instead of promethazine, but do not use them together due to their sedating effects.

For patients who remain highly symptomatic following repeated or escalating antiemetic medications, consider observation or hospitalization for continued management and evaluation for the etiology of the vomiting.

TABLE 25.6 Potential Sequelae of Vomiting

Sequelae	Etiology
Hypovolemia	Loss of water and sodium ions in vomitus
Metabolic alkalosis	Loss of hydrogen ions in vomitus
Hypokalemia	Loss of potassium in vomitus
Mallory-Weiss tears	Forceful retching or vomiting causing a 1-cm to 4-cm tear in the mucosa and submucosa; the cause of 3% of deaths from upper GI bleeds
Boerhaave syndrome	Perforation of the esophagus due to increased intraesophageal pressure during forceful retching or vomiting There is free passage of esophageal contents into the mediastinum, causing a chemical mediastinitis, leading to superinfection, sepsis, multiorgan failure, and death It is a surgical emergency The mortality rate is 50% if surgical repair is not performed within 24 h
Aspiration pneumonitis and pneumonia	A concern in patients with baseline poor mental status and pulmonary findings after an episode of vomiting

GI, Gastrointestinal.

TABLE 25.7 Commonly Used Medications for the Treatment of Nausea and Vomiting

Medication	Class	Site of Antiemetic Action	Dosage	Adverse Effects
Ondansetron (Zofran)	Serotonin antagonist	5-HT_3 receptor at CTZ and vagus nerve terminal in GIT	*Adult:* Usual: 4 to 8 mg IV/PO single dose, may go up to 16	May cause headache, dizziness, and musculoskeletal pain. Questionable teratogenic effects, discuss risks and benefits of this or any medication in pregnancy.
Metoclopramide (Reglan)	Dopamine and serotonin antagonist	D2 and 5-HT_3 receptors in CTZ. D2 in stomach and LES	*Adult:* 10 to 20 mg IM or IV, may repeat every 6 h	May cause dystonic reactions, tardive dyskinesia (black box warning), neuroleptic malignant syndrome, restlessness, drowsiness, diarrhea.
Prochlorperazine (Compazine)	Dopamine antagonist	D1 and D2 receptor in CTZ	*Adult:* 5 to 10 mg IM or PO; 2.5 to 10 mg IV every 4 h as needed; 25 mg by rectum every 12 h as needed	May cause lethargy, hypotension, extrapyramidal effects, dystonic reactions, sedation, and feelings of restlessness. Rarely neuroleptic malignant syndrome, blood dyscrasias, and cholestasis.
Promethazine (Phenergan)	Antihistamine	H1 receptor in CTZ, minimal D2	*Adult:* 12.5 to 25 mg IV, IM, PO, or by rectum every 4 h as needed	Extravasation may cause severe tissue injury (black box warning). May cause sedation, dry mouth, dizziness, blurred vision.
Dimenhydrinate (Dramamine, Gravol)	Antihistamine	H1 receptor in GIT and CTZ	25–50 mg IV, IM, or PO every 6 h as needed	Drowsiness, light-headedness.

CTZ, Chemoreceptor trigger zone; *GIT,* gastrointestinal tract; *IM,* intramuscularly; *IV,* intravenously; *LES,* lower esophageal sphincter; *PO,* per os (by mouth).

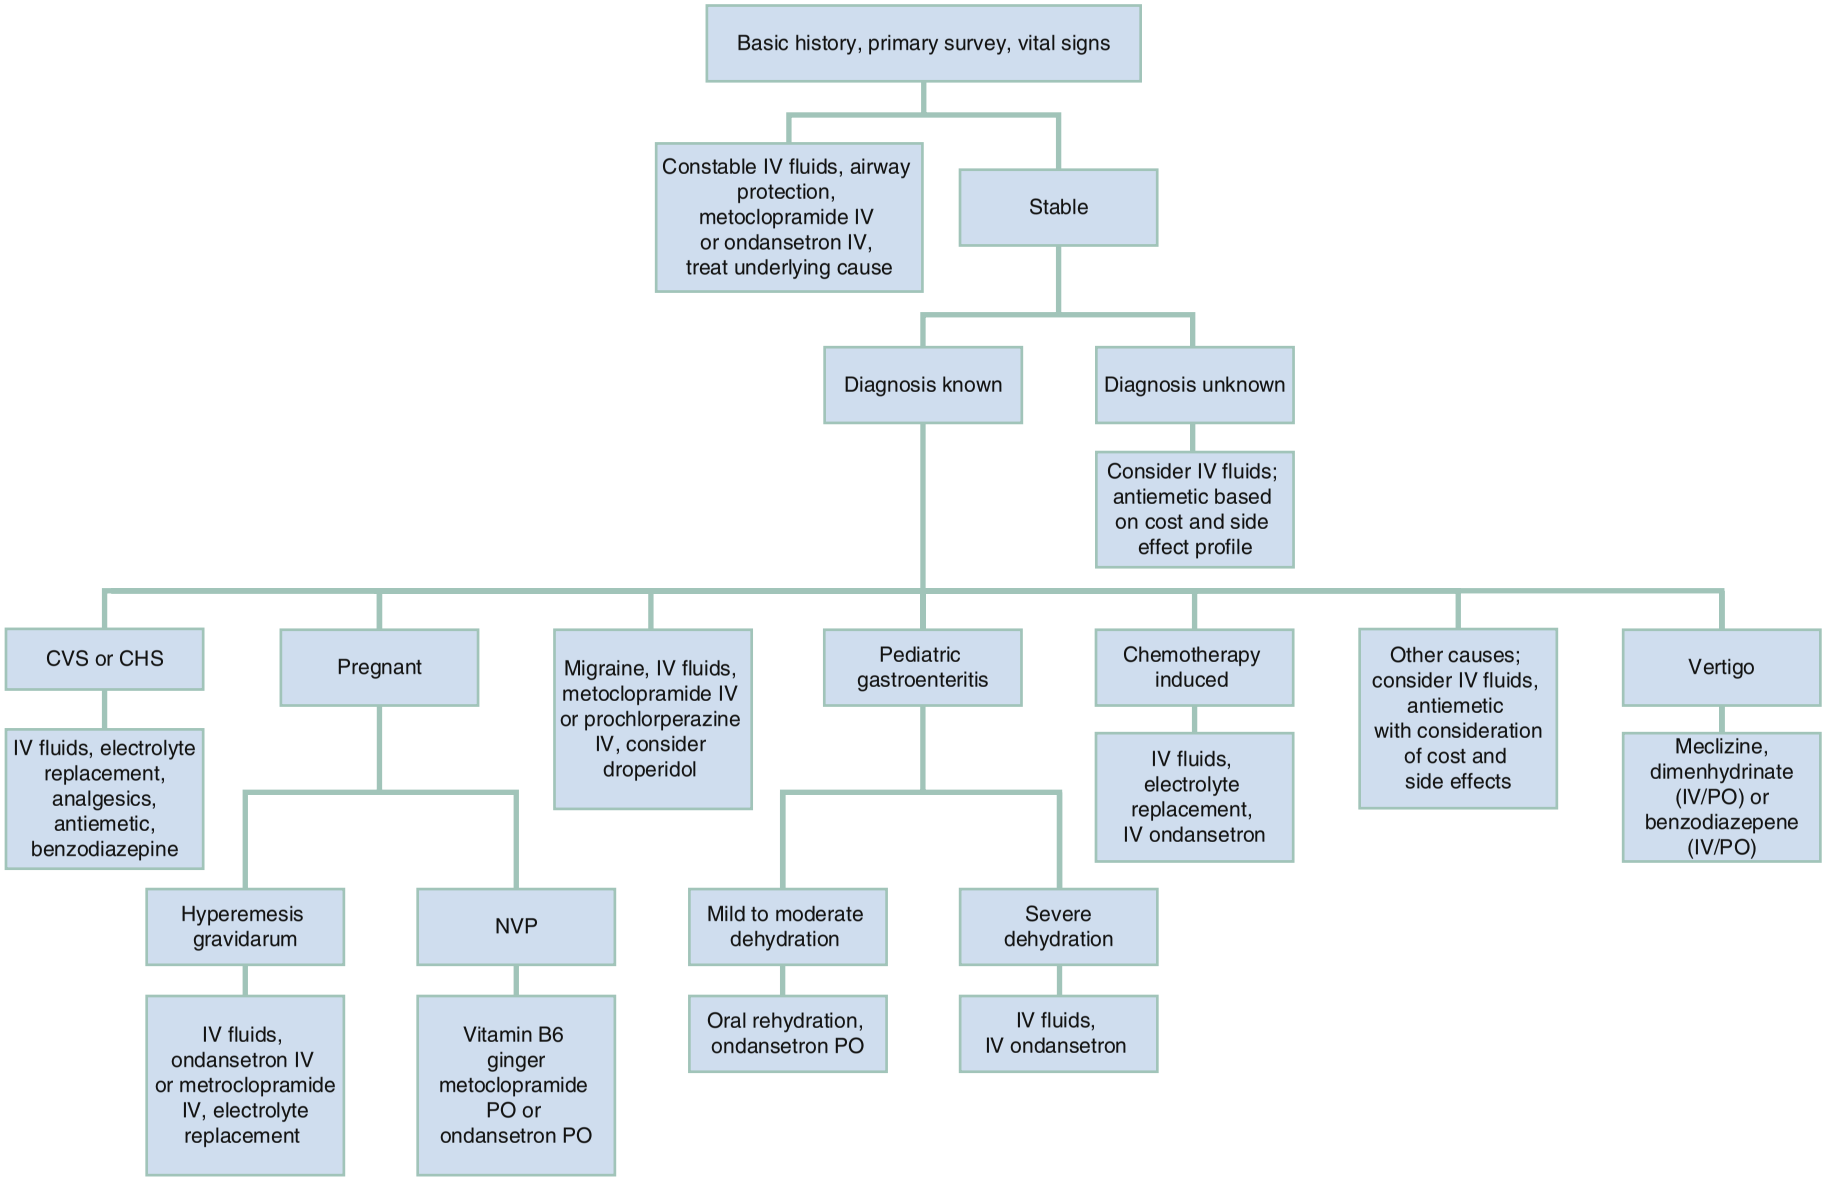


Fig. 25.4 Management Algorithm for the Patient with Nausea and Vomiting. *CHS,* cannabinoid hyperemesis syndrome; *CVS,* cyclical vomiting syndrome; *IV,* intravenous; *NVP,* nausea and vomiting of pregnancy; *PO, per os* (by mouth).

Pediatrics

Acute gastroenteritis is the most common cause of vomiting in the pediatric population (0.15 mg/kg IV or PO). Ondansetron is the first-line agent in children and has the most robust evidence. A 2016 meta-analysis found that ondansetron compared to placebo improved cessation of vomiting after 1 hour while reducing the failure of oral rehydration, the need for IV hydration, and hospitalization rate.[8] Several recent studies have shown the superiority of ondansetron as compared to domperidone or placebo.[9] Of note, all studies that showed benefit with administration of ondansetron were in children who had at least mild dehydration. A randomized control trial on pediatric patients with no dehydration showed no benefit to ondansetron over placebo.[10] All parents received education on appropriate methods of oral rehydration, so it is possible that in these low-risk children, rehydration alone adequately treats the vomiting. Ondansetron is available as an oral dissolve tablet (ODT) or oral solution. The ODT formulation may be superior to the oral solution; however, the evidence for this is weak.[11]

A recent study demonstrated the effectiveness of prochlorperazine in pediatric patients with acute gastroenteritis. A dose of 0.1 to 0.2 mg/kg IV or PO decreased the intensity of vomiting by 88% at 1 hour and 92% at 3 hours.[12] However, due to the relatively high incidence of adverse events (akathisia in 4% to 9% of patients), we recommend that prochlorperazine remain a second-line agent.[13] It is not recommended for children younger than 2 years. For older children, dose should not exceed 7.5 mg daily for patients <14 kg and 10 mg for patients >14 kg.

Special Situations

Opioid-Induced Vomiting

Antiemetic medications do not reduce the incidence of nausea and vomiting associated with the administration of opioid analgesics. Studies have demonstrated that the incidence of nausea and vomiting related to opioid administration is low, and these medications have little efficacy in preventing nausea and vomiting associated with opioids.

Headache

Patients with nausea or vomiting associated with a headache should be given metoclopramide as the first-line agent. Metoclopramide will treat the headache as well as nausea and vomiting. Ondansetron may cause headaches, and therefore is not a preferred first-line agent. Prochlorperazine is a useful second-line agent that is also effective in the treatment of headaches. Droperidol, which also treats headaches and GI symptoms, should be considered if the first two agents fail.

Pregnancy

Many pharmacologic and non-pharmacologic agents have been evaluated in the treatment of nausea and vomiting of pregnancy and hyperemesis gravidarum. A Cochrane review concluded that there was insufficient high-quality evidence to recommend one agent over another.[14] Agents that have shown to be more effective when compared to placebo include ginger, vitamin B6 (pyridoxine), vitamin B6 combination products (such as doxylamine with pyridoxine), ondansetron, phenothiazines, and metoclopramide.[15] A recent meta-analysis on the teratogenic effects of ondansetron showed no conclusive evidence for teratogenicity; however, sensitivity analyses showed a statistically significant increase in cardiac anomalies and cleft palate among fetuses exposed to ondansetron. Overall, the number of affected patients was meager.[16] Metoclopramide and phenothiazine do not have teratogenic effects.[17]

Pregnant patients presenting to the ED with nausea and vomiting may be unable to tolerate oral medication. First-line IV agents include metoclopramide, prochlorperazine, and dimenhydrinate (where available). Metoclopramide is preferred due to limited sedation. Should a first-line agent fail, then ondansetron should be offered. As with any medication in pregnancy, the risks should be discussed with the patient. The benefits frequently outweigh the risks of dehydration from continued vomiting. If these agents do not control the patient's symptoms, then observation or admission should be considered for continued management. Hospitalized patients are started on methylprednisolone 16 mg q8h IV continued for up to 3 days.[17] Methylprednisolone has been shown to decrease hospital readmission.[18]

Chemotherapy

Chemotherapy-induced nausea and vomiting may occur acutely (within the first 24 hours) or delayed (after 24 hours). Ondansetron is the first-line agent, given as repeated doses. Start with 4 mg IV and repeat every 30 minutes up to 16 mg IV. Ondansetron is effective for acute vomiting but is not useful beyond 24 hours. Palonosetron, a second-generation 5-HT_3 antagonist, decreases vomiting after 24 hours and should be given if available.[19] If dexamethasone was not given before chemotherapy then 10 mg IV may be added. Additionally, olanzapine 10 mg orally for 3 days has shown benefit in a randomized control trial.[20] It can be given intramuscularly for patients unable to tolerate oral medications.

Cyclical Vomiting Syndrome and Cannabinoid Hyperemesis Syndrome

Patients with CVS may be difficult to manage. They should receive IV hydration and may require high doses of antiemetic medications, none of which have been deemed superior to others for CVS. Benzodiazepines are recommended as inducing sleep often terminates the episode, especially if antiemetic therapy fails to abort the episode, and admission is considered.

CHS is likely a variant of CVS, and they are managed similarly.[2] Data on ED management of CHS stems from case reports and case series. Combinations of various first-line antiemetics such as ondansetron, metoclopramide, and prochlorperazine are frequently utilized, though none of these medications appears to be effective when given as a single agent. Benzodiazepines and haloperidol given IV have successfully terminated acute episodes. Capsaicin cream applied to the stomach is reported to be helpful in case series. The heating effect of the cream activates receptors that mediate vomiting in the CNS. This is also the purported mechanism for hot showers as a treatment for CHS. While patients with CHS often have severe abdominal pain, opioids should be used with caution as they may worsen vomiting and lead to addiction. Tricyclic antidepressants are used for long-term control of CVS and can be considered upon ED discharge in a reliable patient with close follow-up.

Patients with known or suspected CHS are usually dehydrated, so IV crystalloid fluids, 1 to 2 L, should be given. If the patient has responded well to a medication or combination of medications on previous visits, then those should be administered. Otherwise, it is reasonable to start with ondansetron 4 to 8 mg IV due to its low side effect profile. If there is no relief in 15 to 30 minutes, then a second-line agent should be given. Lorazepam 2 mg IV or haloperidol 5 mg IV can be given along with topical capsaicin cream placed topically over the periumbilical region. The patient may initially note a burning sensation or skin irritation, but both tend to be self-limited. If haloperidol is chosen, an ECG should be obtained prior to the administration to assess the QTc. If there is no relief with the haloperidol or lorazepam, then the other agent should be given. The capsaicin cream can be repeated every 4 hours. If additional agents are needed, then diphenhydramine, metoclopramide, prochlorperazine, and promethazine can be added. Adverse events such as QTc prolongation, extrapyramidal side effects, and sedation should be considered when choosing the combination of antiemetics. Patients who are successfully treated should be instructed to stop using marijuana.[21–23]

Vertigo

Antihistamines are useful in nausea and vomiting associated with motion sickness and vertigo. Agents such as dimenhydrinate (Gravol, Dramamine) and meclizine (Antivert) directly inhibit vestibular stimulation and vestibular-cerebellar pathways. Antihistamines have some role as general antiemetics but are better used in the prevention of motion sickness. The most common side effects of antihistamines are drowsiness, blurred vision, dry mouth, and hypotension. Benzodiazepines are effective as second-line agents. If vertigo is due to benign positional vertigo, the Epley maneuver can be attempted.

Gastroparesis

Gastroparesis is caused by impaired mobility of the stomach and most commonly associated with diabetes. Patients present with severe abdominal pain, nausea, and vomiting. Metoclopramide is the first-line agent due to its promotility effect.[24] Haloperidol has shown benefit in small studies and should be given in patients with refractory symptoms without contraindications.[25,26]

DISPOSITION

Hospital observation or admission is appropriate when the patient has a significant underlying disease, responds poorly to fluid or antiemetic therapy, or continues to experience uncontrolled emesis refractory to medication. Patients in whom the underlying diagnosis remains unclear are still often able to be safely discharged from the ED. Discharge may be considered if no serious underlying illness is identified, response to fluid and antiemetic therapy is adequate, the patient is able to tolerate clear liquids, and the prospects for follow-up are favorable.

Close follow-up often is advisable, preferably with the patient's primary care physician, in 24 to 48 hours. At discharge, the patient is prescribed medications as needed and is advised to restart oral intake with small feedings of a liquid diet, gradually returning to a regular diet. Instructions are given to return to the ED if there is a recurrence, change, or deterioration in symptoms.

CHAPTER 25: QUESTIONS AND ANSWERS

1. **A** 50-year-old male patient presents with a complaint of vomiting. He states the pancakes he ate 12 hours ago for breakfast came out undigested. He admits to several similar episodes in preceding weeks. He is otherwise asymptomatic and has normal vital signs. His physical examination is normal. Which of the following conditions is most likely?

a. Constipation
b. Gastric outlet obstruction
c. Hepatitis
d. Increased intracranial pressure

Answer: b. Vomiting intact food eaten over 12 hours earlier is considered pathognomonic for gastric outlet obstruction. None of the other choices have this as a feature.

2. Antihistamines would most effectively control the nausea and vomiting caused by which of the following conditions?

a. Chemotherapy administration b. Gastritis
c. Gastroparesis
d. Labyrinthitis

Answer: d. Antihistamines are particularly useful in nausea and vomiting associated with labyrinthitis, motion sickness, and vestibular disorders by directly inhibiting vestibular stimulation and vestibular-cerebellar pathways. The anticholinergic effect may also contribute to their effectiveness in vertigo and motion sickness.

3. Which of the following is the most effective for the treatment of cannabinoid hyperemesis syndrome?

a. Capsaicin cream
b. Cessation of marijuana use
c. Haloperidol
d. Lorazepam

Answer: b. Cessation of marijuana use has been demonstrated to decrease syndrome recurrence. The other choices are frequently utilized in the acute treatment of cannabinoid hyperemesis syndrome, and have only been described in case reports or series.

4. **A** 28-year-old female presents to the emergency department with severe vomiting. She is 7 weeks pregnant. She has experienced nausea during this pregnancy which she had controlled with oral ginger and a pyridoxine/doxylamine combination pill, but for the last 3 days she has been unable to tolerate anything by mouth. Her electrolytes and renal function are normal. Bedside ultrasound reveals a single live intrauterine pregnancy. Her urinalysis reveals large ketones. In addition to intravenous fluids, which of the following medications should be selected as the first line intravenous antiemetic agent?

a. Dexamethasone
b. Haloperidol
c. Metoclopramide
d. Ondansetron

Answer: c. Metoclopramide is a first-line agent due to its safety for the developing fetus. Ondansetron should be reserved for second line as there is some suggestion of the capacity for fetal harm. Olanzapine is indicated for chemotherapy-associated vomiting and haloperidol is best used for gastroparesis or cannabinoid hyperemesis syndrome. Dexamethasone is reserved for patients who fail first- and second-line therapies.

5. What is the most common cause of nausea and vomiting in the pediatric population?
a. Acute gastroenteritis
b. Drug side effects
c. Intussusception
d. Motion sickness

Answer: a. In pediatrics, acute gastroenteritis is the most common cause of vomiting. Studies on management of vomiting in this population focus on children with this condition.

26

Gastrointestinal Bleeding

Lindsey M. DeGeorge and Jose V. Nable

KEY CONCEPTS

- Routine placement of a nasogastric tube in patients with suspected upper gastrointestinal bleeding (UGIB) is not recommended, because this procedure fails to reliably provide useful data to guide management and is associated with unnecessary patient discomfort and potential complications.
- Patients older than 35 years with UGIB should have an electrocardiogram (ECG) performed early in their evaluation, because patients with UGIB and coronary disease (including occult coronary disease) may develop an acute coronary syndrome that presents with atypical symptoms, such as nausea and abdominal discomfort.
- A blood urea nitrogen (BUN) to creatinine (Cr) ratio of greater than 35 is 90% specific for UGIB. However, the BUN:Cr ratio is poorly sensitive and cannot be used to rule out UGIB.
- Patients with exsanguinating hemorrhage should receive an emergent transfusion of untyped packed red blood cells. For stable patients without known coronary artery disease, transfusion should be initiated when the hemoglobin level is less than 8 g/dL.
- Standard pharmacologic therapy for UGIB includes intravenous (IV) proton pump inhibitors and prokinetic agents. Patients with cirrhosis and suspected esophageal varices should receive octreotide and antibiotics.
- Based on available evidence, we do not recommend the routine use of tranexamic acid for patients with UGIB.
- Platelet transfusion is not indicated for patients on antiplatelet medications unless the platelet count is <50,000 per μL.
- Empirical administration of fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC) to patients with cirrhosis or anticoagulant use is not indicated.
- Stable patients with lower gastrointestinal bleeding (LGIB) who can tolerate bowel preparation are best managed through urgent gastroenterology consultation for colonoscopy, while unstable patients should be seen by an interventional radiologist for possible selective embolization.

FOUNDATIONS

Acute gastrointestinal (GI) bleeding is a potentially life-threatening condition that requires prompt recognition and treatment. Upper GI bleeding (UGIB) usually presents as hematemesis (blood or coffee-ground emesis) or melena (black, tarry stool). Lower GI bleeding (LGIB) most frequently presents as hematochezia (frank blood per rectum or red or maroon-colored stool). Inpatient mortality from UGIB and LGIB is estimated to be 10% and 4%, respectively.[1] The goals for evaluation and management of the patient with possible GI bleeding are to stabilize the patient, confirm that the gut is the origin of the bleeding, determine the likely site and nature of the bleeding, and provide appropriate therapy.

Hospitalizations for GI hemorrhage related to peptic ulcer disease (PUD) decreased by 66% in the United States between 2000 and 2011, attributed mainly to antimicrobial treatment for *Helicobacter pylori*.[2] Nonsteroidal antiinflammatory drug (NSAID) use remains a significant risk factor PUD-associated bleeds, although the use of proton pump inhibitors (PPIs) in vulnerable patients has mitigated the risk of severe NSAID-related hemorrhage.[3,4]

DIAGNOSTIC APPROACH

Differential Considerations

UGIB originates proximal to the ligament of Treitz, which anchors the small bowel at the duodenal-jejunal flexure, and most often presents as coffee-ground or frankly bloody emesis, melanotic stool, or a combination of these. The most common causes are PUD, erosive disease, and esophageal varices (Table 26.1).

Mallory-Weiss tears, ulcers, gastritis, and esophagitis are the most common causes of UGIB in children, although UGIB can also occur after a caustic ingestion. For neonates, coagulopathy or swallowed maternal blood should also be considered.

LGIB originates distal to the ligament of Treitz. Gastroenterologists subdivide LGIB into small intestinal versus colonic or rectal bleeds.[5,6] Bleeding from the small intestine often presents with a prolonged occult blood loss but also can cause melena if GI transit times are long, and makes up a relatively small proportion (approximately 5% to 10%) of all GI bleeds.[7] Such bleeds were previously considered obscure; however, advances in video capsule endoscopy, computed tomography angiography (CTA), and enteroscopy have greatly enhanced the ability to localize small intestinal hemorrhages. Younger patients (<40 years old) with small bowel bleeding often have underlying inflammatory bowel disease, malignancy, or a Meckel diverticulum, whereas older patients generally bleed from angiodysplasia, NSAID-induced ulcers, or malignancy.

Colonic or rectal bleeds often present with hematochezia. Diverticulosis is the most common cause of bleeding originating from the large bowel, followed by ischemic colitis, postpolypectomy bleeds, hemorrhoids, and malignancy (see Table 26.1).[8]

Common causes of pediatric LGIB include anal fissures, Meckel diverticulum, allergic colitis, enteric infections, and polyps. Necrotizing enterocolitis is a consideration in neonates.

Patients presenting with an apparent GI bleed should be evaluated for non-GI sources. Epistaxis can mimic or cause hematemesis, and vaginal bleeding can be mistaken for hematochezia. Some foods (e.g., beets) and medications (e.g., cefdinir) can discolor stools to appear red and bismuth (e.g., in Pepto-Bismol), or iron use can turn the stool black.

Pivotal Findings

Symptoms

UGIB usually presents as hematemesis (either bright red blood or coffee-ground emesis) or melena, whereas LGIB generally presents

TABLE 26.1 Common Causes of Gastrointestinal Bleeding in Adults and Children

Location	Adults	Children
Upper gastrointestinal	Peptic ulcer disease Erosive disease Esophageal and gastric varices Esophagitis Mallory-Weiss tears Malignancy	Mallory-Weiss tears Gastritis Esophagitis Foreign bodies Caustic ingestion Swallowed maternal blood (neonates) Coagulopathies (neonates)
Lower gastrointestinal	Diverticulosis Hemorrhoids Colitis (inflammatory, infectious, ischemic) Malignancy Postpolypectomy bleeding	Anorectal fissures Meckel diverticulum Allergic colitis Infectious colitis Polyps Angiodysplasia

with hematochezia but can present with melena if the origin is proximal in the small bowel. However, the character of stools is not entirely specific to the location of the hemorrhage. For example, small bowel or colonic bleeding with slow transit times can present with melena. Likewise, hematochezia is not limited to LGIB. It can be seen with a brisk UGIB, and upper GI origin should be considered in a hemodynamically unstable patient with hematochezia.

For patients vomiting blood, the character of the emesis does not reliably indicate the severity of hemorrhage. Bloody and coffee-ground emesis have similar rates of shock, anemia, and mortality.[9] Clinical indicators of shock are more reliable as a gauge of bleeding severity than is the color of the emesis.

Associated symptoms and the context of bleeding may provide important clues. Epigastric pain may indicate PUD. Hematemesis that occurs after vomiting or retching is seen with esophageal tears. Unexplained weight loss is suggestive of malignancy. Constipation or painful bowel movements may precede bleeding from hemorrhoids or an anal fissure, respectively. A recent colonoscopy may indicate postpolypectomy or biopsy bleeding.

Organ systems that may be impaired by significant blood loss should be assessed. Symptoms indicative of cerebral hypoperfusion, such as lightheadedness, are predictive of more severe hemorrhage.[10] Susceptible patients with significant blood loss may develop acute coronary syndrome (ACS).[11] Patients with significant blood loss should be queried for a history of coronary disease, but typical symptoms of ACS, such as chest pain or shortness of breath, may not be present in UGIB patients who instead may develop an ACS with atypical symptoms, such as nausea and abdominal discomfort.

Signs

Patients with acute GI bleeding should be assessed for signs of shock, which increases risk for death.[12] Tachycardia and hypotension are predictive of a severe bleed.[13] A shock index (heart rate divided by systolic blood pressure) can be used to guide resuscitation (see empiric treatment section later).[14]

On physical examination, patients with PUD or severe gastritis may have tenderness in the left upper quadrant. The presence of ascites may indicate portal hypertension, increasing the likelihood of esophageal varices. In such cases, rectal examination may identify varices or dense collateral veins around the anus and rectum. Significant, diffuse abdominal tenderness may indicate GI perforation or bowel ischemia. A digital rectal exam can help in elucidating the type or severity of bleeding. For example, hematochezia suggests either LGIB or brisk UGIB, whereas melena usually indicates an upper GI source. Hemorrhoids or anal fissures may be apparent on rectal exam. Bleeds from fissures are rarely severe and often associated with discomfort with bowel movements.

Ancillary Testing

Laboratory Testing

Laboratory testing is generally focused on risk stratification. Patients with hemodynamic instability require rapid resuscitation before laboratory results become available. Testing helps to guide the management of patients who appear stable on presentation. An initial lactate level greater than 2.5 mmol/L is associated with the development of in-hospital hypotension and increased 30-day mortality.[15] An initial international normalized ratio (INR) greater than 1.5 or a hemoglobin less than 10 g/dL is predictive of increased inpatient mortality and the need for intensive care unit (ICU) admission.[16] An INR is also potentially useful for patients taking antithrombotic medications such as warfarin, because reversal therapy may be required.

Laboratory testing can also provide clues to localize the source of bleeding. Isolated azotemia is often seen in patients with UGIB and results from the degradation of digested blood and reduced blood flow to the kidneys. A blood urea nitrogen to creatinine (BUN:Cr) ratio higher than 35 is 90% specific in identifying UGIB.[17] However, the BUN:Cr ratio is poorly sensitive and not useful in excluding an UGIB.

Blood is typed and screened for stable patients and crossmatched for unstable patients. Use uncrossmatched blood product transfusion for patients with ongoing brisk hemorrhage requiring rapid resuscitation, as detailed in the empiric treatment section later.

Electrocardiogram

The development of concomitant ACS may complicate GI bleeds and present with atypical symptoms. We recommend a screening electrocardiogram (ECG) for patients older than the age of 35 years and those with cardiac risk factors. A history of diabetes, tobacco use, liver cirrhosis, anemia (hemoglobin <9 g/dL), or prior episodes of ACS are risk factors for the development of ACS in patients with UGIB.[11]

Nasogastric Aspirate Testing

We do not recommend the routine placement of a nasogastric tube (NGT) for diagnostic or therapeutic purposes in patients with suspected UGIB. The procedure is both uncomfortable and potentially time-consuming, and it does not reliably predict the source of hemorrhage nor significantly affect patient outcomes.[18] Potential complications from NGT placement include pneumothorax, aspiration, and injury to nasopharyngeal or GI tract structures. Although NGT lavage performed before endoscopy may improve visualization by removing blood and clots, this decision should be left to the endoscopist and performed as part of that procedure.

Imaging

Radiographic imaging is rarely necessary for patients with acute UGIB and may detract from the care of hemodynamically unstable patients who require close monitoring. Bedside ultrasound can confirm the presence of ascites, increasing the likelihood that esophageal varices are the cause of UGIB. The American College of Radiology (ACR) Appropriateness Criteria state that endoscopy is preferred before radiologic imaging for patients with significant UGIB.[19]

In LGIB, emergent colonoscopy can be challenging due to insufficiently prepared bowel and the presence of blood and clots in the GI

lumen, making visualization of the source of bleeding difficult. The ACR recommends angiography as an appropriate alternative in unstable patients with suspected LGIB, because this modality can potentially be used to both localize and embolize bleeding sources.[20]

CTA is capable of detecting bleeding as slow as 0.3 mL/min. It is useful if endoscopic localization of the hemorrhage is not possible or unsuccessful. CTA should be considered, in consultation with gastroenterology, for stable patients with LGIB to assist in identifying the hemorrhage location.[21] This may guide management options, including endoscopy, surgery, or angiography. However, CTA is not optimal in hemodynamically unstable patients with suspected LGIB, because it may delay management. Immediate conventional angiography (with potential embolization) is the preferable strategy for these patients, with CTA reserved for stable patients without immediate access to conventional angiography and suspected LGIB in whom bleeding etiology is crucial prior to the ability to perform a bowel preparation for colonoscopy. For example, patients on anticoagulation (who are at risk for rapidly becoming hemodynamically unstable) may benefit from CTA to assess for bleeding location and etiology.

Nuclear scintigraphy with tagged red blood cell injection can detect bleeding as slow as 0.05 mL/min. However, this study takes up to 18 to 24 hours to obtain results (if delayed image acquisition is needed when initial images do not demonstrate bleeding) and does not explicitly locate the site of hemorrhage, owing to its two-dimensional nature. As such, nuclear scintigraphy is more useful for evaluating patients with possible occult bleeding and is not indicated in the setting of an acute GI bleeding in the emergency department (ED).

DIAGNOSTIC ALGORITHM

Patients with acute UGIB are managed with a stepwise approach aimed at preventing end-organ injury, limiting transfusion complications, averting rebleeding, and managing comorbidities. Fig. 26.1 depicts a combined diagnostic and management algorithm.

The first step is determining if the patient is having a massive GI bleed or not. We suggest defining patients as having a massive bleed if they present with an ongoing active bleed (hematemesis or hematochezia) and a shock index of 0.9 or greater, similar to hemorrhage thresholds for patients following trauma.[22,23] These critically unstable patients with a massive GI bleed require immediate volume resuscitation, which includes placement of at least two large-bore intravenous (IV) catheters, infusion of crystalloids, and transfusion of uncrossmatched blood. Rapid crystalloid infusion should be given as a bolus infusion of 2 L over 30 minutes with a balanced isotonic solution such normal saline or plasmalyte. The primary goal is the maintenance of adequate tissue perfusion, as evidenced by skin perfusion, urine output, and mental status.

The second step is attempting to localize the bleed as either UGIB or LGIB, which is based primarily on the history and physical examination.

The third step is risk stratification, which has important implications for the patient's management and ultimate disposition. High-risk patients have ongoing bleeding requiring interventions such as endoscopy, surgery, or continued blood transfusion. Patients who remain hemodynamically unstable with a shock index of 0.9 or greater despite receiving 2 L of crystalloid infusion and packed red blood cell (PRBC) transfusion require emergent subspecialty consultation (gastroenterology for UGIB; surgery and/or interventional radiology for LGIB) along with ICU admission.

Low-risk patients are generally younger, lack significant comorbidities, are hemodynamically stable, and have a minor source of bleeding identified. Low-risk patients who have access to follow-up care are appropriate for discharge and outpatient management.

Clinical prediction rules can assist in risk stratifying patients with GI bleeding. The Glasgow-Blatchford score (Table 26.2) was developed to assess the likelihood that a patient with UGIB will need an intervention but has also been used to predict the need for admission, blood transfusion, surgery, and mortality. A Glasgow-Blatchford score of 7 or greater is 80.4% sensitive in predicting the need for endoscopic treatment (negative predictive value [NPV] 92.4%), and a score of 5 or greater is 88.7% sensitive in predicting 30-day mortality (NPV 97.9%).[24] International consensus guidelines recommend using a Glasgow-Blatchford score of less than or equal to 1 to identify patients at low risk of rebleeding who may be appropriate for discharge and close outpatient follow-up.[25]

MANAGEMENT

Empiric Treatment

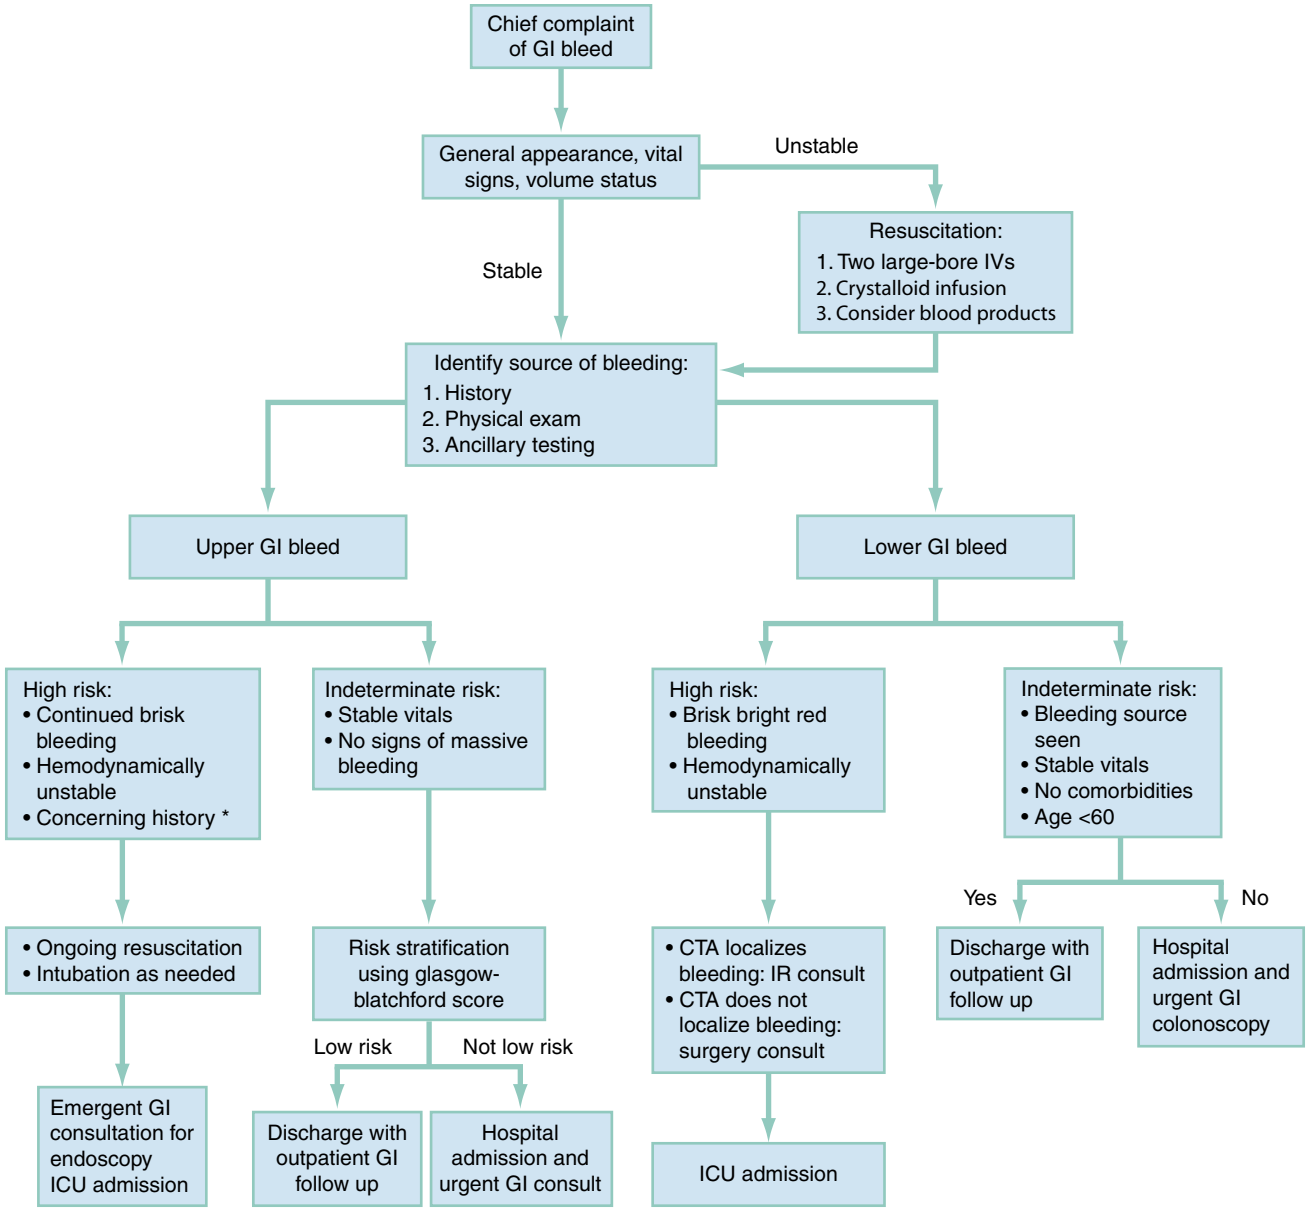
Patients with acute GI bleeding are at risk for rapid deterioration. Empiric treatment involves prompt resuscitation, consideration of blood or platelet transfusion, pharmacologic therapy, and early consultation with gastroenterology, interventional radiology, or surgery. For patients with massive UGIB, early attention to airway protection and intubation may be required.

Resuscitation

We recommend that all patients who present with an acute GI bleed have a minimum of two large bore IV catheters placed. Patients with signs of impending hemodynamic compromise (tachycardia, hypotension, diminished mental status) should have crystalloid fluids rapidly infused, with a goal of delivering 2 L over the first 30 minutes. We further suggest that patients with a massive bleed (active hematemesis or hematochezia with a shock index >0.9) should receive an immediate transfusion of PRBCs. Patients with massive UGIB with uncontrollable hematemesis, respiratory distress, or severe shock limiting their ability to protect the airway or cooperate with treatment should be intubated early in their resuscitative course, unless they respond rapidly to treatment. Optimizing hemodynamic status prior to administering intubation drugs and initiating positive pressure ventilation will mitigate the severe fall in cardiac output that can occur, sometimes leading to circulatory arrest. See Chapter 1 for details pertaining to intubation of the critically ill patient. The need for intubation also correlates with overall worse outcomes. One study found significantly higher rates of unexpected cardiopulmonary events in intubated patients with UGIBs compared with nonintubated patients (20% vs. 6%, $P = .008$) within 48 hours of endoscopy.[26]

Blood Product Transfusion

Rapid bleeding can result in significant loss of oxygen-binding capacity leading to organ ischemia, so patients with exsanguinating hemorrhage should receive an emergent transfusion of untyped PRBCs. Early use of blood products for resuscitation is explained earlier. Stable patients require a more thoughtful transfusion strategy. Although the optimal threshold for transfusion is not clearly established, stable patients with an UGIB without known coronary artery disease (CAD) should receive transfusion of red blood cells to restore their hemoglobin to at least 8 g/dL.[25] A higher hemoglobin target is appropriate for patients with known CAD who are at increased risk of adverse outcomes from anemia. International consensus guidelines do not recommend a specific cutoff, advocating instead to tailor targets based on the severity of both the patient's cardiovascular disease and UGIB.[25] However, we recommend transfusion to a minimum hemoglobin greater than 9 g/dL for patients with known or symptomatic CAD or to the level necessary to resolve cardiac ischemia.



* Concerning history includes:
- Estimated blood loss >500 mL as suggested by symptoms of hypovolemia: dizziness, lightheadedness, syncope, confusion, and weakness
- History of previous abdominal vascular surgeries
- Use of anti-coagulants
- Initial lactate >4
- Hemoglobin <10 or decrease >1 from baseline

Fig. 26.1 Diagnostic and management algorithm for acute gastrointestinal bleeding. *GI,* Gastrointestinal; *ICU,* intensive care unit; *IV,* intravenous; *CTA,* computed tomography angiogram; *IR,* interventional radiology

A systematic review of five randomized controlled trials found that a restrictive transfusion strategy using a hemoglobin threshold of 7 to 8 g/dL in patients with acute UGIB was associated with a lower risk of all-cause mortality and overall rebleeding.[27] For patients with suspected portal hypertension–related bleeding, transfusion response and hemodynamic parameters are closely monitored because overtransfusion may worsen portal hypertension and increase bleeding. Although there are limited data regarding the optimal hemoglobin target for patients with acute LGIB, we advocate for using the same transfusion threshold as discussed earlier for UGIB.

There is a paucity of data regarding the optimal threshold for platelet transfusion in patients with UGIB. We support the American College of Gastroenterology clinical guidelines, which recommend maintaining a platelet count of greater than 50,000 platelets/μL.[6] Empiric platelet transfusion for patients on antiplatelet medications who are not thrombocytopenic is unlikely to be of benefit and therefore not recommended.[28]

The use of fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC) in patients with liver disease, anticoagulant use, or otherwise elevated INR level is controversial. In patients requiring massive

TABLE 26.2 Glasgow-Blatchford Score

	Risk Factor	Score
Blood urea nitrogen, mg/dL	≥18.2 to <22.4	2
	≥22.4 to <28.0	3
	≥28.0 to <70.0	4
	≥70.0	6
Hemoglobin (men), g/dL	≥12.0 to <13.0	1
	≥10.0 to <12.0	3
	<10.0	6
Hemoglobin (women), g/dL	≥10.0 to <12.0	1
	<10.0	6
Systolic blood pressure, mm Hg	100–109	1
	90–99	2
	<90	3

	Melena	1
	Syncope	2
	Hepatic disease	2
	Heart failure	2

transfusion (more than 4 units of PRBCs), we recommend a balanced transfusion approach of 1:1:1 PRBC:platelets:FFP. Coagulation studies such as partial thromboplastin time (PTT) or prothrombin time (PT)/INR in patients with liver failure are poorly representative of actual bleeding risk.[29] Empirically correcting an abnormal PTT or PT/INR with FFP or PCC has not been shown to reduce bleeding and may increase bleeding in UGIB by worsening portal hypertension. The administration of FFP and PCC may increase the rate of thrombotic events, so their routine use in patients with liver failure and acute GI bleeding is not recommended unless receiving massive transfusion.

For patients on vitamin K antagonists, such as warfarin, limited data suggest discontinuation of the medication and anticoagulation reversal to a target INR of 1.5 to 2.5. However, given the known benefits of early endoscopy for acute UGIB, endoscopy should generally not be postponed while awaiting correction of coagulopathy. Treatment options for reversal include FFP and PCC. Vitamin K has less of a role in emergent reversal for acute GI bleeding given its comparatively prolonged time to treatment effect, but it should still be administered to prevent rebound coagulopathy and bleeding due to the short duration of effect from PCC and FFP. The administration of vitamin K is a reasonable option for patients with hemodynamically stable GI bleeding. Although FFP rapidly corrects coagulopathies, its administration requires large infusion volumes, potentially limiting its use in patients at risk for volume overload. PCC allows for rapid correction of coagulopathy with lower volume administration. INR, PT, and PTT have less of a role in the management of GI bleeding in patients on direct oral anticoagulants such as dabigatran or factor Xa inhibitors (apixaban, rivaroxaban, edoxaban). Reversal agents may be used in unstable patients. Idarucizumab can be utilized to reverse dabigatran. PCC or coagulation factor Xa [recombinant], inactivated-zhzo may be used to reverse factor Xa inhibitors.

Pharmacologic Therapy

Several medications improve outcomes in patients with an acute GI hemorrhage. PPIs have long been a mainstay in the treatment of acute GI bleeding. Compared with placebo, treatment with a high-dose, continuous PPI infusion has been shown to decrease rebleeding, surgery, and mortality in patients with bleeding ulcers. As a result, treatment with omeprazole 80 mg IV followed by a continuous infusion of 8 mg/h has almost routinely been used. However, a meta-analysis showed intermittent PPI therapy to be equally effective as a continuous infusion in reducing bleeding.[30] We recommend a single dose of IV omeprazole 80 mg as a cost-effective and less time-consuming treatment option. This is followed by subsequent doses of 40 mg every 12 hours.

Splanchnic vasoconstrictors such as somatostatin and octreotide reduce portal hypertension and decrease risks of bleeding and transfusion requirements in patients with variceal bleeding. We recommend octreotide 50 μg IV bolus (or an equivalent agent), followed by 50 μg/h continuous infusion for patients with acute UGIB and known liver disease, variceal bleeding, alcoholism, or abnormal liver function tests.[31] There is no rationale for the routine administration of these agents in patients with presumed nonvariceal bleeding.

Prokinetic agents such as erythromycin administered prior to endoscopy improve visualization, limit the need for repeat esophagogastroduodenoscopy (EGD), decrease blood transfusion requirements, and decrease hospital length of stay for patients with severe or active UGIB.[32] For patients going directly for EGD from the ED, a single dose of erythromycin 250 mg IV should be administered 30 to120 minutes prior to EGD.

Tranexamic acid is an antifibrinolytic agent that improves outcomes in the settings of postpartum hemorrhage and trauma. However, its effectiveness in patients with acute GI bleeding remains uncertain.[33] There are currently insufficient clinical data to recommend the use of tranexamic acid in patients with GI bleeding.

For the specific subset of patients with UGIB and known or suspected cirrhosis, antibiotic prophylaxis is recommended. Antibiotics reduce the rate of bacterial infection and mortality.[34] Fluoroquinolones (e.g., ciprofloxacin 400 mg IV) or a third-generation cephalosporin (e.g., ceftriaxone 1 to 2 g IV) are appropriate prophylactic antibiotics in these patients.

Balloon Tamponade

For rapidly exsanguinating patients with a presumed variceal bleed, the placement of a balloon tamponade device is indicated when endoscopy is not promptly available. Commercially available devices include the Sengstaken-Blakemore tube and the Minnesota tube. There are significant complications associated with the use of these devices, so they should be used only as a temporizing measure for patients with ongoing, life-threatening bleeding.

Definitive Treatment

Patients with an acute GI bleed and hemodynamic instability warrant early consultation. Patients with significant UGIB need consultation with a gastroenterologist for consideration of endoscopy. Patients with stable LGIB who can tolerate proper bowel preparation may benefit from urgent but not emergent gastroenterology consultation for colonoscopy. For patients with a brisk LGIB, we recommend emergent consultation with an interventional radiologist for possible selective embolization. We also recommend simultaneous consultation with surgery. If a source of bleeding is not readily identified with CTA, unstable patients with brisk LGIB may require urgent surgical intervention.

CHAPTER 26: QUESTIONS AND ANSWERS

1. What is the most common cause of upper gastrointestinal (GI) hemorrhage in adults in the United States?
   - **a.** Esophagitis
   - **b.** Gastritis
   - **c.** Liver cirrhosis
   - **d.** Peptic ulcer disease

Answer: d. Despite a decreasing prevalence with the treatment of *Helicobacter pylori,* peptic ulcer disease (PUD) remains the most common cause of upper GI bleeds in adults in the United States.

2. Management of unstable patients with massive upper gastrointestinal bleeding (UGIB) should include which of the following?
   - **a.** Placement of at least two large-bore IVs.
   - **b.** Avoidance of rapid crystalloid infusion in effort to decrease rebleeding rates
   - **c.** Empiric treatment with fresh frozen plasma (FFP)
   - **d.** Routine intubation for airway protection

Answer: a. Initial resuscitation of unstable patients with massive GI bleeding should include placement of two large bore IV catheters and rapid crystalloid infusion with consideration of early blood transfusion. Intubation should be reserved for patients with altered mental status, respiratory distress, or high concern for aspiration. FFP should be given empirically only for patients receiving a massive transfusion protocol or in select patients with coagulopathy.

3. Which of the following statements is true regarding platelet administration for patients with acute gastrointestinal (GI) bleeding?
   - **a.** Patients requiring massive transfusion should receive a balanced transfusion approach of 1:1:1 packed red blood cells (PRBCs):platelets:FFP.
   - **b.** Platelets should be administered to a target level of >100,000 per μL
   - **c.** All patients with GI bleeding on antiplatelet medications such as aspirin should receive an empiric platelet transfusion
   - **d.** Antiplatelet medications do not increase the risk of acute GI bleeding

Answer: a. Despite a high risk of GI bleeding while taking antiplatelet medications, the routine use of platelet transfusion for patients on antiplatelet medications has not been shown to be beneficial. Platelet transfusion should be reserved for patients who are thrombocytopenic <50,000 per μL or those requiring massive transfusion protocol.

4. Elevations in which of the following serum markers in the setting of an acute gastrointestinal bleed is predictive of increased 30-day mortality?
   - **a.** C-reactive protein
   - **b.** Lactate
   - **c.** Serum osmolality
   - **d.** White blood cell count

Answer: b. An initial lactate greater than 2.5 mmol/L is associated with the development of in-hospital hypotension and an increased rate of 30-day mortality.

5. Appropriate pharmacologic therapy in the emergency department for most acute upper gastrointestinal bleeds (UGIB) includes which of the following agents?
   - **a.** Antibiotics
   - **b.** Erythromycin
   - **c.** Proton pump inhibitor (PPI)
   - **d.** Somatostatin

Answer: c. PPIs decrease rebleeding, surgery, and mortality in patients with an acute UGIB from an ulcer. Because peptic ulcer disease is the most common cause of UGIB, it is appropriate to administer PPIs for most acute UGIB.

27

Diarrhea

Michael Nitzberg and Janet Smereck

KEY CONCEPTS

- Hospital-acquired *Clostridioides difficile* and norovirus infection are the most prevalent causes of fatal illness from diarrhea in the United States.
- Key elements of the history in the patient with diarrhea include recent travel, hospitalization or antibiotic use, dietary factors, immunosuppression, fever, and presence of blood in stool.
- Acute diarrhea is most often viral and treated with supportive therapy.
- Fluids and foods with excess sugar, caffeine, or high fat content should be avoided in patients with diarrhea.
- In selected nontoxic patients, loperamide, initial dose of 4 mg by mouth and subsequent doses of 2 mg by mouth after each loose stool (not to exceed 16 mg in 24 hours), is typically safe and effective in providing symptom control.
- Empiric antibiotics are uncommonly indicated in patients well enough to go home. However, they should be considered in patients with fever or bloody diarrhea who are immunocompromised or in travelers diarrhea. Empiric antibiotics are prudent whenever sepsis is suspected.
- Fluoroquinolones (ciprofloxacin 500 mg by mouth twice daily or levofloxacin 500 mg by mouth daily for 3 to 5 days) or azithromycin (500 mg by mouth daily for 3 days) cover the majority of enteric pathogens if empiric antibiotics are required.
- A single dose of azithromycin, 1000 mg by mouth, is sufficient antibiotic treatment for travelers diarrhea.
- First line treatment for *C. difficile* is vancomycin 125 mg by mouth four times daily for 10 days. Second line treatment is fidaxomicin 200 mg by mouth for 10 days.
- The efficacy of probiotics in reducing stool frequency in acute infectious diarrhea is unclear.

FOUNDATIONS

Introduction

Acute diarrheal illness is defined as the passage of three or more liquid or watery stools in a 24-hour period, for a duration of up to 14 days, as per the updated definition by the World Health Organization (WHO).[1,2] The Greek origin of the word "diarrhea," *"to run or flow straight through,"* is descriptive and distinguishes true diarrhea from a patient complaint of producing more frequent but fully formed bowel movements. Hippocrates (450–380 BC) understood that diarrhea was a symptom of a number of diseases, both infectious and noninfectious, and could be caused by faulty food handling as well as acquired from travel or inadequate hygiene practices.

Diarrhea may be characterized as mild, moderate, or severe based on accompanying symptoms, presence of comorbidities, degree of incapacitating dehydration, and subsequent need for hospitalization.[2,3] A careful history may identify precipitating causes. Although most cases of acute diarrhea require only supportive care, a systematic approach to the patient presenting with acute diarrhea will lead to appropriate testing and treatment.

Epidemiology

Diarrheal illness is frequently associated with extremes of age (children younger than the age of 5 and adults older than 65 years) or immunocompromised status, including immune deficiency syndromes or use of immunosuppressant medications. Severe acute diarrhea, defined as an acute diarrheal episode requiring hospital admission, is associated with significant fluid losses and may be life threatening, particularly in young children, elders, or individuals with impaired immunity.[3] Acute human immunodeficiency virus (HIV) infection may present with acute diarrheal illness, due to impaired enteric defenses in intestinal mucosa resulting from lymphocyte depletion. HIV disease with CD4 counts less than 200 is associated with increased risk of both common and opportunistic viral, bacterial, or parasitic diarrheal enteric infections. In addition, all classes of antiretroviral drugs may cause diarrhea, which can affect more than 25% of individuals taking combined antiretroviral therapy.[4]

Diarrheal illness may be acquired through foods consumed (notably raw or undercooked fish, shellfish, meat, eggs and unpasteurized dairy products, or contaminated raw produce in sporadic outbreaks); occupational exposure including health care and recreational water sport settings; antibiotic use in the preceding 8 to 12 weeks; and international travel. Up to 60% of those traveling from developed to developing countries acquire acute diarrhea, with children at particular risk.[5] Diarrhea may also occur in travel between developed countries, presumably due to lack of immunity to local, low-level microbial contamination of food and water with enteric pathogens. Diarrhea associated with seafood consumption deserves special mention because fish and shellfish may be associated with acute diarrheal illness due to infectious agents (viral, bacterial, parasitic) as well as toxic factors resulting in scombroid, ciguatera, and paralytic shellfish poisonings.[6]

Pathophysiology

Diarrhea is a symptom rather than a diagnosis, and considerations regarding the mechanisms and causes of acute diarrhea assist in guiding management. Acute diarrhea, defined as the passage of three or more large-volume liquid stools in a 24-hour period for up to 14 days, should be distinguished from self-reported increase in frequency of formed stools, or severe constipation and fecal impaction with overflow leakage. Descriptions of what actually constitutes "diarrhea" are further defined by several clinical instruments, including the Bristol stool scale and modified Bristol score for children (Table 27.1).[7]

The evaluation and treatment of diarrhea must take into account comorbid conditions such as immunosuppression, as well as postsurgical complications including short gut syndrome, blind loop dysfunction following bariatric procedures, or peptic ulcer surgery. Incontinence of stool in the setting of profuse watery diarrhea is not necessarily indicative of acute neurologic impairment. Diarrhea is a symptom of a number of pathophysiologic entities: *osmotic diarrhea* due to the presence

TABLE 27.1 Summarized Descriptions, Bristol Stool Scales for Adults and Children

Adult Bristol Stool Scale
Type 1 Hard separate "lumps", hard to pass
Type 2 Sausage shaped, formed but hard and lumpy
Type 3 Sausage shaped with fissured surface
Type 4 Sausage shaped with smooth, soft texture
Type 5 Soft separate "lumps" passed easily
Type 6[a] Unformed, "mushy" stool
Type 7[a] Entirely liquid, watery, with no solid pieces

Modified Bristol Stool Scale for Children (ages 8–18 years)
Type 1 Hard separate small "lumps", hard to pass
Type 2 Sausage shaped, formed but hard and lumpy
Type 3 Sausage shaped with smooth, soft texture
Type 4[a] Unformed, "mushy" stool
Type 5[a] Entirely liquid, watery, with no solid pieces

[a]Bristol stool types 6 and 7 for adults, and 4 and 5 for children, when 3 or more passed in a 24-hour period, indicate diarrhea.

of poorly absorbed solutes within the gut, *secretory diarrhea* due to toxin-producing infectious agents, *exudative diarrhea* due to infectious or inflammatory conditions, *motility-related diarrhea* associated with diabetes mellitus or scleroderma as well as prokinetic medications, and *malabsorptive diarrhea* related to infectious agents, lactose intolerance, celiac disease, or pancreatic insufficiency. The term *dysentery* is used to describe infectious diarrhea in which enteropathogens and their toxic metabolites have invaded the intestinal mucosa, resulting in fever, abdominal pain, and visible blood mixed with stools.[8]

DIAGNOSTIC APPROACH

A thorough history should note onset and duration of symptoms; character of stools including estimated volume and presence of blood or purulent mucus; fever; abdominal pain; nausea and vomiting; and ability to maintain oral hydration. Key historical features include foods consumed prior to onset of symptoms, alcohol or substance use, travel history, antibiotic use within the preceding 8 to 12 weeks, ill contacts, medications and dietary supplements, and comorbid conditions such as diabetes mellitus, collagen vascular disease, immune deficiency, malignancies, or transplant status.

Differential Considerations

Broadly, diarrheal illness may be divided into two categories, infectious and noninfectious. In the acute care setting it is not always possible to reliably distinguish infectious from noninfectious causes. Although the etiology may not be precisely identified in the emergency department (ED) and most cases of infectious diarrhea have a self-limited course, some causative agents have specific presentations and may require targeted therapies. Acute diarrhea of infectious etiology is suggested by the presence of fever, abdominal cramps or pain, tenesmus, or presence of blood mixed with the stool.[2,9] A number of pathogens are associated with acute diarrhea; some enterotoxins can produce dangerous volume losses, and enteroinvasive pathogens may lead to septicemia.

Acute infectious diarrhea is associated with numerous viral and bacterial agents as well as some parasitic pathogens (Box 27.1). Viral agents most commonly identified in hospitalized patients with acute diarrhea include norovirus, rotavirus, and adenovirus.[3] Norovirus is frequently implicated in travelers diarrhea and large population-based outbreaks. Vaccination against rotavirus has made this a less common pathogen, particularly in children.[10,11] Gastrointestinal cytomegalovirus is associated with immunosuppression and advanced HIV infection (CD4+ counts less than 50) and can lead to severe hemorrhagic colitis.[4]

BOX 27.1 Common Causative Agents of Acute Infectious Diarrhea

Viral
Cytomegalovirus
Enteric adenovirus
Human immunodeficiency virus (HIV) enteropathy
Norovirus
Rotavirus

Bacterial
Invasive
Campylobacter species
Clostridioides difficile
Enteroinvasive *Escherichia coli*
Salmonella species
Shigella species
Vibrio vulnificus
Yersinia enterocolitica

Toxigenic
Food Poisoning With Preformed Toxins
Bacillus cereus
Staphylococcus aureus

Toxin Formation After Colonization
Shiga toxin–producing *E. coli* 0157:H7 (STEC) [also known as enterohemorrhagic *E. coli* (EHEC) or verocytotoxin-producing *E. coli* (VTEC)]
Enterotoxigenic *E. coli*
Shigella species
Vibrio cholerae

Protozoa
Cryptosporidium
Cyclospora
Entamoeba histolytica
Giardia

Most frequently identified bacterial pathogens include *Campylobacter* spp., *Clostridioides difficile*, various pathogenic *Escherichia coli*, *Salmonella* spp., *Shigella* spp., and *Yersinia enterocolitica*.[3] *E. coli* O157:H7 is associated with hemolytic uremic syndrome, and enterotoxigenic *E. coli* (ETEC) is implicated in some cases of travelers diarrhea. The overall incidence of *C. difficile* is increasing. Although generally associated with antibiotic use or overnight hospital stay in the preceding 3 months, community-associated *C. difficile* is increasingly identified in patients without traditional risk factors, which may be due to gastric acid–suppressing medications, hypervirulent strains, or improved testing.[12,13] *Campylobacter* and *Yersinia* have been identified in cases of diarrhea with accompanying right lower quadrant pain mimicking appendicitis, presumably due to accompanying mesenteric adenitis.[11]

Vibrio cholera, associated with contaminated water or seafood from tropical and subtropical zones, is associated with secretory enteritis leading to profuse watery diarrhea with large fluid and electrolyte losses and may lead to shock, renal failure, and death. *Vibrio vulnificus*, associated with raw shellfish consumption, has been associated with septicemia and carries a high mortality rate, particularly in patients with liver disease.[6]

Most parasitic infections present as chronic diarrhea. *Giardia lamblia* may lead to acute as well as chronic malabsorptive diarrhea and

BOX 27.2 Selected Causes of Noninfectious Diarrhea

Pharmaceuticals
Antacids (magnesium)
Antimicrobials
Antiretrovirals
Chemotherapeutic agents
Cholinergic agents
Cholinesterase inhibitors
Colchicine
Lactulose
Laxatives/Cathartics
Prostaglandins

Dietetic supplements
Caffeine
Sorbitol
Xylitol

Seafood-Associated Toxins
Ciguatera
Paralytic shellfish poisoning
Scombroid

Plant and herbal preparations
Aloe vera juice
Senna
Pokeweed
Turmeric

Miscellaneous
Pesticides—organophosphates
Opiate withdrawal

Gastrointestinal Pathology
Celiac disease
Irritable bowel syndrome with diarrhea
Lactose intolerance
Malabsorption syndromes
Post vagotomy
Radiation enteritis
Short gut syndrome

Endocrine-Related Conditions
Carcinoid syndrome
Adrenal insufficiency
Diabetic enteropathy
Pancreatic insufficiency

Systemic Illness and Other Causes
Alcoholism
Connective tissue disease/scleroderma
Cystic fibrosis
Runners diarrhea

is associated with contaminated food and unprocessed water, including well water or unchlorinated water consumed by campers and backpackers.[5]

There are numerous noninfectious causes of diarrhea, including foods (osmotically active agents such as sorbitol and xylitol, seafood-associated toxins), pharmaceuticals (including prokinetic agents, laxatives, colchicine, chemotherapeutic agents, antimicrobials, immune checkpoint inhibitors, and all classes of antiretrovirals), and endocrinopathies (Box 27.2). Runners diarrhea has been described as an acute exercise-related diarrhea which may have multiple causes, including transient mesenteric ischemia as well as dietary factors, particularly intake of large quantities of carbohydrates and beverages containing monosaccharides and polysaccharides.[14]

Pivotal Findings

Signs and Symptoms

Initial assessment of the patient with a chief complaint of diarrhea begins with ensuring clinical stability with attention to volume status. Indications of hypovolemia and hypoperfusion include tachycardia, hypotension, dry mucosa, cool extremities, diaphoresis, poor skin turgor, decreased urine output, or mental status changes. Increased respiratory rate or Kussmaul respirations may indicate an associated acid-base disorder. Young, healthy adults and especially children may maintain a normal blood pressure and heart rate even in the setting of severe dehydration. The heart rate in patients taking antiarrhythmic medications or who are reliant on a pacemaker may be an unreliable indicator of volume status. Clinical signs of dehydration in the pediatric patient may include sunken eyes, depression of the fontanel, reduced number of wet diapers, or decrease in energy, alertness, or activity.

The secondary evaluation assesses the patient's overall health condition, including the presence of fever and the potential for an acute abdomen. Focal abdominal pain in the setting of diarrhea may mimic an acute surgical abdomen. Serial abdominal examinations may be helpful. Rectal examination can detect melena, hematochezia, or fecal impaction. Rectal examination may be beneficial for a patient who cannot describe his or her stools and therefore the presence/abscess of gross blood is unclear, or if fecal impaction is considered possible after obtaining the history. Gross blood may be indicative of invasive, infectious diarrhea, although there are other pathologic states that manifest with gastrointestinal bleeding, including inflammatory bowel disease. Parasitic infection, such as *Strongyloides stercoralis,* may be accompanied by histamine-induced changes, such as urticaria or bronchospasm. Systemic findings of jaundice or scleral icterus demonstrate associated liver pathology. In addition, clinical presentations of toxic syndromes (e.g., anticholinergic or sympathomimetic) may include diarrhea.

Ancillary Testing

In many cases of acute diarrhea, laboratory and further diagnostic testing is not necessary. Testing is guided by the clinical severity of the illness, including vital signs alterations, presence of comorbidities, or physical examination findings suggestive of serious intra-abdominal disease or diarrhea related to serious systemic illness. A toxic appearance with fever, moderate-to-severe volume depletion, blood- or mucus-containing stools, frequent voluminous stools, peritoneal findings, or serious comorbidities, especially immune suppression or chronic inflammatory gastrointestinal disease, should prompt consideration of further investigation to guide appropriate therapy.

Blood tests. Leukocytosis has been reported in *C. difficile* infections, although an isolated white blood cell count elevation is not sensitive or specific enough to aid in diagnostic decision making. Eosinophilia may be seen in parasitic infections with an extraintestinal migration phase. Hemoglobin levels may be assessed to screen for anemia secondary to blood loss or hemolytic uremic syndrome in the setting of *E. coli* O157:H7 infection. A basic metabolic panel to check electrolytes and renal function can be useful when moderate to severe hypovolemia is suspected, or if there has been voluminous diarrhea. Liver function tests including aspartate transaminase (AST), alanine transaminase (ALT), and coagulation times may be helpful when there is jaundice or other evidence of liver disease. Other laboratory studies are rarely indicated but may be obtained when there are particular findings on history or physical examination. For example, a lipase level may be helpful if the diarrhea is part of a syndrome that includes epigastric pain and tenderness accompanied by vomiting. An elevated lactate level may aid in identifying and directing therapy in patients with severe dehydration, sepsis, or causes of noninfectious diarrhea (e.g., mesenteric ischemia, gastrointestinal bleeding).

Stool studies. Fecal leukocytes are not sufficiently specific or sensitive as the sole criterion to determine which patients should be treated with antibiotics. Inflammatory diarrhea of varied causes, including bacterial or parasitic infection as well as noninfectious causes, may lead to red or white blood cells visualized on stool examination. A history of gross blood in the stool accompanying acute diarrhea is usually sufficient to guide consideration of antibiotic therapy; a positive stool guaiac should not be used in isolation. The assays for fecal calprotectin and fecal lactoferrin produced by leukocytes are not typically useful in guiding ED patient evaluation, treatment, or disposition.

Testing for specific pathogens. There are multiple tests available to identify the specific pathogen causing a patient's symptoms; however, the results are generally not available until after the ED encounter and thus are unable to assist in guiding initial therapy.

Testing for bacterial infection. Stool cultures are generally not indicated in the ED given their low sensitivity and delayed results. Stool culture panels for pathogenic enteric bacteria generally screen for *Campylobacter*, *Salmonella*, and *Shigella*. If available, polymerase chain reaction (PCR) testing can result in faster diagnosis but does not provide information regarding antibiotic sensitivities. However, bacterial testing is generally indicated for toxic patients being admitted to hospital, immunocompromised patients, or those with high clinical concern for bacterial source of illness (bloody diarrhea, fever). Bacterial testing is also indicated for patients with persistent or chronic diarrhea not previously tested for these pathogens, although this can be deferred for outpatient follow-up.

***Clostridioides difficile* assay.** Testing for *C. difficile* should be considered if the patient is immunocompromised or reports antibiotic use during the preceding 3 months, recent hospitalization, nursing home residence, employment in a health care setting, or significant diarrhea (>5/day) for several days (generally without vomiting). Diarrhea associated with *C. difficile* most commonly occurs during or closely following the completion of the antibiotic course. Cephalosporins, penicillins, fluoroquinolones, and clindamycin are most frequently implicated, but any antibiotic use potentially places a patient at risk for *C. difficile* infection. Quantitative PCR is the assay of choice for diagnosis of *C. difficile* infection. Reports suggest that rates of community-acquired *C. difficile* infection are increasing, even in patients without traditional risk factors.[12]

***Escherichia coli O157:H7* toxin assay (Shiga toxin).** This assay should be considered when there is a known outbreak or if the presentation occurs in an endemic area. It should also be considered for patients with suspected hemolytic uremic syndrome with associated anemia, thrombocytopenia, and renal dysfunction.

Stool examination for ova and parasites. These tests may be useful in patients with chronic diarrhea (*Entamoeba histolytica* and *Cryptosporidium*), patients with a history of travel or recent immigration from developing countries (*Cryptosporidium*, *Giardia*, and *Cyclospora*), or patients with HIV infection or other immunocompromised state (*E. histolytica* and *Giardia*).

***Giardia* antigen assay and serologic testing for amebiasis.** *Giardia* antigen assay and serologic testing for amebiasis should be considered in patients exposed to poor sanitation or those with immune compromise, a history of travel to developing countries, or recent camping with ingestion of stream or spring water.

Radiographic studies. Radiographic studies are not commonly used in the evaluation of acute diarrhea. Plain radiography is rarely indicated. If peritoneal signs are present or abdominal perforation is suspected, abdominal computed tomography (CT) scan with intravenous (IV) contrast is typically the imaging modality of choice. Abdominal CT is also useful in the diagnosis of fistula, mesenteric ischemia, inflammatory bowel disease, or other acute surgical conditions.

Gastrointestinal Referral

Patients with diarrhea concerning for inflammatory bowel disease or other chronic gastrointestinal conditions should be referred to their primary care provider or a gastroenterologist for further diagnostic testing, much of which is beyond the scope of the ED (including endoscopy, biopsy, or other stool studies).

DIAGNOSTIC ALGORITHM

Unlike many presenting symptoms and signs, critical and emergent diagnoses for patients with diarrhea depend much more on the effects of the diarrhea (hypovolemia, renal compromise) and patient comorbidity (immune compromise, advanced age, inflammatory bowel disease) than on the cause (Fig. 27.1).

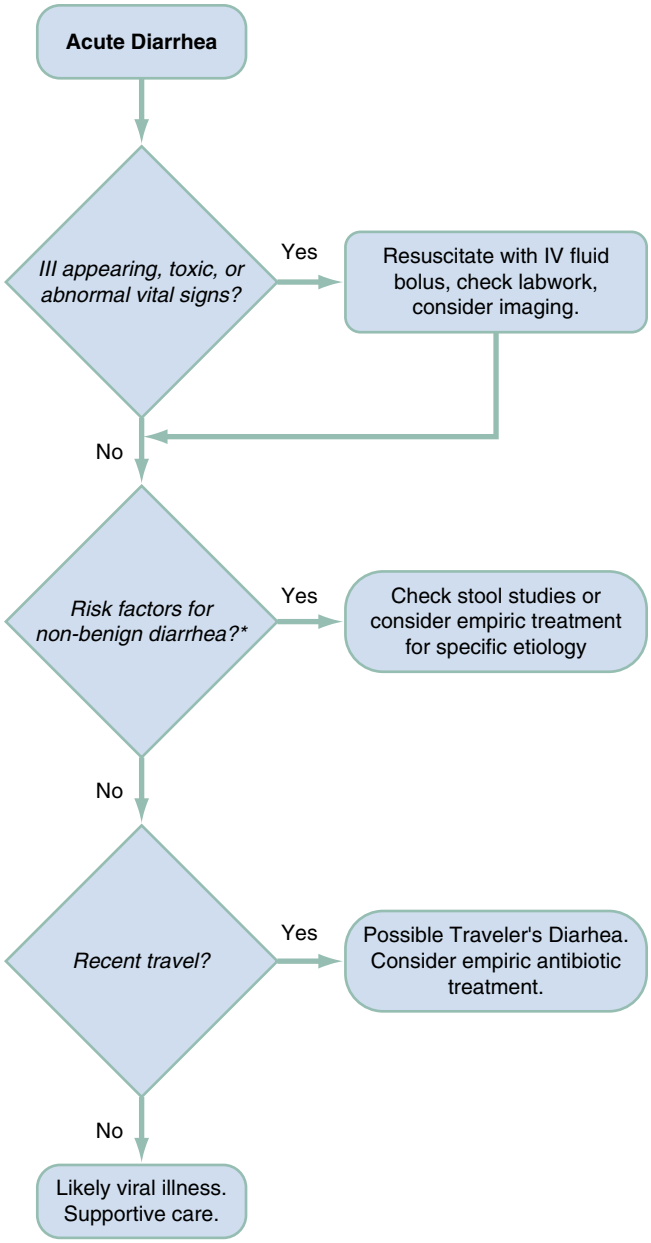

Fig. 27.1 Diagnostic Algorithm. *See Table 27.2.

Critical Diagnoses

Patients with diarrhea accompanied by abnormal vital signs are suspected of having a critical condition and are evaluated for shock. Resuscitation, including IV fluids, is prudent while the underlying etiology of shock is investigated, whether it be hypovolemic, septic, or hemorrhagic. In addition, consideration should be made for possible drug- (e.g., cholinergic poisoning) or food-related toxicity. Laboratory studies may include a creatinine to assess renal status, hemoglobin to assess for gastrointestinal bleeding or hemoconcentration, and a lactate to assess for organ perfusion. An elevated white blood cell count is nonspecific, although it can be associated with *C. difficile* infection, invasive causes of diarrhea, or simply the stress effects of the illness and volume loss. Even viral infectious diarrhea perceived as "self- limited" may result in life-threatening illness in patients presenting with

TABLE 27.2 Factors Increasing Probability of Nonbenign Diarrhea

Factor	Specific Pathogen(s) and Other Considerations
Travel history	Especially foreign travel or to endemic areas of dysenteric disease
Recent hospitalization	*Clostridioides difficile* from antibiotic exposure
Day care attendance	Rotavirus, *Shigella, Giardia*
Nursing home residence	*C. difficile,* medication side effects, tube feedings, ischemic colitis, or fecal impaction with overflow leakage
Wilderness or untreated water exposure	*Giardia* or *Cryptosporidium*
Antibiotic therapy	*C. difficile,* antibiotic-associated diarrhea
Raw shellfish, farm animals or fair livestock, pet reptiles or amphibians, petting zoos	*Salmonella* species, *Escherichia coli* O157:H7, and non-O157 Shiga toxin–producing *E. coli, Vibrio* species
Epidemic of multiple patients within a short time of onset	Norovirus, and less commonly *Campylobacter jejuni, Salmonella* species, or *Cryptosporidium*
Epidemic of severe gastroenteritis traced to eggs, poultry, meat, or dairy products	*C. jejuni*, *Salmonella* species
Abdominal pain, bloody stool, fever, rectal pain, tenesmus	Severe bacterial infections: *Salmonella, Campylobacter, Shigella,* EPEC, *Yersinia* or *Vibrio* species Also consider surgical abdomen, gastrointestinal bleeding, inflammatory bowel disease
Diarrhea (>7–14 days duration)	Protozoa or microsporidia, *C. difficile, Campylobacter,* Shiga toxin–producing *E. coli*
Chronic disease (e.g., cirrhosis, DM)	Complicated course expected with any form of diarrheal illness
Organ transplantation (immunosuppression)	Abnormally severe illness from rotavirus or adenovirus Increased frequency of *Cytomegalovirus* Severe illness from dysenteric diarrhea Spore-forming protozoa or microsporidia
HIV or other immunodeficiency	Severe illness from common bacteria, spore-forming protozoa, or microsporidia Increased frequency of *Cytomegalovirus* or *Mycobacterium avium* complex

DM, Diabetes mellitus; *EPEC,* enteropathogenic *E. coli*; *HIV,* human immunodeficiency virus.

severe dehydration. If vomiting accompanies diarrhea or if the patient appears jaundiced, liver function tests may help delineate other causes of diarrhea, including infectious hepatitis. At particular risk for shock are the elderly, pediatric populations, or the immunocompromised.

Emergent Diagnoses

In patients who have stable vital signs and are nontoxic appearing, it is important to consider risk factors for nonbenign illness (Table 27.2). Most cases of acute diarrhea will resolve on their own without specific medical intervention; however, patients with a history suggestive of a specific nonbenign cause require further investigation. In most well-appearing patients, determining the specific cause of diarrheal illness is not important, because treatment is supportive and the course is expected to be self-limited. In addition to consideration of the etiology of the diarrhea, it is important to assess for secondary complications of diarrhea, such as renal impairment (due to hypovolemia or hemolytic uremic syndrome), electrolyte disturbances, or anemia (see Fig. 27.1).

EMPIRIC MANAGEMENT

Rehydration

Oral rehydration is the treatment choice for mild fluid losses and can be accomplished with sports beverages, commercial rehydration solutions, or a balanced clear liquid diet at home. The WHO has outlined an oral rehydration solution (WHO-ORS) that can be made by dissolving the following in 1 L of clean water: 3.5 g of sodium chloride, 2.9 g of trisodium citrate or 2.5 g of sodium bicarbonate, 1.5 g of potassium chloride, and 20 g of glucose or 40 g of sucrose. In developing countries, 10 mg daily oral zinc supplementation has been shown to decrease the length of symptoms with a greater effect on children appearing chronically malnourished.[15]

The choice of rehydration fluids is dependent on the extent of dehydration and the underlying status of the patient. In otherwise healthy patients with mild dehydration, fluids including sports drinks and diluted fruit juices may be supplemented with soups, broths, or crackers. Diluted fruit juice may be preferred by children and can frequently prevent the need for IV hydration.[16] However, some "clear liquids" may contain excess sugars and insufficient sodium content, resulting in an osmotic diarrhea. Caffeine should be avoided because it increases cyclic adenosine monophosphate levels and may lead to a secretory diarrhea.

Pathogens responsible for acute diarrhea may cause a transient lactase deficiency causing malabsorption and osmotic diarrhea if lactose-containing milk products are subsequently ingested. Patients should be cautioned that, if persistent diarrhea appears to be related to dairy consumption, these products should be avoided for at least 2 weeks. Foods that have high-fat content delay gastric emptying. The BRAT (bananas, rice, apples, toast) diet is often recommended because it is relatively constipating and nonstimulating. Fruit pectin, such as is found in apple peel, was the "pectate" in the older formulation of Kaopectate (kaolinite and pectin), an over-the-counter antidiarrheal product; however, Kaopectate has been reformulated as bismuth subsalicylate. Bananas contain an insoluble fiber which helps to regulate stool consistency and also assists in replenishing potassium which is lost through excessive diarrhea.

Patients who are severely dehydrated should receive IV fluid replacement with normal saline or lactated Ringers solution, which generally is given by bolus (1 to 2 L in adults) followed by infusion at 300 to 500 mL/hour until the patient is well hydrated and passing

normal or dilute urine. Fluid replacement rates are reduced for patients with heart failure. Pediatric patients receive an initial bolus of 20 mL/kg of normal saline, which may be repeated. There is no significant clinical difference between normal saline or lactated Ringers solution, so either may be used in children.[17] In adults, the same conclusion can be extrapolated for low volumes of solution, although direct evidence in this exact clinical scenario is lacking. We generally prefer lactated Ringers solution for patients with diarrhea, because the composition of lactated Ringers solution more resembles the electrolyte composition lost in diarrhea, as compared with normal saline.

Antibiotics

Antibiotic therapy in the ED is often empirical because the specific pathogens causing infectious diarrhea are rarely identified (see Box 27.1). Viral and noninvasive bacterial gastroenteritis are most frequently self-limited, and thus symptomatic therapy and attention to hydration are all that is needed. Empiric antibiotics should be considered for patients who are immunocompromised or demonstrating signs of sepsis. Fluoroquinolones (ciprofloxacin 500 mg by mouth twice daily or levofloxacin 500 mg by mouth daily for 3 to 5 days) or azithromycin (500 mg by mouth daily for 3 days) cover the majority of enteric pathogens. Importantly, guidelines discourage empiric antibiotics for the majority of patients with bloody diarrhea, because their use may increase the risk of developing hemolytic uremic syndrome in patients with Shiga toxin–producing *E. coli*.[15] This is especially pertinent in pediatric patients, in whom the risk of hemolytic uremic syndrome is higher. Empirical antibiotic treatment can reduce the duration of symptoms of travelers diarrhea. A single dose of azithromycin 1000 mg by mouth will effectively reduce time to formed stool in travelers diarrhea.[8] IV antibiotics may be necessary for patients with significant illness or sepsis. Reasonable choices of IV antibiotics include ciprofloxacin 400 mg IV twice daily or ceftriaxone 1–2 gm IV daily.

Although the results of testing for *C. difficile* are unlikely to be available during the patient's visit in the ED, it is reasonable to start empiric treatment with targeted antibiotics if there is a high clinical suspicion. The 2021 guidelines on management of C. difficile infections recommends fidaxomicin (200 mg by mouth twice daily for 10 days) over vancomycin if resources allow, due to decreased episodes of recurrent infection and a narrower spectrum. Vancomycin (125 mg by mouth four times daily for 10 days) is still an acceptable first line option if fidaxomicin is not available. Metronidazole (500 mg by mouth three times daily) is now used only if oral vancomycin or fidaxomicin is not available and is acceptable only for nonsevere disease.[13] Although the initial antibiotic response rates are high, recurrence rates are approximately 35% in weeks 1 through 8; following retreatment, recurrence occurs in 50% to 65% of patients. The high recurrence rate has propelled the employment of a unique microbial replacement therapy, fecal microbiota transplant, in the treatment of patients with recurrent *C. difficile* infections.

Antimotility Agents

Nontoxic patients with acute watery diarrhea often obtain significant relief of symptoms with antimotility agents. In adults, an initial dose of loperamide 4 mg orally with subsequent doses of 2 mg (not to exceed 16 mg in 24 hours) is safe and effective with relief of symptoms. Adding simethicone (60 mg to 125 mg by mouth up to 4 times per day) to loperamide produces a synergistic effect and decreases time to formed stool. Loperamide is also safe and effective for travelers diarrhea when used in combination with antibiotics but can lead to toxic megacolon in patients with severe colonic inflammation.[18] For patients with more severe colitis in which loperamide may lead to significant complications, bismuth subsalicylate (525 mg every 30 mins to 1 hour orally up to maximum 4.2 gm [8 doses] per 24 hour period) is an acceptable alternative for symptomatic relief, although it is slightly less effective. Diphenoxylate with atropine is generally as effective as loperamide but with higher frequency of side effects, and as such is not our recommended choice of agent. In the pediatric population, the use of antimotility agents has been associated with the precipitation of obstruction and toxic megacolon and possibly hemolytic uremic syndrome; therefore it is not recommended. Antimotility agents are also used with caution in any patient at high risk for intestinal obstruction.

Probiotics

Probiotics have been proposed as an alternative to antibiotic therapy for diarrhea, although there is no consensus on dosage or frequency of specific products. Oral ingestion of lactobacillus or other "probiotic" bacteria may be effective in restoring the normal gastrointestinal flora that is disrupted during diarrhea illness, and is safe in immunocompetent patients. Studies are mixed as to the efficacy of probiotics in acute infectious diarrhea, with more recent studies failing to find a benefit.[19] There is moderate evidence demonstrating a protective effect of probiotics in preventing *C. difficile*–associated diarrhea when antibiotics are prescribed for another reason.[20] We do not routinely advise the use of probiotics in the context of acute diarrhea unless we believe the diarrhea to be associated with previously prescribed antibiotics.

DISPOSITION

Patients with uncomplicated, acute diarrhea are usually discharged following assessment and symptomatic treatment in the ED or observation unit. Hospitalization may be indicated for patients with hemodynamic instability, toxic appearance, or inability to maintain adequate oral hydration or in cases where the diagnosis is unclear and there is suspicion of significant underlying disease. For patients with multiple comorbidities who are being discharged home with likely uncomplicated diarrhea, it is prudent to arrange close outpatient follow-up. Even for otherwise healthy patients, outlining specific return precautions to the ED is essential prior to discharge (Fig. 27.2).

CHAPTER 27: QUESTIONS AND ANSWERS

1. Which of the following is not a common cause of diarrhea in a patient with human immunodeficiency virus (HIV) disease?
   - **a.** Antiretroviral therapy
   - **b.** Cytomegalovirus
   - **c.** Giardia
   - **d.** Intestinal lymphocyte proliferation in acute HIV infection
   - **e.** Shigella

Answer: d. Acute HIV infection is associated with depletion (not proliferation) of intestinal lymphocytes from intestinal mucosa, which alters the gut microbiome leading to increased incidence of viral, bacterial, and protozoal causes of diarrhea. Gastrointestinal cytomegalovirus is associated with advanced HIV infection (CD4+ counts less than 50), which can lead to severe hemorrhagic colitis. In addition, all classes of antiretroviral drugs may cause diarrhea, which can affect more than 25% of individuals taking combined antiretroviral therapy.

2. In which of the following patients would *Clostridioides difficile* testing be least useful?
   - **a.** Patient with diarrhea who is taking omeprazole for known peptic ulcer disease.
   - **b.** Patient with diarrhea after recent tonsillitis treated with amoxicillin.
   - **c.** Patient with diarrhea who is a long-term resident of a skilled nursing facility.
   - **d.** Patient with acute vomiting and watery diarrhea following contact with a toddler with similar symptoms.
   - **e.** Patient with uncontrolled HIV and acute watery diarrhea.

Answer: d. Patient in answer D likely has a viral gastroenteritis, and C. difficile testing is more likely to result in false positive result or identify chronic colonization. Risk factors for C. difficile colitis include antibiotic or gastric acid suppressive therapy, skilled nursing facility residence, and chronic medical conditions.

3. Evaluation of stool for ova and parasites would prove least beneficial in which of the following subsets of patients presenting with diarrhea?
   - **a.** Patients concurrently taking clindamycin with diarrhea for 1 week
   - **b.** Patients recently returning from a backpacking trip
   - **c.** Patients returning from a trip to Nepal
   - **d.** Patients with chronic diarrhea
   - **e.** Patients with human immunodeficiency virus (HIV) infection

Answer: a. The assessment of stool for ova and parasites is not routinely recommended in most cases of diarrheal illness. This study is used in patients with chronic diarrhea (Entamoeba histolytica and Cryptosporidium); patients with a history of travel to developing countries, particularly to Nepal or areas of Russia (Cryptosporidium, Giardia, and Cyclospora); patients with exposure to infants in day-care centers (Cryptosporidium and Giardia); and patients with HIV infection (E. histolytica and Giardia). Acute diarrhea can last up to 2 weeks.

4. In which of the following patients is loperamide a safe treatment option?
   - **a.** Adult patient with acute watery diarrhea of unknown etiology
   - **b.** Adult patient with sepsis and bloody diarrhea
   - **c.** Elderly patient with a history of bowel obstruction with watery diarrhea
   - **d.** Pediatric patient with acute watery diarrhea from norovirus
   - **e.** Pediatric patient with travelers diarrhea

Answer: a. Loperamide, a bowel-selective opioid agonist, is an effective tool to reduce diarrhea severity. Although generally safe, it has been associated with toxic megacolon and obstruction in select groups, such as the elderly, pediatric patients (especially younger than age 3), and patients with a severe inflammatory colitis. Adult patients in which the risk of obstruction or severe inflammatory colitis is low are candidates for loperamide treatment.

5. In which of the following patients is empiric antibiotic treatment the most reasonable option?
   - **a.** Adult patient returning from Mexico with watery diarrhea.
   - **b.** Adult patient with bloody diarrhea during outbreak of *Escherichia coli O157:H7*
   - **c.** Pediatric patient returning from Thailand with bloody diarrhea.
   - **d.** Pediatric patient with fever and bloody diarrhea.
   - **e.** Well-appearing adult patient with suspected norovirus based on ill contacts.

Answer: a. Travelers diarrhea generally responds well to a single dose of azithromycin 1000 mg PO which can decrease time to resolution of symptoms with limited side effects. The choice to initiate antibiotics must be tailored to weigh potential benefits and harms of the treatment for the individual patient. Empiric antibiotics are generally contraindicated in children, as well as patients in which E. coli O157:H7 is a possibility, as antibiotics increase the risk of hemolytic uremic syndrome. In cases of suspected viral-mediated diarrhea, such as a clustered norovirus outbreak, antibiotics are generally not indicated.

28

Constipation

Jessica Palmer

KEY CONCEPTS

- Constipation is a variable term used by patients and may refer to straining with defecation, hard or infrequent stools, pain with a bowel movement, a sensation of incomplete evacuation, or abdominal bloating.
- Primary constipation is caused by functional abnormalities of the gastrointestinal tract.
- Secondary constipation is due to diet, related medical or psychiatric disorders, or medication side effects.
- The etiology of constipation can frequently be discovered through a thorough history.
- The physical examination of patients with constipation focuses on the patient's appearance, the presence of pain, and structural abnormalities identified on abdominal or rectal examination.
- Lab work to evaluate constipation is typically not indicated.
- Imaging to evaluate constipation is not typically indicated when the physical examination is normal.
- The treatment of constipation for most patients is empiric and focuses on lifestyle modifications in addition to laxatives.
- Patients with constipation should be referred for outpatient evaluation and testing when they fail empiric treatment.
- Opioid-induced constipation is common and may require peripherally acting μ-opioid receptor antagonists for management.

FOUNDATIONS

The term *constipation* refers to a symptom or complex of symptoms and not a specific diagnosis. Patients and health care providers may define constipation differently. Most health care providers define constipation based on stool frequency. Patients often use the term *constipation* to describe a broad set of complaints, including straining, hard or infrequent stools, pain during a bowel movement, a feeling of incomplete evacuation, or abdominal bloating. Constipation may be acute (new for the patient) or chronic. *Chronic constipation* is defined as the presence of symptoms for at least 3 months. In clinical practice, attempting to identify the cause of the symptoms often results in the best chance of effective treatment and helps determine disposition. A definitive diagnosis often is not possible in the emergency department (ED) setting, and appropriate follow-up evaluation should be arranged. When constipation becomes severe with constant pain, some clinicians use the term *obstipation*. Obstipation represents the progression of the symptom of constipation toward bowel obstruction.

ED visits for constipation have continued to increase over the past 10 years.[1] In adults, constipation is more common in women, the elderly, and those with high body mass index, sedentary lifestyle, or low socioeconomic status. A consistent trend of increasing prevalence of constipation is observed with age, with significant increases after the age of 70 years. The high prevalence among elders is multifactorial and related to a diet low in fiber (soft diets due to dysphagia or chewing difficulties), lack of adequate fluid intake, sedentary habits, multiple medications, and various disease processes that impair neurologic and motor control.[2]

Pathophysiology

Normally the gastrointestinal tract receives 9 to 10 L/day of secretions and ingested fluids, of which the small intestine routinely absorbs all but approximately 500 mL. The colon mixes the ileal effluent, ferments and salvages the unabsorbed carbohydrate residues, and desiccates the contents to form stool. The process of stool transport and evacuation is complex and is regulated by neurotransmitters, intrinsic colonic reflexes, and a multitude of learned and reflex mechanisms that are not fully understood. Constipation may result from structural, metabolic, mechanical, neurologic, or behavioral disorders that affect the colon or anorectum either directly or indirectly.

Constipation is either primary or secondary (Table 28.1). Primary constipation, or functional constipation, can be separated into three subtypes—normal transit constipation, slow transit constipation, and disorders of defecation. Patients may experience multiple subtypes at the same time. Normal transit constipation occurs when patients have bowel movements with regularity, but the bowel movements may be hard or require excessive straining. Slow transit constipation occurs due to neurologic changes in the bowels, which impact the colon's ability to contract.[3] Colorectal contraction is mediated by the cells of Cajal, which are responsible for both segmental contraction (used to mix colonic contents) and high-amplitude contractions (used to propel colonic contents). Patients with chronic constipation have been shown to have reduced numbers of cells of Cajal, which leads to reduced amplitude of contractions, a diminished gastrocolic reflex after meals and often retrograde propulsion. Disorders of defecation involve impaired smooth muscle contraction in the rectum or difficulty relaxing the muscles of defecation. Dyssynergistic defecation occurs when a patient has difficulty coordinating the pushing effort of the abdominal muscles along with the relaxation effort of the pelvic floor muscles necessary to have a bowel movement.[4] Finally, rectal sensorimotor dysfunction, common in elders, may blunt the patient's ability to sense the need to defecate when stool builds up in the rectal vault. This may result in significant stool buildup and rectal distension.[3] Irritable bowel syndrome, constipation-predominant (IBS-C), is also considered a functional gastrointestinal motility disorder, and although there is significant overlap with chronic constipation and its subtypes, it remains a separate entity.[5]

Secondary constipation is due to diet, medications, and certain medical or psychiatric conditions. Low-fiber diets or diets with decreased water and liquid consumption are associated with constipation. Fiber increases stool weight, which can lead to decreased colonic transit time in patients with normal colonic transport.[2]

TABLE 28.1 Causes of Constipation

Primary Constipation (Functional constipation)	Secondary Constipation	
Normal transit constipation	Congenital	Hirschsprung disease Imperforate anus Anorectal atresia Aganglionosis
Slow transit constipation	Neurologic	Chronic diseases (multiple sclerosis, Parkinson disease, diabetic neuropathy) Spinal cord injury Cerebrovascular accident
Disorders of defecation	Metabolic	Diabetes Hypercalcemia Hypokalemia Hypothyroidism Hypomagnesemia
Irritable bowel syndrome (predominant constipation)	Myopathies	Systemic sclerosis Amyloidosis
	Structural	Obstructing tumor or stricture Intussusception Rectocele Rectal prolapse Rectal abscess
	Medication side effect (Most common listed here)	Opiates Iron or calcium supplements Calcium channel blockers Antidepressants Diuretics Antipsychotics Anticholinergics Antiepileptics Antiparkinson drugs
	Psychological	Abuse (psychological, physical, sexual) Eating disorders (bulimia, anorexia nervosa) Affective disorders
	Others	Dehydration Immobility Pregnancy Postoperative pain Dietary factors

DIAGNOSTIC APPROACH

The etiology of constipation is usually discovered through thorough history. Start by having the patient define what is meant by "constipation." Patients may express varying definitions. Important features include the presence of fever, anorexia, nausea, vomiting, blood in the stool, anemia, significant weight loss, a family history of colon cancer, onset of constipation after the age of 50, or acute onset of constipation in an elderly patient.

Additional elements of the history are directed toward elucidating a possible cause. Symptoms that have evolved quickly and are worse with defecation may point toward acute rectal pathology such as a perirectal abscess, whereas consistent rectal pain and difficulty defecating over the course of a few years may be more consistent with a chronic rectal sensorimotor issue. Questions about the character of the stools may reveal a decrease in caliber of the stool, suggesting possible mass lesion, or diarrhea alternating with constipation, which may indicate irritable bowel provide important clues. A medication history should include any recent changes in dosage of any prescription medications, as well as the use of herbal agents or over-the-counter (OTC) medications. It is also important to ask about diet and dietary changes, given the relationship between constipation and diet.

Differential Considerations

In the ED, patients often present with acute constipation resulting from side effects of medications or avoidance of defecation secondary to presence of painful perianal lesions, such as fissures, hemorrhoids, or perirectal abscesses. Excluding emergent conditions related to constipation is the priority. Establishing a timeline and trajectory for a patient's symptoms will assist with diagnosis and subsequent management. Many patients experience constipation as a side effect of a medication or drug of abuse, with opioids commonly implicated. Elders in particular are at risk for constipation and are sometimes prescribed opioids for pain. Thus warnings about the potential for constipation and instructions for both prevention and treatment remain prudent. Other drugs that may cause constipation include iron supplements, calcium channel blockers, or antidepressants.

Pivotal Findings

The examination should begin with a general inspection of body habitus and nutritional status. Metabolic abnormalities related to a patient's nutrition and hydration status may play a significant role in the etiology of constipation. Focus should then shift to the abdominal and rectal examinations. The abdominal examination in patients with constipation is often normal, and abnormal findings (e.g., tenderness, mass, distention, or abnormal bowel sounds suggesting obstruction) prompt further directed evaluation.

Anorectal inspection may reveal fissures, hemorrhoids, abscess, or a rectal prolapse. The digital rectal examination should include palpation for impacted stool or mass, and the presence or absence of pain should be noted. Having the patient bear down may be helpful in assessing sphincter function and may reveal milder forms of prolapse. The quantity and the characteristics of the stool should be recorded. Testing the stool for occult blood may yield additional information, although straining with stooling can produce local anal lesions and bleeding. If results of occult blood testing are positive, diverticular disease, carcinoma, and local anal bleeding from repeated attempts at straining are possibilities.

Ancillary Testing

The majority of patients with a presenting complaint of constipation do not require any testing. Plain abdominal radiography is of significantly limited value, and patients whose history and examination suggest a need for imaging should undergo ultrasound or computed tomography (CT), depending on the working differential diagnosis. Plain radiographs documenting an increased stool load in the constipated patient should not be used to exclude more serious underlying causative disorders, especially if the patient has a significant amount of abdominal pain or tenderness on examination. Interpretation of abdominal films tends to be variable and can lead to misdiagnosis. In addition, a recent study showed that patients who received plain abdominal radiographs in the ED frequently required additional abdominal imaging, rendering the plain films unnecessary.[6]

Clinical laboratory studies are not routinely indicated in the evaluation of constipation. When blood is found in the stool, a hemoglobin level or complete blood count (CBC) may reveal an accompanying anemia, which may suggest an occult carcinoma or recurrent blood loss from localized colon disease, such as diverticulosis. The white blood cell count is nonspecific and of limited value.

Patients with acute constipation without an apparent emergent cause should receive symptomatic treatment, with referral for outpatient evaluation and reassessment as needed. The patient in the ED with chronic constipation and no alarming signs or symptoms should receive empirical treatment without any ancillary testing. Outpatient testing typically occurs after a patient has failed empirical treatment and may include blood tests to investigate metabolic or endocrine causes, or possibly specialized tests, such as colonic transit studies and anorectal manometry.[7]

Critical Diagnoses

The approach to the patient with constipation starts with assessing whether there is associated abdominal pain. If abdominal pain is present, the evaluation should be geared toward this symptom accordingly, which may ultimately reveal the cause of constipation. Constipation itself may cause abdominal pain; however, this should be a diagnosis of exclusion once other, more serious potential causative disorders have been excluded.

Fig. 28.1 is a diagnostic algorithm for the management of patients with constipation. Initially, history will be very helpful in differentiating among causes, such as medication side effect or possible neurologic disease. The presence of abnormalities on physical examination will dictate appropriate testing and management. For most patients with a normal examination, treatment will be empiric.

Emergent Diagnoses

Constipation is rarely associated with morbidity or mortality. Most negative outcomes are a result of missed diagnosis of bowel obstruction or perforation. These conditions are generally diagnosed through physical examination and appropriate imaging. Stercoral perforation, resulting from severe chronic constipation causing fecal impaction

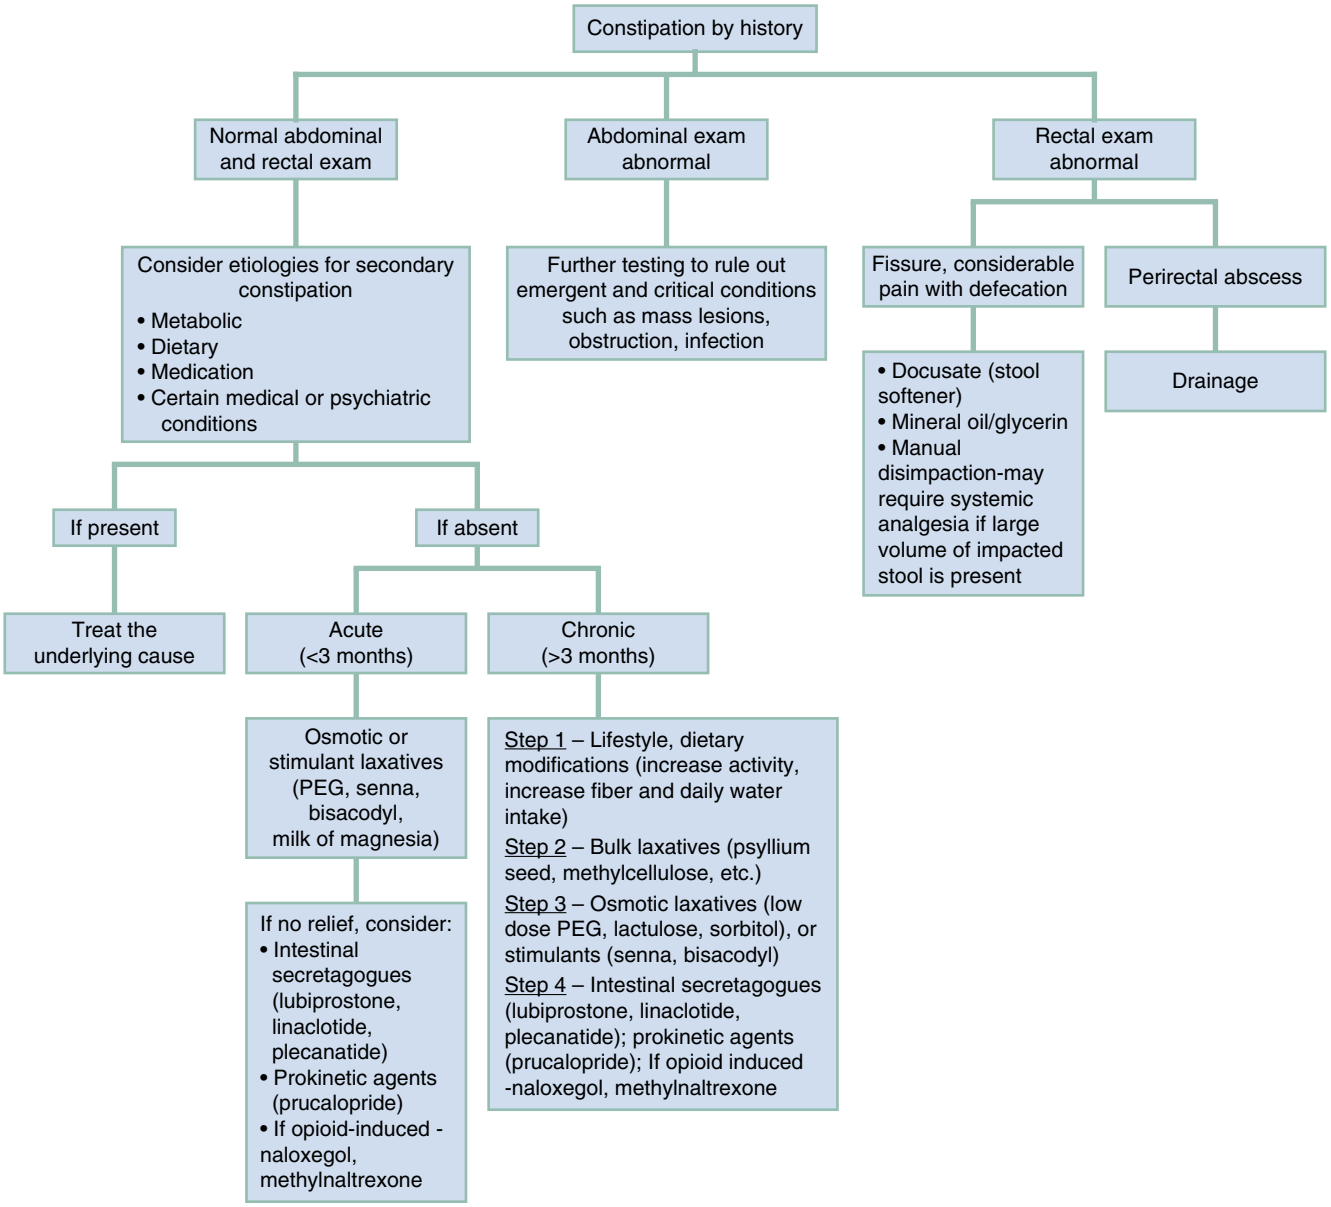

Fig 28.1 Algorithmic Approach to the Diagnosis of Constipation. *5HT$_4$,* 5-Hydroxytryptamine 4; *PEG,* polyethylene glycol.

in the large bowel and associated pressure necrosis and perforation, should be considered in patients with chronic fecal retention. This is typically diagnosed on CT imaging. Surgical consultation is necessary for suspected perforation or obstruction.

EMPIRICAL MANAGEMENT

Treatment of acute constipation is directed toward identifying the underlying cause and providing symptom relief. Prevention of further episodes may include recommending increased fluid intake, increased exercise, increased dietary fiber, and, if necessary, additional sources of bulk in the form of synthetic bulking agents. These interventions will not usually help the acutely constipated patient in the short term. Initial treatment for acute constipation without concern for structural abnormality should focus on the addition of osmotic or stimulant laxatives. If unsuccessful, treatment should be escalated including referral for outpatient testing. Therapeutic choices and recommendations for patients should be customized based on patient preferences, as well as prior personal history of efficacy with various treatments. Specific recommendations may also include withholding a causal medication, management of an anal fissure, or drainage of a perirectal abscess. Stool softeners (e.g., docusate sodium), although commonly recommended, should not be a first-line agent for most patients with constipation. Docusate has not been shown to be any more effective than placebo in relieving acute constipation, although it may be somewhat helpful in patients with anal fissures or hemorrhoids because it may make defecation less painful.

Specific agents for symptomatic treatment of constipation are listed in Table 28.2. There are seven main classes of commonly used laxatives. These include softeners, bulking agents (fiber), osmotic agents, stimulants, intestinal secretagogues, prokinetic agents, and peripherally acting μ-opioid receptor antagonists (PAMORAs). These agents aid defecation by decreasing stool consistency, stimulating colon motility, or both.

Intestinal secretagogues are a relatively new class of medications used to treat both chronic constipation and constipation predominant IBS. These drugs work by stimulating intestinal fluid secretion, increasing the amount of fluid in the stool and decreasing colonic transit time.[8] In recent studies, intestinal secretagogues performed better than placebo at reducing constipation and related symptoms, although direct comparison to laxatives has not yet been performed.[8,9] Diarrhea is the one major side effect of these medications, and their cost can be prohibitive as well.

TABLE 28.2 Preparations Used in the Symptomatic Treatment of Constipation

Medication	Maximal Recommended Dosage	Onset of Action	Comments
Bulk Laxatives			Indigestible fiber attracts water, which leads to larger, softer fecal mass.
Psyllium (Metamucil)	Titrate up to 21 g (females) to 30 g (males)	12–72 h	Natural fiber that undergoes bacterial degradation, which may contribute to bloating and flatus. Should be taken with plenty of water to avoid intestinal obstruction.
Methylcellulose (Citrucel)	Titrate up to 6 g per day		Semisynthetic cellulose fiber that is relatively resistant to colonic bacterial degradation.
Polycarbophil (Fibercon)	Titrate up to 5 g per day	12–72 hrs	Synthetic fiber of polymer of acrylic acid, resistant to bacterial degradation.
Osmotic Laxatives			Draw water into the intestines along osmotic gradient.
Magnesium or sodium salts			
Magnesium hydroxide (milk of magnesia)	4800 mg per day either at bedtime or in divided doses	1–6 h	A small percentage of magnesium is absorbed—use caution in patients with renal insufficiency or in children.
Magnesium citrate	300 mL per day	0.5–6 hr	
Sodium phosphate (Fleet Phospho-Soda)	15 mL per dose up to 45 mL/day	3–6 h	Hyperphosphatemia may result in setting of renal insufficiency. Commonly used before colonoscopy.
Poorly absorbed sugars			
Lactulose	60 mL by mouth per day	24–48 h	Synthetic disaccharide not absorbed by the small intestine. Gas and bloating common.
Sorbitol	45 mL by mouth per day (as 70% solution)	0.25–1 hr	Poorly absorbed by small intestine.
Polyethylene glycol and electrolytes (GoLYTELY, MiraLax)	34 g per day	24–96 h	Organic polymers that are poorly absorbed and not metabolized by bacteria; thus may cause less bloating and cramping. Can be mixed with noncarbonated beverages.
Stimulant Laxatives			Stimulate intestinal motility or secretion.
Senna (Senokot, Ex-Lax)	100 mg daily	6–12 h	Stimulates secretion and motility of small intestine and colon.
Bisacodyl (Dulcolax, Correctol)	15 mg by mouth daily	6–10 h	

TABLE 28.2 Preparations Used in the Symptomatic Treatment of Constipation—cont'd

Medication	Maximal Recommended Dosage	Onset of Action	Comments
Stool Softeners			Increase water penetration and soften stool.
Docusate sodium (Colace)	360 mg by mouth daily	12–72 h	In many studies, no better than placebo. Not recommended as first-line or solo therapy.
Mineral oil (Fleet mineral oil)	45 mL by mouth daily	6–8 h	Provides lubrication for the passage of stool. Long-term use is not recommended. Lipid pneumonia can occur in patients predisposed to aspiration.
Intestinal secretagogues			
Lubiprostone (Amitiza)	24 μg twice per day	1 h	Used in CIC.
Linaclotide (Linzess)	145 μg daily in CIC and 290 μg daily in IBS-C		Used in IBS-C and CIC.
Plecanatide (Trulance)	3 mg daily		Used in IBS-C and CIC.
5-HT$_4$ Agonists			
Prucalopride (Motegrity)	2 mg daily		Used in CIC.
Peripherally Acting μ-Opioid Receptor Antagonists			
Methylnaltrexone (Relistor)	450 mg orally daily or 12 mg SC daily	30–60 min	Used in opioid-induced constipation.
Naldemedine (Symproic)	0.2 mg daily		Used in opioid-induced constipation.
Naloxegol (Movantik)	25 mg unncessary daily		Used in opioid-induced constipation.

CIC, Chronic idiopathic constipation; *5HT$_4$,* 5-hydroxytryptamine 4; *IBS-C,* irritable bowel syndrome with constipation; *SC,* subcutaneously.

Prokinetic agents that target the serotonin receptor (5-hydroxytryptamine 4 [5-HT$_4$] receptor agonists) have been found to be effective as well for patients with chronic idiopathic constipation. When bound specifically to the 5-HT$_4$ receptor, they increase colonic propulsion without the cardiac side effects of older, less selective 5-HT agents.[10]

Constipation frequently occurs in patients who are taking medically necessary medications that cause constipation on a chronic basis (e.g., opioids in patients with chronic pain or cancer). Constipation is a nearly universal side effect of opioid pain medication due to the presence of opioid receptors in the gastrointestinal system.[11] Patients with chronic opioid use should be on bowel regimens designed to prevent constipation, which usually includes measures such as high levels of dietary fiber (e.g., added prunes or figs), as well as daily administration of stimulant laxatives. PAMORAs were developed to manage opioid-induced constipation in this class of patients who have failed other therapies. These drugs selectively block the gastrointestinal μ-opioid receptors without compromising the centrally mediated effects of opioid analgesia or precipitating withdrawal. There are three drugs in this category—methylnaltrexone (Relistor), which is administered both subcutaneously and orally, and naldemedine (Symproic) and naloxegol (Movantik), which are orally administered. All three medications have been shown to be more beneficial than placebo in patients with opioid-induced constipation.[11]

Enemas are sometimes necessary if laxatives have failed to provide relief or if the patient has a large volume of stool in the lower colon or rectum that cannot be expelled. Warm tap-water enemas are generally the safest choice. For immediate relief, manual disimpaction may be necessary in some patients, especially in elders with large amounts of stool present in the rectal vault. In rare cases, disimpaction may need to be performed with analgesia or even procedural sedation.

CHAPTER 28: QUESTIONS AND ANSWERS

1. A 48-year-old female with no known past medical history presents to the emergency department with the chief complaint of constipation. She states she has not had a bowel movement in the past 7 days. She has no history of similar symptoms. She denies taking any medications or any past surgical history. On examination, she has no abdominal tenderness with palpation or masses. Her rectal examination is unremarkable for fissures, and the patient does not have any blood or stool in her rectal vault. What is the next step in this patient's management?

a. A plain film abdominal x-ray
b. Discharge home with recommendation for laxatives and plan for lifestyle modification
c. Emergent outpatient gastroenterology follow-up
d. Trial of at home docusate and strict return precautions if plan fails

Answer: b. The patient in this question has acute constipation. Because her history and examination does not have any red flag concerns, this patient can be safely discharged home without any testing. This patient will require laxatives to help her acute constipation, but lifestyle management should help to prevent similar episodes in the future. There is no utility for plain film abdominal x-rays in the emergency department for the evaluation of constipation. Docusate has been shown to be ineffective as first line management for constipation unless the patient has a rectal abnormality or rectal pain that prevents the passage of stool. This patient is well-appearing on examination and therefore, she does not require intravenous (IV) hydration. Because this patient's constipation is acute and she has a benign examination, she does not require emergent gastroenterology follow-up.

2. A 96-year-old male from a nursing home presents with the chief complaint of constipation. He has a past medical history significant for cerebrovascular accident and now receives all of his medications, hydration, and feedings through a gastrostomy tube due to dysphagia. The patient has been on a bowel regimen of twice daily polyethylene glycol through his gastrostomy tube with minimal, watery stool output over the past week. The patient appears to be uncomfortable, but he is afebrile and hemodynamically stable. On examination, the patient's abdomen is soft and there is no focal tenderness. On rectal exam, you feel a large amount of firm stool in the rectal vault. What is the appropriate next step in this patient's management?

a. Admission for colonoscopy
b. Analgesia and disimpaction
c. Glycerin suppository
d. Oral milk of magnesia

Answer: b. This is an elderly male with chronic constipation for a multitude of reasons. Because of his age and possibly due to his cerebrovascular accident, he has denervation of his rectum preventing him from sensing rectal fullness. The large volume of stool in his rectum needs to be removed for his comfort, and disimpaction with analgesia will be necessary. The use of a glycerin suppository to lubricate the stool to be expelled is unlikely to be successful as this patient has lost the ability to expel stool on his own. Because this patient does not receive medications by mouth, milk of magnesia should not be given orally. Because his abdominal examination is benign and he is hemodynamically stable, the likelihood that he has a critical intra-abdominal process requiring imaging is low. Finally, this patient does not require admission to the hospital, nor does he require an emergent colonoscopy at this time.

3. A 32-year-old female with chronic pain followed closely by a pain management specialist presents with constipation. She normally takes a bowel regimen of bisacodyl daily in addition to consuming a high-fiber diet. Her physician recently increased her opioid medication dosage. Since then, she has had difficulty having more than one small, hard stool per week. She complains of abdominal discomfort but has not had any nausea or vomiting. On examination, her abdomen is soft without focal tenderness. Her rectal examination is normal. What is the appropriate next step in this patient's management?

a. A trial of a peripherally acting μ-opioid receptor antagonist and plan for close outpatient follow up with her care team
b. Consultation with her pain management specialist to decrease her medication dosage back to previous levels
c. Lab testing to rule out an electrolyte abnormality causing this patient's symptoms
d. Nonopioid pain medication for her discomfort while in the emergency department and plan for gastroenterology follow-up

Answer: a. This is a patient experiencing opioid-induced constipation. Her previous bowel regimen was sufficient until her medication doses increased. Because this patient has failed her bowel regimen, it is reasonable to try a peripherally acting μ-opioid receptor antagonist to block the effects of the opioids on the colonic μ receptor. Decreasing this patient's pain medications back to previous doses may lead to withdrawal. Lab testing is unlikely to be of benefit. Providing analgesia for discomfort will not relieve constipation.

4. Which of the following is true regarding constipation?
   - **a.** The diagnosis of constipation requires lab testing and imaging in the emergency department.
   - **b.** Most patients with constipation and a normal examination can be safely discharged home with empiric treatment.
   - **c.** Constipation is less common in the elderly due to low fiber, mechanical soft diets.
   - **d.** Chronic constipation occurs when a patient experiences decreased stool output for at least 1 year.

Answer: b. The term constipation refers to a multitude of symptoms, not a medical diagnosis. Patients often have different personal definitions for the term "constipation." Chronic constipation refers constipation symptoms for 3 or more months. Constipation is more common in the elderly due to sedentary lifestyles and low-fiber, mechanically soft diets. In the ED, lab testing and imaging is often unnecessary for patients with a normal physical exam. Most well-appearing patients with constipation and a normal examination can be discharged home with empiric management.

5. Which of the following is true regarding treatment options for constipation?
   - **a.** Bisacodyl works by increasing water penetration and thereby softens the stool.
   - **b.** Docusate sodium should be prescribed to all patients with chronic constipation given its effectiveness as a laxative.
   - **c.** Lifestyle modification is the first line treatment for patients with acute constipation.
   - **d.** Sodium phosphate and magnesium hydroxide should be avoided in patients with renal impairment.

Answer: d. The side effect profiles for many common treatments of constipation should be considered prior to prescribing to special patient populations. Both sodium phosphate and magnesium hydroxide can increase the levels of phosphorus and magnesium in the body, respectively, in patients with renal insufficiency/impairment. Bisacodyl is a laxative and works by stimulating intestinal motility. Docusate sodium is a stool softener, not a laxative, that should not be used as first line or solo therapy due to its marginal efficacy. Patients with acute constipation should be prescribed both a laxative for immediate treatment and lifestyle modification for longer-term management.

29

Acute Pelvic Pain

Ari M. Lipsky and Danielle Hart

KEY CONCEPTS

- Acute pelvic pain in women is often from a gynecologic source, but urinary and intra-abdominal sources are also common. Less frequently, the pain may arise from vascular, musculoskeletal, neurologic, or psychiatric disorders.
- Potentially lethal diagnoses associated with acute pelvic pain include ectopic pregnancy, ovarian cyst with significant hemorrhage, and domestic violence; highly morbid conditions presenting with acute pelvic pain include pelvic inflammatory disease and ovarian torsion.
- Nearly all women of childbearing age with pelvic pain should have a pregnancy test performed, and most should have a pelvic ultrasound examination.
- Ectopic pregnancy should be excluded in the pregnant patient with pelvic pain. Bedside ultrasound is an excellent test for confirming an intrauterine pregnancy (IUP); it excludes ectopic pregnancy with a high degree of certainty in patients who are not using assisted reproductive technology.
- Pregnant patients with acute pelvic pain may also have non–pregnancy-related disorders; appendicitis, nephrolithiasis, and ovarian torsion, among others, remain in the differential diagnosis.
- Many patients with acute pelvic pain require imaging as part of their assessment. If a gynecologic source is suspected, begin with an ultrasound and then progress to computed tomography (CT) or magnetic resonance imaging (MRI), if needed. The presence of an ovarian cyst on imaging does not necessarily explain the patient's pain, and further evaluation may be required. Ultrasound after normal CT is unlikely to be informative. Ovarian torsion may be radiographically occult.

FOUNDATIONS

Epidemiology

Acute pain caused by pelvic pathology is common, and the presenting complaint may be diffuse or lower abdominal pain, pelvic pain, or low back pain. A patient with chronic pelvic pain may also have an acute process related to the chronic condition or arising de novo.

More than one-third of reproductive age women will experience nonmenstrual pelvic pain. Among diagnoses for women with pain caused by gynecologic disorders in the emergency department (ED), pelvic inflammatory disease (PID) and lower genital tract infections (e.g., cervicitis, candidiasis, Bartholin abscess) account for almost 50%. Other common diagnoses are menstrual disorders, noninflammatory ovarian and tubal pathology (including cysts and torsion), and ectopic pregnancy. Ectopic pregnancy accounts for up to 20% of diagnoses among women presenting with vaginal bleeding or abdominal pain in the first trimester of pregnancy.

Younger patients and those with multiple sexual partners are more likely to have PID, and a previous episode increases the likelihood of a subsequent episode. The risk of ectopic pregnancy is higher in women who have had PID, pelvic surgery, prior ectopic pregnancy, or are using an intrauterine device (IUD). Heterotopic pregnancy is of special concern in women using assisted reproductive technology (ART). Although the rate of heterotopic pregnancy in spontaneous pregnancy is 1 in 30,000, this rate increases to as high as 1:1000 in patients undergoing ART.[1] Common nongynecologic diseases such as appendicitis, diverticulitis, urinary tract infection, and urolithiasis remain important considerations in the woman with acute pelvic pain. Box 29.1 lists conditions accounting for most cases of pelvic pain in women.

Some causes of pelvic pain may lead to serious sequelae. PID carries the short-term risk of tubo-ovarian abscess and the long-term risks of impaired fertility, chronic pelvic pain, and increased predisposition to ectopic pregnancy. Rupture of an ectopic pregnancy or hemorrhagic ovarian cyst may be life threatening. Unrecognized abuse may also have serious or even lethal consequences.

Pathophysiology

The female pelvis contains the vagina, uterus, fallopian tubes and ovaries, ureters and urinary bladder, and sigmoid colon and rectum, as well as components of the vascular and musculoskeletal systems. Although pelvic pain often originates from the reproductive organs, it may arise from any structures that lie adjacent to or course through the pelvis. Visceral pain afferents supplying the pelvic organs have common innervation with the appendix, ureters, and colon. Their significant overlap makes accurate localization difficult for both patient and emergency clinician. Pain may be initiated by inflammation, distention, or ischemia of an organ, or by spillage of blood, pus, or other material into the pelvis. Pain may become more localized when the afferent nerves in the parietal peritoneum adjacent to an affected organ are stimulated.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis of pelvic pain is broad (see Box 29.1). Most causes of pelvic pain fit into three categories: (1) reproductive tract; (2) urinary tract; and (3) intestinal tract. Because a subset of pelvic pain is found only in pregnancy, the pregnancy test is a key branch point in the diagnostic process. Potential pregnancy-related disorders can be divided into complications of early pregnancy and complications that occur further along in pregnancy. Although the specific cause of pelvic pain cannot always be determined at the initial ED visit, an organized approach usually leads to the confirmation or exclusion of disorders most likely to result in significant morbidity or mortality.

Pivotal Findings

The pelvic examination may at times provide crucial information. However, some findings on bimanual examination are subjective and may be unreliable; they are perhaps most helpful in localizing the process to one side or the other or in helping to plan further work-up. There are not currently sufficient data to select reliably women in whom the pelvic examination need not be performed, although the

BOX 29.1 Causes of Pelvic Pain in Women

Reproductive Tract
Ovarian torsion
Ovarian cyst
Pelvic inflammatory disease
Salpingitis
Tubo-ovarian abscess
Endometritis
Endometriosis
Uterine perforation
Uterine fibroids
Dysmenorrhea
Vulvar/vaginal trauma
Neoplasm

Pregnancy Related
First Trimester
Ectopic pregnancy
Threatened abortion
Nonviable pregnancy
Ovarian hyperstimulation syndrome

Second and Third Trimesters
Placenta previa
Placental abruption
Round ligament pain
Labor or Braxton Hicks contractions
Uterine rupture

Intestinal Tract
Appendicitis
Diverticulitis
Ischemic bowel
Perforated viscus
Bowel obstruction
Incarcerated or strangulated hernia
Fecal impaction or constipation
Inflammatory bowel disease
Gastroenteritis/colitis
Irritable bowel syndrome

Urinary Tract
Pyelonephritis
Cystitis

Vascular
Septic pelvic thrombophlebitis
Ovarian vein thrombosis
Sickle cell disease
Pelvic congestion syndrome

Musculoskeletal
Muscular strain or sprain
Hernia
Abdominal wall hematoma
Pelvic fracture

Neurologic, Psychiatric, and Other
Depression
Domestic violence
Sexual abuse
Abdominal migraine
Herpes zoster

pelvic examination may be deferred in patients for whom immediate imaging is planned for a suspected critical condition such as ruptured ectopic pregnancy.[2–4] Depending on imaging results, a subsequent speculum or bimanual pelvic examination may still be necessary.

It is unlikely that any particular finding on history or physical examination, summarized in Table 29.1, is reliable enough to make or exclude a particular diagnosis conclusively, so ancillary testing beyond a pregnancy test is commonly needed in the evaluation of patients with acute pelvic pain. Focused pelvic ultrasound or computed tomography (CT) scan is often required, depending on the clinician's level of suspicion for reproductive tract versus intestinal tract pathology. Patients with severe pain or tenderness, or peritoneal signs should undergo expedited imaging: bedside ultrasound, if available, should be performed emergently to evaluate for pelvic or intra-abdominal free fluid.

Symptoms

The location of pain and pattern of radiation often are helpful in focusing the differential diagnosis toward a specific cause or group of causes. Lateral pelvic pain is often related to a process in the tube or ovary. However, with right-sided pain, appendicitis is considered, and in left-sided pain (especially in patients >40 years), the differential diagnosis includes diverticulitis and colitis. Urolithiasis may also manifest as lateral pelvic pain, especially when the stone is at the ureterovesicular junction, or as pain radiating to the labia or vaginal area. Central pelvic pain usually is caused by processes involving the uterus, bladder, or both adnexae. Pain radiating to the rectum may be secondary to pooling of fluid or blood in the cul-de-sac, or a rectosigmoid process. Diffuse pain may occur with a central or bilateral process such as PID or with diffuse peritonitis from infection or intra-abdominal hemorrhage.

Information regarding the onset and duration of pain may be useful. Patients with uncomplicated appendicitis (without perforation or abscess) typically are seen within 48 hours of symptom onset. Sudden-onset pain suggests acute intrapelvic hemorrhage, cystic rupture, ovarian torsion, or ureterolithiasis. Ovarian cyst pain may also fluctuate through several menstrual cycles before rupture. Gradual-onset pain is more consistent with inflammation such as in PID or appendicitis. Chronic or recurrent pain is consistent with endometriosis, recurrent ovarian cysts, or persistent ovarian mass. The quality of pain may differentiate the crampy, intermittent pattern of muscular contractions along a hollow viscus (arising from uterine, ureteral, or bowel pathology) from the steady progressive pain associated with inflammatory or neoplastic causes.

Fever and chills are more common with an infectious process. Nausea and vomiting occur more frequently when the process originates within the gastrointestinal tract but may accompany any pain of visceral origin such as ovarian torsion and ureteral colic, any severe pain, and normal pregnancy. Dysuria occurs in many local vulvar and vaginal processes such as herpesvirus infection, candidiasis, and other types of vulvovaginitis, but urinary urgency typically signals an irritated bladder or urethra and should focus attention on the urinary tract.

Information about the patient's last menstrual period, pattern of menses, and sexual activity pattern may be useful but does not necessarily exclude pregnancy. In a pregnant patient, the obstetric history may provide some helpful diagnostic clues. Recurrent spontaneous abortion or previous ectopic pregnancy increases the likelihood of these conditions, respectively. Patients who are actively undergoing infertility treatment are at increased risk for ectopic pregnancy, heterotopic pregnancy, ovarian torsion, and ovarian hyperstimulation syndrome. Round ligament pain is usually noted in the second trimester. Postpartum patients are at increased risk for endometritis.

The presence, quantity, and duration of associated vaginal bleeding should be ascertained (see Chapter 30). In a nonpregnant patient, bleeding may be associated with abnormal uterine bleeding (e.g., from PID, ovulatory dysfunction, cancer) or trauma (e.g., vaginal laceration due to pelvic fracture, direct vaginal irritation or trauma). In a pregnant patient, bleeding may also be associated with a subchorionic hemorrhage in an otherwise viable pregnancy, ectopic pregnancy, nonviable intrauterine pregnancy (IUP) (which may continue to cause bleeding after expulsion of the uterine contents, especially if any products of conception are retained), or later in pregnancy with placenta previa or abruption. In some cases, the amount of bleeding may be substantial enough to necessitate blood transfusion and surgical intervention. The presence of vaginal discharge (color, consistency, odor) should also be ascertained.

Sexual history is important, with emphasis on recent sexual contact and previous history of sexually transmitted disease. A history of any recent gynecologic procedures should be obtained because the onset of pelvic pain shortly after uterine instrumentation increases the possibility of uterine perforation or infection. Similarly, the presence of an IUD should be ascertained because of the risks of infection and perforation, as well as the increased prevalence of ectopic pregnancy among pregnant women with IUDs. All women should be interviewed in private to permit disclosure of sensitive information such as sexual history, pregnancy, recent abortion, and abuse.

Signs

The physical examination is directed toward the abdomen and pelvis. Pelvic examination is performed in almost all patients; exceptions will

TABLE 29.1 Differentiation of Common or Potentially Catastrophic Causes of Pelvic Pain

Causative Disorder or Condition	Pain History	Associated Symptoms	Supporting History	Prevalence in ED	Physical Examination	Useful Tests	Atypical or Additional Aspects
Ectopic pregnancy (critical if ruptured; otherwise emergent)	Classically severe, sharp, lateral pelvic pain, but severity, location, and quality highly variable	Vaginal bleeding (often mild, can be absent)	Missed period; history of previous ectopic pregnancy, infertility, pelvic surgery, PID, or IUD use	Common	Classically unilateral adnexal tenderness, adnexal mass, CMT	Pelvic US, quantitative β-hCG, T&C, laparoscopy	Cannot reliably exclude diagnosis based on history and physical examination; severe pain, hypotension, or peritonitis suggests rupture.
Ruptured ovarian cyst (emergent—critical with significant hemorrhage; otherwise, urgent)	Abrupt moderate to severe lateral pain	Light-headedness if bleeding is severe; rectal pain arises from fluid in cul-de-sac.		Rupture—common; significant hemorrhage—uncommon	Hypotension and tachycardia if blood loss is significant; possible peritonitis	Pelvic US, CBC, T&C	Physical examination findings often do not correlate with volume of blood in pelvis at US.
Ovarian torsion (emergent)	Acute onset of moderate to severe lateral pain	Nausea and vomiting	History of ovarian mass or cyst	Uncommon	Adnexal mass and tenderness, possible peritonitis	US with Doppler flow studies, laparoscopy	Torsion can be intermittent.
Appendicitis (emergent)	Duration often <48 h, generalized followed by localized RLQ pain	Low-grade fever, nausea, anorexia	Migration of pain to RLQ from center, abdominal pain before vomiting	Common	RLQ tenderness, possible peritonitis	US, CT, or MRI	Early in course, tenderness may be minimal or poorly localized.
PID, TOA (TOA: emergent; PID: urgent-emergent)	Without TOA, pain usually bilateral; may manifest acutely within 48 h, but PID may also be chronic.	Fever, vaginal discharge	Vaginal discharge, history of PID, history of unprotected intercourse or multiple partners	PID—common; TOA—uncommon	Pus from cervical os, CMT, adnexal tenderness; peritonitis suggests TOA or severe PID	CBC, ESR, CRP, pelvic US, laparoscopy, cervical cultures, cervical smear for WBCs	History and physical examination may be inaccurate for diagnosis, particularly in patients with subacute presentations.
UTI (urgent)	Pain with urination; patient may have flank pain from associated pyelonephritis.	Urinary urgency and frequency; fever and vomiting if patient has associated pyelonephritis	Prior history of UTI, recent urologic procedure	Common	Suprapubic tenderness; flank tenderness and fever with pyelonephritis	Urinalysis, urine culture (if recurrent or complicated)	WBCs can be present in urine with PID and appendicitis; RBCs present in urine with hemorrhagic cystitis.
Ureteral colic (urgent)	Acute onset, manifests within hours; pain is lateral, usually moderate to severe. Often radiates into the groin or costovertebral angle or flank	Nausea and vomiting	Prior history of stones	Common	Patient often appears uncomfortable, but physical examination can be otherwise unremarkable	Urinalysis—hematuria present in ≈80% of cases; renal ultrasound for hydronephrosis; abdominal CT	If stone is at ureterovesicular junction, patient may have localized pain that can mimic appendicitis or other acute pelvic pathology.
Unruptured ovarian cyst or tumor	Lateral ache, gradual onset	Often minimal	Prior history of similar pain	Common	Lateral pelvic tenderness, with or without a mass	Pelvic US	
Endometriosis	Unilateral or bilateral pelvic pain, often recurrent	Dysmenorrhea, dyspareunia.	Prior history of same type of pain in association with menstrual cycle	Common	Unilateral or bilateral adnexal tenderness, occasionally pelvic mass present, peritoneal findings uncommon	Pelvic US, laparoscopy	Symptoms can mimic other types of pelvic pathology; laparoscopy often is needed for confirmation.

CBC, Complete blood count; *CMT*, cervical motion tenderness; *CRP*, C-reactive protein; *CT*, computed tomography; *ED*, emergency department; *ESR*, erythrocyte sedimentation rate; *β-hCG*, β-human chorionic gonadotropin; *IUD*, intrauterine device; *MRI*, magnetic resonance imaging; *PID*, pelvic inflammatory disease; *RBC*, red blood cell; *RLQ*, right lower quadrant; *T&C*, type and crossmatch; *TOA*, tubo-ovarian abscess; *US*, ultrasonography; *UTI*, urinary tract infection; *WBC*, white blood cell.

be noted later in the discussion of the diagnostic algorithm. Pregnant patients beyond 20 weeks' gestation with complaints of vaginal bleeding should undergo transabdominal pelvic ultrasound for placental localization before the pelvic examination (see Chapter 173), should have a fetal heart rate measured and documented, and may need timely obstetric consultation.

Abnormal vaginal discharge may be seen in a variety of conditions, including vaginitis, cervicitis, endometritis, PID, and retained foreign body. Cervical motion tenderness usually indicates reproductive tract inflammation but can also occur with irritation of adjacent structures (e.g., cystitis, appendicitis). An open os is most consistent with an incomplete or inevitable abortion but does not definitively exclude an ectopic pregnancy. A large uterus in a nonpregnant patient may indicate fibroids. Fundal tenderness is often difficult to distinguish from cystitis but may suggest PID, endometritis, or necrotic fibroids. Unilateral adnexal masses and tenderness are suggestive of an ovarian cyst, ectopic pregnancy, tubo-ovarian abscess, or ovarian torsion.

The constellation of cervical motion tenderness, uterine tenderness, and adnexal tenderness is classically associated with PID, although only one sign is required to initiate treatment in certain clinical settings per the most recent Centers for Disease Control and Prevention (CDC) guidelines (2015).[5]

Ancillary Testing

Laboratory Tests

A pregnancy test is required in almost all patients of childbearing age with a complaint of abdominal or pelvic pain, irrespective of sexual history or reported contraception use, because pregnancy changes both the differential diagnosis and the management of many non–pregnancy-related conditions. Very few exceptions to the need for pregnancy testing exist, such as documented bilateral salpingo-oophorectomy or a woman who is known to be pregnant. A positive test result may indicate current or recent intrauterine or extrauterine pregnancy or, rarely, molar pregnancy or cancer.

Urinalysis of a clean-catch specimen may identify nitrites and pyuria from a urinary tract infection, or hematuria, consistent with urolithiasis or hemorrhagic cystitis. The absence of hematuria does not exclude the possibility of a ureteral stone, although it lowers the likelihood, and mild pyuria may be seen in extravesicular conditions such as appendicitis. Urinalysis should be performed in all pregnant patients with pelvic pain, even if their symptoms do not include urinary tract complaints, because urinary tract infection, including asymptomatic bacteriuria, is associated with morbidity for both mother and fetus.

Patients who may be hemorrhaging internally or externally should have their hemoglobin level checked, and type and crossmatching should be performed if the hemorrhage is substantial. Pregnant patients with concern for fetomaternal transfusion (e.g., vaginal bleeding) also require blood typing to identify Rh-negative patients who will require Rho(D) immune globulin.

Imaging

Bedside ultrasound is a core part of the evaluation of most women with pelvic pain and, along with the history and physical examination, should be considered as an integral part of the initial examination.[6] Patients with a positive pregnancy test result should undergo focused bedside ultrasound or formal (consultative) ultrasound examination to evaluate for ectopic pregnancy. Identification of a definite IUP by ultrasound imaging excludes ectopic pregnancy with a high degree of certainty in patients who are not undergoing assisted reproduction. Conversely, a patient with a positive pregnancy test in whom a definite IUP cannot be seen is presumed to have an ectopic pregnancy until further evaluation is completed. In addition, the presence of a gestational sac alone is not sufficient to confirm an IUP; experienced sonographers may use the double decidual sac sign, but it is recommended that less experienced sonographers visualize a yolk sac or embryo for definitive ultrasonographic confirmation of an IUP. A complex adnexal mass, tubal ring, extrauterine yolk sac or embryo, or free fluid is indicative of a probable ectopic pregnancy. The presence of free intraabdominal fluid on ultrasound with a negative urine pregnancy test is consistent with hemorrhage or a ruptured ovarian cyst. Regardless of cause, intra-abdominal free fluid is presumed to be blood and should be addressed expediently.

When the diagnosis of acute appendicitis is being considered, a CT scan (for nonpregnant patients) or magnetic resonance imaging (MRI) test (for pregnant patients) should be obtained.

DIAGNOSTIC ALGORITHM

The algorithm in Fig. 29.1 is designed to focus further testing and progress to a rational provisional diagnosis. However, it is not unusual to pursue evaluation of gynecologic and intra-abdominal causes of pain in parallel, when the initial history and physical examination do not provide clear direction. It is also possible for common diseases to manifest in uncommon ways, for more than one disease to be present, or for a positive finding not to explain the entirety of the patient's presentation. For example, patients with an abnormal urinalysis may have appendicitis, pregnant patients may also have ovarian torsion or appendicitis, and simple ovarian cysts seen on imaging may be asymptomatic. Tests are therefore interpreted in the context of the individual patient's presentation. With certain diseases such as endometriosis, definitive testing is not available in the ED and the patient's history may be the most important discriminator.

After an initial history and physical examination, the pregnancy test determines the subsequent priorities. Remember, however, that pregnant patients may also suffer from non–pregnancy-related conditions; for example, if a threatened abortion is most likely (i.e., there is an IUP on ultrasound imaging), unilateral pain may prompt further evaluation for torsion. An empty uterus on ultrasound imaging, or any ultrasound study that cannot confirm a definite IUP, could be consistent with an ectopic pregnancy, spontaneous abortion, or very early normal pregnancy. Patients past 20 weeks' gestation will likely require observation with fetal monitoring.

Nonpregnant patients with pain that seems to be gynecologic in nature should be assessed for hemorrhage from a ruptured or hemorrhagic ovarian cyst, for ovarian torsion, and for infection, including cervicitis, endometritis, PID, salpingitis, and tubo-ovarian abscess. Although the history and physical examination often are sufficient to diagnose infection, ultrasound assessment is helpful if torsion, tubo-ovarian abscess, or ruptured hemorrhagic cyst is suspected. Ultrasound findings also may support a diagnosis of PID if evidence of salpingitis is noted or a diagnosis of a simple ruptured cyst if a characteristic ovarian appearance is combined with the presence of a small amount of free fluid. Although not as reliable as CT, ultrasound may be able to identify appendicitis.

It is difficult to differentiate some gynecologic origins of pain from intra-abdominal causes (e.g., right ovarian pathology from appendicitis), so ancillary testing may require an ultrasound study, CT, or both. If the cause is most likely gynecologic, an ultrasound examination of the pelvis, and subsequently (if feasible) the appendix, is reasonable. These studies may be followed by CT if the ultrasound findings are unremarkable and the presentation remains consistent with appendicitis or other concerning diagnoses. Conversely, pelvic ultrasound performed after a normal CT is unlikely to yield additional useful information.[7] (Ovarian torsion may be radiographically occult, and if suspected, gynecologic consultation should be considered because a laparoscopy

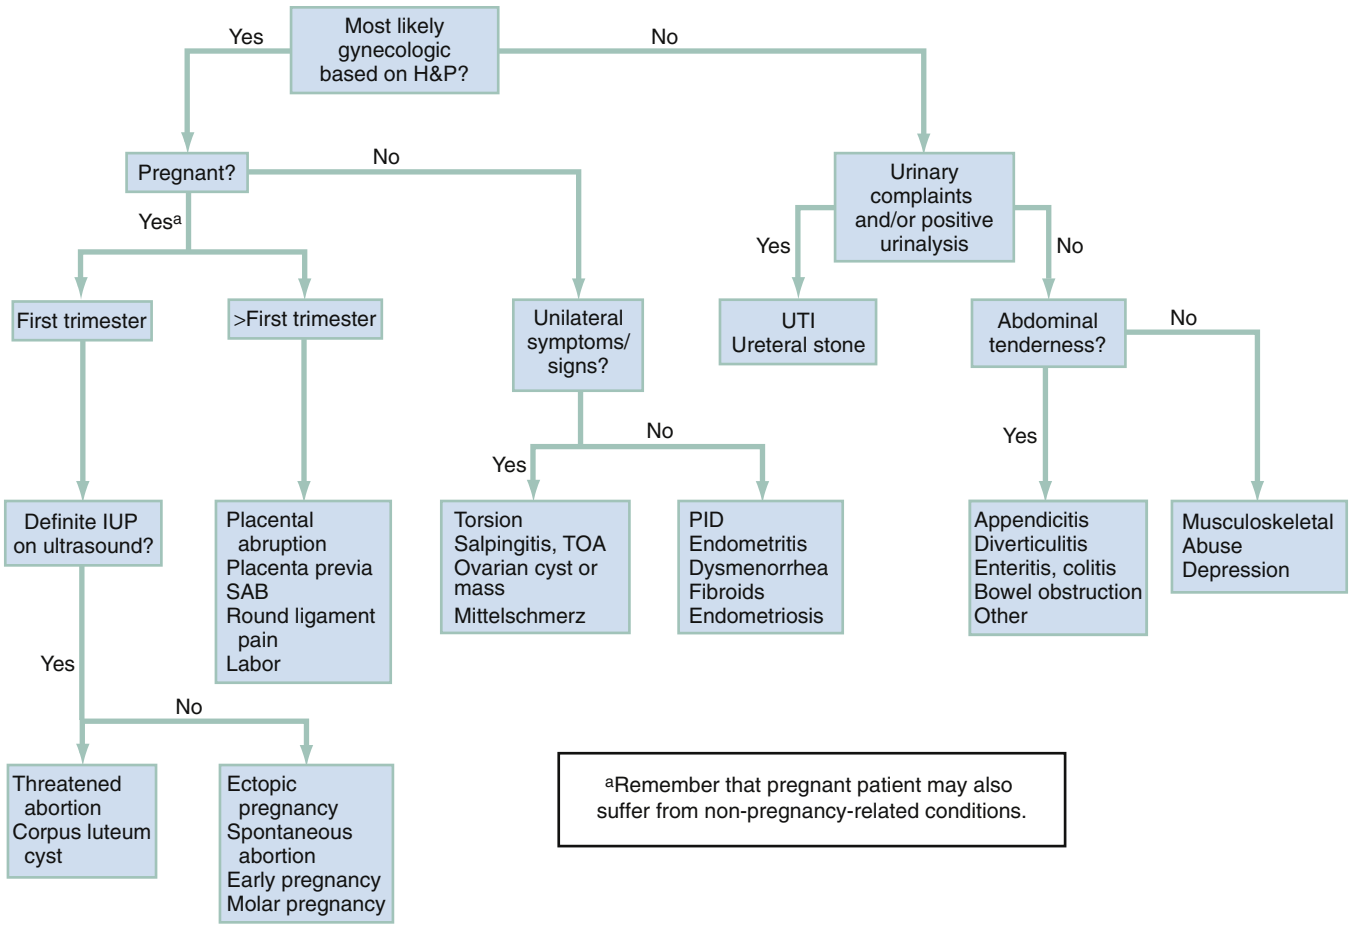

Fig. 29.1 Diagnostic algorithm for acute pelvic pain; see text for details. *H&P,* History and physical; *IUP,* intrauterine pregnancy; *PID,* pelvic inflammatory disease; *SAB,* spontaneous abortion; *TOA,* tubo-ovarian abscess; *UTI,* urinary tract infection.

may need to be performed to obtain a definitive diagnosis.) When ultrasound is nondiagnostic in a pregnant patient suspected of having appendicitis, we recommend MRI, which avoids the risk of disease progression during a prolonged observation period and obviates the need for ionizing radiation from CT. Patients whose pain does not seem to be from the reproductive tract often have urinary infections or stones, intra-abdominal sources of pain, musculoskeletal pathology, or may be victims of abuse or have depression. Vascular or neuropathic causes of pain are possible but less common.

If the available data do not make sense or conflict with clinical gestalt, the following three steps should be considered:

1. Ensure that emergent, life-threatening diagnoses have been addressed (e.g., ectopic pregnancy).
2. Reassess whether the presentation may be atypical (e.g., reconsider appendicitis).
3. If emergent causes are unlikely and sufficient consideration was given to less likely disorders without uncovering a cause, address the possibility of depression or abuse. Follow-up planning for all patients is recommended.

EMPIRICAL MANAGEMENT

An algorithm for the management of patients with acute pelvic pain is presented in Fig. 29.2. Patients in extremis are most likely hemorrhaging, although on occasion septic shock may be the cause. Ectopic pregnancy, placental abruption, and hemorrhagic ovarian cyst may cause life-threatening hemorrhage, with no or minimal vaginal bleeding. Patients with these disorders need rapid treatment with fluid and blood products and may require surgical intervention before stabilization can be achieved. A bedside ultrasound generally will help the clinician reach these presumptive diagnoses expediently. Septic shock may be a consequence of abdominal or pelvic processes and may require general surgical and gynecologic consultations, as well as admission to an intensive care setting.

We recommend early administration of analgesia for patients with significant pain, a practice that greatly improves patient comfort and the reliability of the physical examination, which is otherwise hampered by the patient's extreme pain, tenderness, or both. For severe pain, intravenous opioids such as morphine or hydromorphone are rapid and effective, titratable, and generally considered safe in pregnancy. After critical and emergent diagnoses have been excluded, well-appearing patients for whom a definitive or reasonable provisional diagnosis is reached may be discharged with close follow-up and appropriate treatment and precautions. Pregnant patients at a stage of fetal viability (20 weeks' gestation or as per institutional guidelines) should be referred to the obstetric service for fetal monitoring before discharge. Pregnant patients at a stage of fetal viability who have suffered abdominal trauma should undergo fetal monitoring before discharge.

CHAPTER 29: QUESTIONS AND ANSWERS

1. Which of the following statements regarding the evaluation of patients with pelvic pain is true?

a. Ancillary testing can be limited to a urine pregnancy test in most patients.
b. Bimanual examinations have been shown to result in highly reliable findings, with substantial interobserver agreement.
c. Patients typically localize visceral pain with a high degree of accuracy.
d. Thorough history taking is adequate to exclude most life-threatening conditions.
e. None of the above.

Answer: e. It is rare that any particular finding on history or physical examination is reliable enough to make or exclude a particular diagnosis conclusively in patients presenting with pelvic pain, so ancillary testing (beyond a simple pregnancy test) is commonly required in the evaluation of these patients. Ultrasound is the most useful adjunct for most patients. The bimanual examination may, at times, provide important information. Unfortunately, however, findings on pelvic examination are somewhat subjective and unreliable and may serve more to localize the process to one side or the other rather than diagnose it or even limit it to the reproductive organs. Although pelvic pain often originates from the reproductive organs, it may arise from any structures that lie adjacent to or course through the pelvis. Visceral pain afferents supplying the pelvic organs have common innervation with the appendix, ureters, and colon. Their significant overlap makes accurate localization difficult for both patient and emergency clinician.

2. A 26-year-old female presents with right lower quadrant (RLQ) abdominal pain. She states her last menstrual period was 8 weeks ago. Bimanual pelvic examination reveals tenderness in the RLQ and right adnexal area. The patient's vital signs include a regular pulse of 120 beats/min and a blood pressure of 110/65 mm Hg. Urinalysis is unremarkable, and the urine pregnancy test is positive. What is the most appropriate next test?

a. Pelvic ultrasonography
b. Cervical cultures
c. Complete blood count (CBC)
d. Computed tomography (CT)
e. Magnetic resonance imaging (MRI)

Answer: a. This follows the algorithms in Figs. 29.1 and 29.2. The most life-threatening pathology requiring urgent or emergent intervention is hemorrhage from a ruptured ectopic pregnancy. Pelvic ultrasound scan is rapid and is the first step in an evaluation of a suspected ruptured ectopic pregnancy. In this case, bedside ultrasonography, if available, is strongly recommended.

3. A 30-year-old female presents with lower abdominal pain. She is not ill appearing and has lower abdominal, uterine, bilateral adnexal, and cervical motion tenderness on pelvic examination. She has a negative urine pregnancy test and urinalysis. What is the most appropriate next step in the patient's management?

a. Await cervical culture results.
b. Obtain a complete blood count.
c. Obtain a CT scan.
d. Obtain an erythrocyte sedimentation rate (ESR).
e. Treat with antibiotics.

Answer: e. The constellation of uterine tenderness, bilateral adnexal tenderness, and cervical motion tenderness is classically associated with pelvic inflammatory disease (PID), particularly when the pain onset is during or just after menstruation. However, the diagnosis may be made without the presence of all three signs, and treatment may be initiated with only one sign in an at-risk patient, as given in the 2015 Centers for Disease Control and Prevention (CDC) guidelines. Ultrasound is not strictly necessary in this case but should be performed if there is any concern for a complication, such as tubo-ovarian abscess.

4. A 35-year-old female using assisted reproductive technology presents with severe lower left quadrant (LLQ) abdominal pain and tenderness isolated to the left adnexal area on pelvic examination. The urine pregnancy test is positive, and the urinalysis is unremarkable. Rapid bedside ultrasonography reveals an intrauterine pregnancy with a gestational age of 6 weeks, 5 days, and moderate free pelvic fluid. Which diagnosis should be expediently further investigated?

a. Heterotopic pregnancy
b. Round ligament pain
c. Simple ovarian cyst
d. Tubo-ovarian abscess
e. None of the above

Answer: a. Women who are actively undergoing infertility treatment are at increased risk for ectopic pregnancy, heterotopic pregnancy, ovarian torsion, and ovarian hyperstimulation syndrome.

5. A 28-year-old female presents with sudden-onset, severe left adnexal pain that started 1 hour ago. The patient has left adnexal tenderness to palpation, but there is no vaginal discharge or bleeding, and no cervical motion tenderness. Urinalysis and urine pregnancy are negative. Pelvic ultrasound is unremarkable, and you do not suspect intra-abdominal pathology. The patient has required multiple doses of opiates for pain control in the emergency department (ED). What is the most appropriate next step in management?

a. Admit the patient for serial abdominal examinations.
b. Consult gynecology.
c. Discharge the patient with pain control and clinic follow-up.
d. Discharge the patient with treatment for PID and clinic follow-up.
e. Obtain a CT scan of the pelvis.

Answer b. Ovarian torsion should be suspected based on this patient's history and examination. Because torsion can be a radiographically occult diagnosis, gynecology should be consulted as laparoscopy may be needed for definitive diagnosis. Less emergent conditions, such as nephrolithiasis, could also be considered.

6. A 26-year-old female who is pregnant at 30-weeks' gestation presents with vaginal bleeding and pelvic cramping. She states the cramping and bleeding started 2 hours ago and she has filled one pad so far. She has not had any prenatal care. Which of the following should be initially avoided during this patient's evaluation?

a. Obstetrics consultation
b. Intravenous (IV) fluids
c. Pelvic examination
d. Type and Screen
e. Ultrasound

Answer c. Pregnant patients beyond 20-weeks' gestation with complaints of vaginal bleeding should undergo transabdominal pelvic ultrasound for placental localization before the pelvic examination. The concern is that placenta previa, which can be worsened by pelvic examination, may be the cause of the bleeding. Obstetrics will need to be involved in this patient's care, as two important potential diagnoses are placenta previa and placental abruption. In any case, the patient will need obstetric observation and fetal monitoring. A type and screen should be performed as Rho(D) immune globulin is indicated if the patient is Rh negative.

7. A 34-year-old female presents with severe abdominal pain. She does not allow for an abdominal examination and keeps pushing your hand away any time you attempt to even mildly palpate her abdomen. Her vital signs are stable. What is the most important and appropriate next step in this patient's care?

a. IV fluids
b. IV opiates
c. Oral (PO) opiates
d. PO acetaminophen
e. Do not give any medications at this time

Answer b. We recommend early administration of analgesia for patients with significant pain. Analgesia greatly improves patient comfort and the reliability of the physical examination, which is otherwise hampered by the patient's extreme pain, tenderness, or both. For severe pain, intravenous opioids such as morphine or hydromorphone are rapid and effective, titratable, and generally considered safe in pregnancy. In a patient who may require surgery, it is recommended to keep the patient nil per os (NPO).

Vaginal Bleeding

Joelle Borhart

KEY CONCEPTS

- Pregnancy status is the single most important determination to make in evaluating a patient with vaginal bleeding.
- The use of the term *dysfunctional uterine bleeding* is no longer recommended, and the term *abnormal uterine bleeding* is preferred.
- The etiologies of abnormal uterine bleeding can be divided into structural and nonstructural causes using the PALM-COEIN classification. Structural causes include ***p***olyps, ***a***denomyosis, ***l***eiomyomas, and ***m***alignancy (**PALM**). Nonstructural causes include ***c***oagulopathy, ***o***vulatory dysfunction, ***e***ndometrial, ***i***atrogenic, and ***n***ot yet classified causes (**COEIN**).
- For nonpregnant patients, the numerous causes of abnormal uterine bleeding are best categorized by patient age. The possibility of cancer should always be considered in postmenopausal women.
- Hormonal and nonhormonal treatments can be initiated in the emergency department to temporize an acute bleeding episode in a nonpregnant patient until they can follow up with their gynecologist.
- Vaginal bleeding is common in early pregnancy. Most patients will be diagnosed with threatened miscarriage, but ectopic pregnancy should always be considered at any level of serum β-hCG.
- Vaginal bleeding after the 20th week of pregnancy is less common and is often associated with significant morbidity and mortality for the mother and fetus. These patients should be managed in close consultation with an obstetrician.

FOUNDATIONS

Background and Importance

Abnormal uterine bleeding (AUB) occurs in women of all ages and can significantly impair quality of life. Abnormal vaginal bleeding in nonpregnant patients is rarely life threatening but may herald serious underlying pathology, such as cancer. Bleeding as a complication of pregnancy poses significant risk of morbidity and mortality to the fetus and mother.

Pathophysiology

Nonpregnant Patients

The mean time between menstrual periods is 28 days (±7 days), with menstruation generally lasting for 5 days. It is considered abnormal to bleed for more than 7 days. The average blood loss per menstruation is 35 mL; a loss of more than 80 mL is abnormal.

Since 2011, the American College of Obstetricians and Gynecologists (ACOG) has recommended the PALM-COEIN classification system, which uses the all-inclusive term *abnormal uterine bleeding* (AUB) and divides the causes of AUB into structural and nonstructural causes. Structural causes include ***p***olyps, ***a***denomyosis, ***l***eiomyomas, and ***m***alignancy (**PALM**). Nonstructural causes include ***c***oagulopathy, ***o***vulatory dysfunction, ***e***ndometrial, ***i***atrogenic, and ***n***ot yet classified causes (**COEIN**).[1] The use of the term *dysfunctional uterine bleeding* is no longer recommended.

Approximately 50% of cases of excessive menstruation fall under the nonstructural PALM-COEIN category of ovulatory dysfunction, which includes anovulatory bleeding. If a woman does not ovulate, there is no corpus luteum to produce progesterone, which results in estrogen being unopposed. Unopposed estrogen causes the endometrium to proliferate to the point at which it becomes unstable and begins to break down, causing irregular and unpredictable bleeding to occur. Cyclical heavy bleeding can also occur in the setting of regular ovulation (ovulatory bleeding).

Leiomyomas (fibroids) are benign tumors of the uterus that can be associated with significant morbidity including excessive menstrual bleeding.[2] Submucosal fibroids (fibroid that project into the uterine cavity) are especially prone to unpredictable and heavy uterine bleeding because they result in increased endometrial surface area that prevents uterine contractions from adequately compressing the vessels on the surface of the endometrium.[3] Fibroids are common and occur almost exclusively among reproductive-age women. The incidence increases with age and is highest for women ages 45 to 49 years. Black women are disproportionally affected (rates twofold to threefold higher).[4] Cervical polyps, which commonly occur in multiparous women in their 40s and 50s, are friable and prone to bleeding.

Pregnant Patients

Pregnant women may experience bleeding throughout their pregnancy. In early pregnancy, ectopic pregnancy causes hemorrhage into the fallopian tube by disrupting of the blood supply to the ectopic gestational sac. In addition, the size of the growing gestational sac can rupture through the tubal wall.

After the 20th week of pregnancy, vaginal bleeding can be caused by placenta previa, in which the placenta completely or partially covers the internal cervical os. As the lower part of the uterus becomes thinner during the third trimester in preparation for labor, bleeding can occur. Placental abruption causes bleeding when the placenta tears away from the uterine wall. This can occur spontaneously or secondary to abdominal trauma, with transmission of forces to the uterus. It is important to note that a large amount of concealed blood can be retained between the detached placenta and uterus, and the extent of the hemorrhage may not be fully appreciated until delivery. The most significant risk factor for abruption is a history of abruption in prior pregnancies (10-fold increased risk). An increased incidence is also seen in pregnancies complicated by hypertensive disorders, including preeclampsia, eclampsia, the HELLP (***h***emolysis, ***e***levated ***l***iver enzymes, and ***l***ow ***p***latelets) syndrome, and abnormal implantation of the placenta (e.g., placenta previa, accreta, increta, percreta). Smoking and cocaine use also increase the risk for abruption.

In the immediate postpartum period (first 24 hours), bleeding is usually the result of uterine atony if the uterus fails to contract. Atony is

more likely to occur with conditions that overdistend the uterus, such as a large-for-gestational-age fetus, polyhydramnios, and multiparity. Prior history of postpartum hemorrhage, prolonged labor, induced labor, augmentation of labor with oxytocin, and instrumentation delivery also increase the risk of postpartum hemorrhage.[5] After 24 hours postpartum, retained products of conception (POCs) are the most common cause of bleeding.

DIAGNOSTIC APPROACH

Differential Considerations

Nonpregnant Patients

In nonpregnant women, there are numerous causes of AUB (Box 30.1), and it is helpful to categorize the differential diagnosis by the age of the patient. In *prepubescent girls*, causes of vaginal bleeding include vaginitis, foreign bodies, sexual abuse, tumors, and trauma. In *adolescent girls*, a common cause of abnormal vaginal bleeding is persistent anovulation due to immaturity of the hypothalamic-pituitary-ovarian axis.[6] Underlying bleeding disorders and coagulopathies, such as von Willebrand disease, may also first present in adolescence.[7] Sexually transmitted infections may also cause abnormal bleeding in this age group. For *women in their reproductive years*, structural lesions such as polyps and fibroids frequently cause abnormal bleeding. Black women are more likely to have fibroids, and they experience disproportionally more morbidity from heavy bleeding.[4] Endocrine causes, such as polycystic ovarian syndrome, should be considered in women with signs of androgen excess—obesity, acne, hirsutism. In *perimenopausal women*, anovulatory cycles become common as ovarian function declines. Endometrial atrophy is the most common cause of abnormal bleeding in *postmenopausal women*; however, the possibility of cancer should always be considered in this age group.

Regardless of age, review a patient's medication list for drugs that are known to cause abnormal bleeding (e.g., antiplatelet agents, anticoagulants), antiepileptic agents (especially valproic acid), and typical and atypical antipsychotics and steroids can cause AUB.

Pregnant Patients

For pregnant women with vaginal bleeding, the differential diagnosis is refined based on whether the bleeding occurs in early or late pregnancy or postpartum. For patients with vaginal bleeding in early pregnancy (before the 20th week of gestation and prior to fetal viability), common causes include miscarriage, ectopic pregnancy, implantation bleeding, molar pregnancy, and ruptured corpus luteum cyst. Bleeding in early pregnancy is common, affecting up to 20% of pregnancies. Miscarriage, defined as the spontaneous termination of pregnancy before the 20th week of gestation is also common; approximately 50% of women with early bleeding will miscarry. Miscarriages are described as threatened, missed, inevitable, incomplete, or complete depending on the status of the internal cervical os and if any POCs have been passed. The most concerning diagnosis in patients with bleeding in early pregnancy is ectopic pregnancy, a pregnancy implanted outside the uterus. Ectopic pregnancy is a leading cause of first-trimester maternal death, and the prevalence among emergency department (ED) patients presenting with pain or bleeding or both in the first trimester of pregnancy has been reported to be as high at 18%. Risk factors for ectopic pregnancy include pelvic inflammatory disease, previous ectopic pregnancy, prior tubal surgery, use of an intrauterine device, and endometriosis. However, half of women diagnosed with an ectopic pregnancy do not have any identifiable risk factors.

An important subgroup of patients are women undergoing assisted reproduction or in vitro fertilization (IVF). These patients are at increased risk for heterotopic pregnancy, which is a simultaneous intrauterine pregnancy (IUP) and ectopic pregnancy. Heterotopic pregnancies are rare in the general population.

Vaginal bleeding after the 20th week of pregnancy is less common, occurring in approximately 4% of pregnancies. Bleeding complications in late pregnancy generally occur in the third trimester and include placenta previa, placental abruption, and uterine rupture.

Pivotal Findings

Symptoms

Begin by eliciting the timing and duration of bleeding. Volume of blood loss is difficult to quantify because historical features, such as the frequency of changing a sanitary pad or tampon, have not been shown

to reliably predict blood loss; however, soaking more than one pad or tampon every 1 to 2 hours is suggestive of heavy bleeding.[6] Normal menstrual blood does not clot; therefore the presence of clots indicates heavy bleeding. A report of dizziness, syncope, or weakness could also indicate significant blood loss. Associated symptoms such as abdominal pain, fever, vaginal discharge or odor, and postcoital bleeding may indicate a possible sexually transmitted infection or pelvic inflammatory disease. Postcoital bleeding can also indicate a cervical lesion and occurs more commonly in pregnancy due to increased cervical blood flow.

A history of trauma should be noted. Vaginal injuries can be sustained in a number of ways and range in severity from minor contusions to deep lacerations. The most common mechanism of genital injury in adult women is coitus. In pregnancy, blunt trauma, such as falls, motor vehicle accidents, and interpersonal violence, is associated with a significantly increased risk of maternal and fetal morbidity and mortality.

Signs

For any patient presenting with vaginal bleeding, begin by determining the patient's hemodynamic status and performing a complete abdominal and pelvic examination. The pelvic examination may reveal the source of bleeding because masses, polyps, ulcers, foreign bodies, and evidence of trauma or inflammation may be visualized. After the 20th week of pregnancy, a pelvic examination should be deferred until after an ultrasound has been performed to exclude placenta previa as the cause of bleeding. In pregnant patients of sufficient gestational age, the fetal heart rate and fundal height should also be assessed. Fetal heart rate can be measured using the M mode on bedside ultrasound as opposed to Doppler because this is thought to transmit less acoustic energy to the fetus. Fetal cardiac activity may be measured as early as 6 weeks. Uterine size can be estimated by palpating the fundus. The uterus is palpable at the level of the umbilicus at 20 weeks. The fetal age is more than 24 weeks (i.e., viable) if the uterus can be felt at least four fingerbreadths above the umbilicus. This method may be less reliable in multiple pregnancies or other conditions that might affect the distention of the uterus or abdomen, such as large fibroids, polyhydramnios, oligohydramnios, intrauterine growth restriction, and obesity. Bedside ultrasound can also be used to estimate fetal age.

Ancillary Testing

Determination of pregnancy status is essential in the evaluation of any woman of reproductive age presenting with vaginal bleeding. Other critical laboratory tests in hemodynamically unstable patients include complete blood count, type and crossmatching of blood, coagulation studies, and, if pregnant, a quantitative β-human chorionic gonadotropin (β-hCG) level and Rh status determination.

Bedside ultrasound has become increasingly used in the ED evaluation of pregnant women with vaginal bleeding to determine whether an IUP is present. A yolk sac is the first sonographic evidence of a definite IUP and can be visualized using transvaginal ultrasound (TVUS), beginning around the 5th week of pregnancy. *Pregnancy of unknown location* (PUL) is the term used to categorize pregnancy in a patient with a positive pregnancy test when neither an IUP nor an ectopic pregnancy can be visualized using ultrasound.[8] In this case, the quantitative β-hCG level has traditionally been used to determine if the level is in the discriminatory zone. The discriminatory zone is the level of β-hCG in which an IUP, if present, should be seen consistently by ultrasound. For TVUS the discriminatory zone has traditionally been accepted to be around 2000 IU/mL. However, the value of the discriminatory zone has been called into question because it is not as reliable at excluding a viable pregnancy as previously thought.[9] Multiple studies have reported that a viable IUP not visualized on ultrasound is possible if β-hCG levels are greater than the traditional discriminatory zone.[10] ACOG now advises that if the concept of the discriminatory zone is to be used to help diagnose ectopic pregnancy, the value should be as high as 3500 IU/mL to avoid the potential for misdiagnosis and possible disruption of a desired IUP.[8]

Caution should be used when interpreting a single β-hCG measurement, because a single measurement alone cannot diagnose viability or location of a pregnancy; serial hCG measurements can be trended over days to help differentiate normal from abnormal pregnancies. It is appropriate to repeat TVUS and β-hCG measurements in hemodynamically stable patients instead of initiating medical or surgical intervention for possible ectopic pregnancy based on the discriminatory zone alone. There is no β-hCG level at which an ectopic pregnancy could be completely ruled out.

Additional testing for the stable, nonpregnant ED patient, such as thyroid and other hormonal studies, is usually performed on an outpatient basis. This also includes a complete pelvic ultrasound because the results will rarely change ED management.

DIAGNOSTIC ALGORITHM

Begin the evaluation by determining whether the patient is pregnant (Fig. 30.1). If the patient is not known to be pregnant or immediately postpartum, a urine pregnancy test should be performed. Next, determine the age of the pregnancy in weeks. The most critical diagnoses to consider in patients less than 20 weeks pregnant are ectopic and heterotopic pregnancies. Bedside ultrasound is useful to establish if an IUP is present. If the ultrasound is indeterminate, a quantitative β-hCG determination can help risk-stratify the patient further. Usually, the diagnosis will be threatened miscarriage.

For patients of more than 20 weeks' gestation, the crucial diagnoses to consider are placenta previa, placental abruption, uterine rupture, and arteriovenous malformation. Ultrasound should be performed before a pelvic examination in these patients.

For nonpregnant patients, the pelvic examination may reveal a cause of bleeding, but for most women in the ED, no cause will be identified. These patients will be diagnosed with AUB and should be referred for further gynecologic testing.

EMPIRIC MANAGEMENT

Patients with hemodynamic instability unresponsive to crystalloid fluid resuscitation require blood transfusion. For women of childbearing age, use Rh-negative blood if the Rh status of the patient is unknown. In addition to hemodynamic stabilization for severe bleeding in nonpregnant women, high-dose intravenous conjugated estrogen (Premarin) is considered first line treatment and may be administered every 4 to 6 hours for up to 24 hours (suggested dose, 25 mg). If bleeding continues, the vagina may be packed with long continuous gauze, which may be used with topical tranexamic acid (TXA). Alternatively, a Foley catheter or Bakri balloon may be inserted transvaginally into the uterus to tamponade bleeding. Vaginal packing, catheters, and balloon tamponade devices may be left in place for up to 24 hours.

Treatment of stable nonpregnant patients includes nonhormonal treatments such as nonsteroidal antiinflammatory drugs (NSAIDs) and antifibrinolytic medications such as tranexamic acid (TXA). Despite their varying degree of platelet activity inhibition, NSAIDs decrease blood loss by reducing endometrial prostaglandin levels and promoting vasoconstriction in the uterus. Different types of NSAIDs

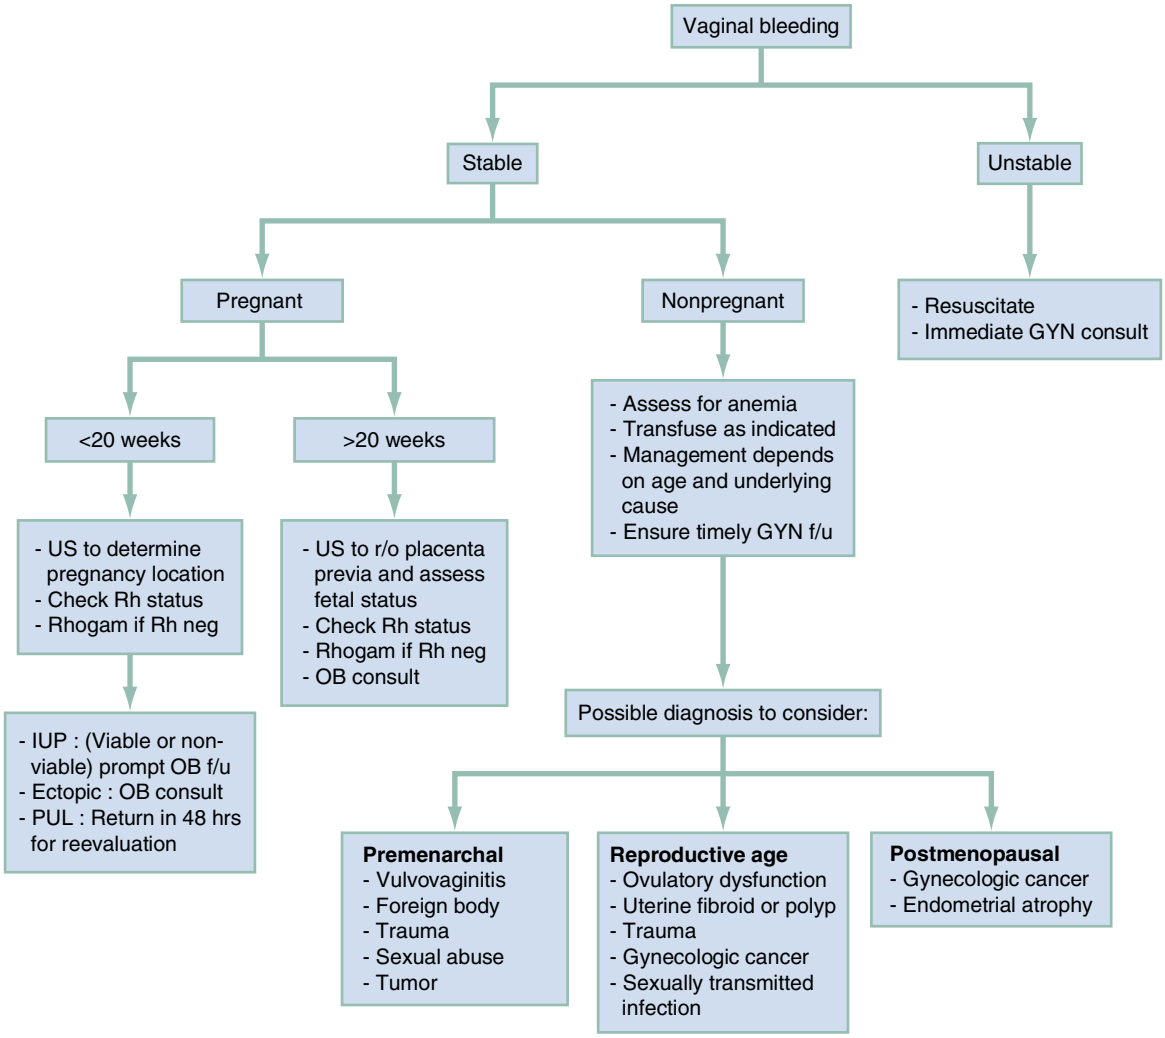

Fig. 30.1 Diagnostic Algorithm for Patient With Vaginal Bleeding. *GYN,* Gynecology; *IUP,* intrauterine pregnancy; *OB,* obstetrics; *PUL,* pregnancy of unknown location; *US,* ultrasonography.

appear to be equally effective at reducing bleeding.[11] TXA works by preventing clot degradation and has been shown to significantly decrease menstrual blood loss, especially for women with fibroids.[3,12] Hormonal treatments such as monophasic oral contraceptive pills are also frequently used to temporize a heavy bleeding episode and are typically prescribed as a taper. Hormonal treatment is likely to be most effective for women with suspected anovulatory bleeding. Any of the monophasic pills containing less than 35 µg of ethinyl estradiol can be used; a common low-dose regimen is one pill twice daily for 5 days and then one pill daily for the remainder of the pack.[13] Contraindications to the use of estrogen include a history of a thromboembolic event or stroke, pregnancy, active liver disease, severe uncontrolled hypertension, and women older than 35 years who smoke. High-dose, progestin-only treatment is a frequently used alternative therapy for women with contraindications to estrogen. A common regimen is medroxyprogesterone acetate (Provera) 10 mg, once daily, for 10 days (Table 30.1).

All unstable pregnant and postpartum patients should be managed in close consultation with an obstetrician. Patients with viable pregnancies may require emergency cesarean section. Unstable patients with confirmed or suspected ectopic pregnancies, heterotropic pregnancies, or previable IUPs may also require operative management. Stable patients with threatened, missed, incomplete, or inevitable miscarriages may be managed expectantly or medically with uterotonic medications such as misoprostol or may require dilation and evacuation or curettage. Rh status should be checked, and Rho(D) immune globulin treatment should be initiated in the ED for patients who are Rh negative. Management of the complications of pregnancy are discussed in detail in Chapter 173.

DISPOSITION

Most nonpregnant patients presenting to the ED with vaginal bleeding can be discharged home with timely gynecology follow-up. Adolescents with abnormal bleeding most likely have anovulatory cycles but should be evaluated for a possible underlying bleeding disorder. Perimenopausal and menopausal women with abnormal bleeding should have expedited follow-up for evaluation of possible malignancy. If sexual abuse is suspected in prepubertal girls, a safe environment for the patient must be ensured before considering discharge. Hospitalization

TABLE 30.1 Pharmacologic Treatment Regimens for Acute Abnormal Uterine Bleeding

Drug	Suggested Dose[a]	Contraindications and Cautions[b]
Hormonal treatments (conjugated equine estrogen)	25 mg IV every 4–6 h until bleeding stops, up to 24 h	• Contraindicated in patients with active or past thromboembolic disease, breast cancer, or liver disease • Use with caution in patients with cardiovascular or thromboembolic risk factors
Combination oral contraceptive pills	Monophasic oral contraceptive pills containing <35 μg ethinyl estradiol recommended: One pill tid PO for 7 days *or* One pill bid PO for 5 days, then one pill qd until pack is finished	• Contraindicated in women >35 years who smoke • Contraindicated in women who have a history of deep vein thrombosis or pulmonary embolism, breast cancer, liver disease, known thromboembolic disorders, pregnancy, ischemic heart disease, cerebrovascular disease, or uncontrolled hypertension
Progestin-only oral contraceptive pills (medroxyprogesterone acetate)	20 mg tid PO for 7 days	• Contraindicated in patients with active or past deep vein thrombosis or pulmonary embolism, liver disease, or breast cancer
NSAIDs		• NSAIDs contraindicated in patients with advanced renal disease • Use NSAIDs with caution in patients with history of GI ulcers or GI bleed and in patients with bleeding disorders
Ibuprofen	200–400 mg tid or qid PO for 5 days	
Mefenamic acid	500 mg tid PO for 4 or 5 days or until bleeding stops	
Naproxen	500 mg PO initially, then 250 mg tid or qid for 5 days	
Tranexamic acid	1.3 g PO every 6-8 hours up to 5 days	• Contraindicated in patients with current or past thromboembolic disease, acquired impaired color vision • Do not use with combined oral contraceptives

GI, Gastrointestinal*; IV,* intravenous; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PO,* by mouth.
[a]Other dosages and schedules also may be effective.
[b]Partial list of contraindications. The US Food and Drug Administration's labeling contains exhaustive lists of contraindications for each of these treatments. In making treatment decisions for women with abnormal uterine bleeding, emergency clinicians should consider the risks of treatment against the risk of continued bleeding on a case-by-case basis.
Adapted from Borhart J. Emergency department management of vaginal bleeding in the nonpregnant patient. *Emerg Med Pract* 2013;15:1–20.

should be considered for patients with significant or symptomatic bleeding.

Pregnant patients with ruptured ectopic or heterotopic pregnancies, placenta previa, placental abruption, or uterine rupture should be admitted to the hospital. Stable patients with threatened, inevitable, incomplete, or missed miscarriage can often be managed expectantly as outpatients, with close gynecology follow-up.

CHAPTER 30: QUESTIONS AND ANSWERS

1. To avoid the potential for misdiagnosis and possible disruption of a desired intrauterine pregnancy, American College of Obstetricians and Gynecologists (ACOG) recommends using which value of β-human chorionic gonadotropin (β-hCG) for the discriminatory zone?
   a. 1500 IU/mL
   b. 2000 IU/mL
   c. 3500 IU/mL
   d. 4500 IU/mL

Answer: c. The discriminatory zone has traditionally been accepted to be approximately 2000 IU/mL for transvaginal ultrasound (TVUS). However, viable intrauterine pregnancies may not yet be visualized on TVUS at β-hCG levels greater than 2000 IU/mL. Therefore ACOG currently advises that if the concept of the discriminatory zone is to be used to help diagnose ectopic pregnancy, the value should be as high as 3500 IU/mL to avoid the potential for misdiagnosis and possible disruption of a desired intrauterine pregnancy.

2. What is the most common cause of uterine bleeding in the immediate postpartum period?
   a. Uterine rupture
   b. Vaginal lacerations
   c. Retained products of conception
   d. Uterine atony

Answer: d. Postpartum hemorrhage is a leading cause of maternal mortality. Within the first 24 hours after delivery, this is usually caused by uterine atony. After 24 hours, the cause is frequently retained products of conception.

3. A 30-year-old woman with a history of polycystic ovarian syndrome (PCOS) and prior deep vein thrombosis (DVT) presents to the ED with 10 days of irregular, heavy uterine bleeding. Her vital signs are normal. What is the first step in her ED management?
   a. Check complete blood count (CBC).
   b. Order urine pregnancy test.
   c. Administer 25 mg intravenous conjugated estrogen.
   d. Prescribe a taper of oral contraceptive pills.

Answer: b. Pregnancy status is the single most important determination to make when evaluating a patient with vaginal bleeding and should be determined after assessing stability.

4. A 30-year-old woman with a history of polycystic ovarian syndrome (PCOS) and prior deep vein thrombosis (DVT) presents to the emergency department (ED) with 10 days of irregular, heavy uterine bleeding. Her vital signs are normal, and a urine pregnancy test is negative. She currently takes no medication. Which of the following is the most appropriate treatment?
   a. Oral contraceptive taper
   b. Medroxyprogesterone acetate
   c. Oral tranexamic acid
   d. Ibuprofen

Answer: d. Patients with PCOS may have anovulatory cycles and frequently benefit from hormonal treatment such as oral contraceptive pills. However, as the patient has a history of prior DVT she has a contraindication to hormonal treatments as well as oral tranexamic acid. Ibuprofen would therefore be the most appropriate treatment.

5. A 32-year-old woman who is 26 weeks pregnant describes a 1-hour history of painless vaginal bleeding after tripping and falling from a standing height. Her vital signs are normal, and physical examination of the abdomen reveals a nontender uterus with a fundal height 1 cm above the umbilicus. Of the following, which would be the most appropriate next step in evaluating this patient?
   a. Abdominal magnetic resonance imaging (MRI)
   b. Bimanual examination
   c. Sterile speculum examination
   d. Ultrasound

Answer: d. Painless vaginal bleeding after the 20th week of pregnancy is suggestive of placenta previa. Pelvic examination (speculum or bimanual) should be deferred until ultrasound has excluded placenta previa as the cause of bleeding.

31

Back Pain

Brian Niall Corwell and Natalie L. Davis

KEY CONCEPTS

- Acute low back pain is a common, costly, recurring and painful condition that often has no recognizable or dangerous cause.
- While most cases of back pain are non-specific and improve without laboratory evaluation or imaging, the aim of the emergency department (ED) assessment is to identify those serious and emergent pathologies that require urgent treatment.
- A thorough history and physical examination is performed with the goal of uncovering high-risk features predisposing the patient to an emergent or life-threatening etiology.
- The presence of multiple key clinical findings may increase the probability of disease and is often an indication for further investigation of patients with back pain. However, blindly allowing the presence or absence of these individual findings to guide diagnostic treatment will lead to potentially unnecessary, misleading, and costly investigations in most patients.
- Key clinical findings should supplement, not replace, clinical judgement when selecting appropriate laboratory and radiologic testing of patients with back pain. Imaging and laboratory studies are indicated only when there is evidence of neurologic deficit or multiple key clinical findings suggesting a dangerous or systemic pathologic cause.
- Patients who have low back pain emergencies are generally classified into five groups: (1) new onset back pain with neurologic findings in a patient with a malignancy history; (2) back pain and symptoms of epidural compression syndrome; (3) back pain with symptoms suggesting an infectious cause; (4) back pain with gross muscle weakness or paralysis; and (5) back pain with severe or progressive neurologic deficits.
- When a critical or emergent diagnosis is strongly suspected, MRI and spine surgery consultation should be undertaken emergently.
- Adherence to published guidelines will decrease improper laboratory studies and imaging, thereby lowering costs, improving ED throughput and improving overall patient care.
- Conservative therapies are recommended for most patients with nonemergent back pain given the high likelihood for recovery.

FOUNDATIONS

Background and Importance

Back pain is one of the most common chief complaints of emergency department (ED) patients in the United States.[1,2] It is an enormous source of health care expenditures and lost productivity, and causes more disability globally than any other condition. Most patients with acute back pain (defined as lasting less than 6 weeks) are ultimately diagnosed with mechanical or nonspecific back pain, or pain in the absence of a specific serious pathology. Patients with mechanical back pain generally have improvement in pain and disability in the first 6 weeks, though 65% report persistence of pain at least 1 week following an ED visit.[3] Those with chronic back pain (defined as lasting >3 months) will often experience persistence or a recurrence within 12 months. Three months after an ED visit for non-specific back pain, 30% to 40% report functional impairment and 16% report persistent moderate to severe pain.[3,4]

The goal of ED assessment is to separate the common benign causes of back pain from those that could result in significant morbidity or mortality if not promptly recognized. The key to accurate clinical decision-making in identifying the roughly 1% to 7% of ED patients with an emergent diagnosis is performance of a thorough history and physical examination with focus on identifying potential markers of serious disease that we will refer to as key clinical findings (Box 31.1).[5–10]

Pathophysiology

Back pain is a symptom rather than a disease. Just as headache or shortness of breath, it can have many causes both benign and serious. Back pain may be caused by a vascular, visceral, infectious, mechanical, or rheumatologic processes. Pain may originate from the spinal cord, nerve root, vertebral column, surrounding musculature, or an extraspinal origin (including thoracic, abdominal, or pelvic organs). The pathophysiology of non-radicular musculoskeletal back pain is frequently indeterminate; possible causes include muscle or ligament injuries, degenerative spinal disease, and disc herniation. Statistically significant modifiable risk factors for the diagnosis of back pain and sciatica include nicotine dependence (smoking), alcohol abuse, obesity, and depressive disorders.[7] Disc herniation occurs when the annulus fibrosis thins and tears, and the nucleus pulposus prolapses, usually laterally, compressing and inflaming a nerve root. Clinical symptoms are typically self-limited, with a high rate of spontaneous improvement and low likelihood of progression to a neurologic emergency. The natural history of disc herniation is that pain from pressure and nerve irritation improves as local inflammation subsides. The size of the disc protrusion may naturally decrease over time.

Although we commonly consider disc herniation and radiculopathy together, herniation is usually asymptomatic and likely only causes symptoms of sciatica occasionally. Radiculopathy is a clinical diagnosis of nerve root irritation and compression leading to symptoms in the distribution of the affected lumbar or sacral nerve root, such as pain, weakness, numbness or paresthesias. The most common causes are disc herniation and foraminal stenosis caused by spondylotic degeneration. The symptoms associated with disc disease resolve over time, while those associated with spinal stenosis tend to persist or worsen over time. Thickening of the ligamentum flavum and other degenerative changes with age contribute to spinal stenosis. The spinal cord ends at L1 in the adult, where it gives rise to the cauda equina. Compressive lesions above the cauda equina (i.e., the conus medullaris) cause upper motor neurologic signs. Compression of the cauda equina leads

BOX 31.1 Key Clinical Findings in the History and Physical Examination

Historical Information

Recent significant trauma
Sensation of ripping/tearing
Associated chest or abdominal pain
History of cancer
Anticoagulant use
Intravenous drug use
Immunocompromised status
History of prolonged glucocorticoid use
History of osteoporosis
History of abdominal aortic aneurysm
Patient >50 years
Unrelenting night or rest pain
Worsened with cough, Valsalva, sitting
Unexplained weight loss
Recent bacterial infection (skin/soft tissue, pneumonia, urinary tract infection)
Recent GI/GU procedure
Failure to improve after 6 weeks of conservative therapy
Bowel, bladder, and/or sexual dysfunction
Saddle anesthesia

Physical Examination

Abnormal vital signs—hypotension, hypertension, tachycardia, fever
Unequal blood pressure readings in the upper extremities
Murmur of aortic insufficiency
Pulse deficit or circulatory compromise of the lower extremities
Pulsatile abdominal mass
Urinary retention
Urinary or stool incontinence
Loss of rectal sphincter tone
Severe or progressive neurologic deficit
Focal lower extremity weakness
New ataxia or difficulty walking
Decreased perianal sensation

BOX 31.2 Differential Considerations in Acute Back Pain

Extraspinal Causes

Chest—aortic dissection, bacterial endocarditis, pulmonary embolism, pneumonia, pleural effusion, myocardial infarction
Abdominal—ruptured or expanding aortic aneurysm, esophageal disease, penetrating peptic ulcer disease, pancreatitis, pancreatic cancer, cholelithiasis (biliary colic), cholecystitis, cholangitis
Renal—nephrolithiasis (renal colic), perinephric abscess, pyelonephritis
Genitourinary—ovarian torsion or tumor, pelvic inflammatory disease, endometriosis, pregnancy, prostatitis
Musculoskeletal—acute muscle strain, acute ligamentous injury, osteoporosis, spinal curvature (lordosis, kyphosis), osteoid osteoma
Other—herpes zoster, retroperitoneal hemorrhage, psoas abscess, nonspecific low back pain

Spinal Causes

Cauda equina syndrome, spinal epidural abscess or hematoma, vertebral osteomyelitis, infectious discitis, fracture (traumatic, pathologic), malignancy (metastatic, leukemia/lymphoma, multiple myeloma, spinal cord tumor), transverse myelitis, spondylitis (ankylosing, psoriatic), spondylolysis or spondylolisthesis, disc herniation, degenerative disease (discs, facet joints), spondylosis (spinal osteoarthritis), isolated sciatica, spinal stenosis.

to lower motor neurologic findings. Cord compression can be caused by central disc herniation or other space occupying lesions such as abscesses, tumors, hematomas, or bone fragments.

Referred pain is perceived in a location other than that of the noxious stimulation. Irritation in a visceral organ frequently produces pain that may be perceived in somatic structures some distance away, such as a symptomatic abdominal aortic aneurysm (AAA) being felt as low back pain or ureteral colic being perceived as flank pain.

DIAGNOSTIC APPROACH

Differential Considerations

Following the history and physical examination, patients with acute back pain can be divided into three main categories: (1) those with serious extraspinal causes, such as abdominal aneurysm; (2) those with critical or emergent spinal pathology, such as epidural compression syndrome; and (3) those with musculoskeletal or nerve root pain. In the absence of radicular pain, the pain is classified as nonspecific low back pain (Box 31.2).

Myelopathy

Myelopathy is an injury of the spinal cord due to compression (from trauma, spinal stenosis, epidural tumor or abscess, degenerative disease or disc herniation), inflammation (such as transverse myelitis), or ischemia (from compression or embolization of the spinal blood supply). Depending upon the cause, its presentation may be acute or insidious with the gradual onset of lower extremity sensory deficits, loss of pain sensation, weakness, or gait disturbances that may be spastic and scissoring in quality. Upper motor neuron signs are present, such as hyperreflexia, hypertonia, Babinski sign as well as bladder dysfunction and multilevel neuropathic symptoms.

Radiculopathy

Radiculopathy is injury of the nerve root caused by irritation or compression resulting in pain, sensory abnormalities (in 90%) such as paresthesias, and less frequently weakness (in 15%) of the affected nerve root. The causes are similar to those for myelopathy. Differentiating myelopathy from radiculopathy is extremely important. Patients with evidence of acute myelopathy require urgent neuroimaging in the ED and appropriate consultation, while urgent imaging is generally not needed for radiculopathies unless progressive neurologic impairment exists.

Spondylosis

Spondylosis is a term for non-specific progressive degenerative changes (including spinal arthritis) of the vertebral bodies, facet joints, and central canal which typically affects patients greater than 60 years of age. This process can lead to neck or back pain due to nerve root compression and irritation (radiculopathy) or spinal cord compression (myelopathy) due to a variety of related processes including stenosis of the central spinal canal (spinal stenosis) and disc herniation.

With advancing age, spondylosis worsens, intervertebral discs lose height, the ligamentum flavum calcifies, and facet joints deteriorate, leading to narrowing of the vertebral column and foramina (spinal stenosis) and increasing risk of nerve and cord compression. This may be asymptomatic or present with classic symptoms of neurogenic claudication, or pain in the buttocks and/or legs provoked by standing and walking, which reduces canal size, and relieved by rest and bending forward (shopping cart sign), which increases canal size. Symptoms

may be unilateral but are more commonly bilateral and asymmetric. Poor correlation exists between symptom severity and degree of narrowing found on magnetic resonance imaging (MRI).[11] In the absence of acute myelopathy or progressive neurologic deficits, ED management is conservative.

Disc Herniation

Disc herniations occur when the annulus fibrosis thins and tears, and the nucleus pulposus prolapses. They may be asymptomatic or severely painful when they occur. The posterior longitudinal ligament does not extend laterally, so lateral herniation is most common. This can cause impingement and inflammation of the nerve root and radiculopathy symptoms. Clinical symptoms are typically self-limited, with a high rate of spontaneous improvement and low likelihood of progression to a neurologic emergency. The natural history of disc herniation is that pain from pressure and nerve irritation improves as local inflammation subsides. The size of the disc protrusion may naturally decrease over time. However, herniation of a large disc in the midline can cause cord compression and symptoms of myelopathy.

Spinal Infections

Bacterial spinal infections (epidural abscesses and vertebral osteomyelitis) are challenging but important diagnoses to make as they are life-threatening causes of back pain. These can occur due to contiguous spread from adjacent soft tissue infections, direct inoculation due to spinal procedures or trauma, or hematogenous spread. The presentation is often insidious with non-specific symptoms such as fatigue and nausea. Intraspinal abscess may be the most serious missed emergent condition in patients diagnosed with non-specific back pain.[12] No source is identified in one-third of epidural abscess cases. Symptoms may initially improve with conservative measures such as rest, making the diagnosis challenging and often leading initially to a non-infectious diagnosis such as musculoskeletal back pain. Almost half of patients are initially misdiagnosed and average two ED visits are made before diagnosis.

The most common symptom is diffuse spine pain and most common sign is severe local spinal tenderness. The classic triad of epidural abscess is fever, back pain, and focal neurologic deficits, but all three components are present in only 15% of cases. Fever is only present in 30% to 50% of patients at presentation and the neurological examination is normal in two-thirds of patients at first their ED visit. Suspect infectious etiology with new or progressive back pain in patients with recent intravenous drug use (IVDU). A recent study noted almost 40% of patients with a history of IVDU presenting to the ED with the onset of acute back pain had evidence of spinal infection on MRI performed within 24 hours.[13] Other risk factors include immunocompromised states, recent bacterial infection, chronic illnesses such as diabetes, and recent spinal procedures or trauma.

Staphylococcus aureus is the most common pathogen, though other gram positive and gram negative bacteria, as well as *Candida* species may cause infection as well.[9] The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) tests aid in risk stratification. If suspicion exists due to risk factors and examination findings, perform MRI with contrast, which is the gold standard for diagnosis of spinal infection.[14] The lumbar region is the most common site of infection but MRI of the entire spine is performed as extension to additional vertebral levels (average 3 to 5 cord segments) and non-contiguous skip lesions are common. Spinal infections are increasing in incidence due to more frequent invasive procedures as well as an aging population. Almost half of survivors are left with residual neurologic deficits and irreversible paralysis can occur if treatment is delayed.

Spinal Tumors

Neoplastic epidural spinal cord compression is a neurologic emergency that is caused by both benign and malignant tumors. The most common source is metastatic spread to the vertebrae from primary sources including lung, prostate, and breast cancers as well as multiple myeloma and lymphoma. Metastatic cord compression develops in 2.5% to 5% of patients with terminal cancer diagnoses and is the first sign of systemic cancer in 20% to 34%. The thoracic spine is involved most commonly and severe local back pain is the primary symptom in 80% to 95% of presentations. Infiltration leads to spine instability and risk of fractures and cord compression. Pain may precede weeks before neurologic symptoms and is described as dull, constant, not relieved by rest, and may be worse at night. Neurologic symptoms of myelopathy may include gait ataxia, bladder dysfunction, and weakness or paralysis. Suspect this diagnosis in patients with new onset back pain and new neurologic symptoms and a history of cancer. Timely diagnosis and treatment are important to reduce permanent injury. If neoplastic cord compression is suspected, obtain MRI with contrast of the full spine since pain and neurologic deficits may not correlate with the spinal level of the lesion.

Cauda Equina Syndrome

Cauda equina syndrome (CES) is a neurologic emergency caused by compression of the nerves of the cauda equina. CES is most often caused by disc herniation at L4/5 or L5/S1, as well as by other space occupying lesions such as abscesses, hematomas, fractures, lumbar spondylosis, and tumors. Compression in the lower region of the spinal cord (conus medullaris) can lead to both lower and upper motor deficits due to nerve root and spinal cord injury, while compression of the cauda equina leads to lower motor deficits only.

Clinical presentation is variable and no symptoms or signs are 100% sensitive or specific in isolation, which is why the time from first symptoms to diagnosis averages 11 days. This diagnostic difficulty was demonstrated in a study in which only 56% of patients with MRI positive for CES were accurately identified by senior neurosurgical residents based on history and physical examination. Classic features include bladder dysfunction (found in ~90%), bowel dysfunction (~50%), sexual dysfunction, saddle anesthesia (decreased perianal and genitourinary sensation, found in 80%), and unilateral or bilateral radiculopathy (progressively worsened back and lower extremity pain that is worse with recumbent positioning, weakness, and sensory abnormalities like paresthesias, found in ~96%).[15] Saddle anesthesia has the highest predictive value in diagnosing MRI-proven CES. However, these features are often late findings and signs and symptoms do not develop in a predictable manner. Further clouding this picture is that up to two-thirds of patients have preexisting chronic back pain. Because of the variable presentation, clinicians should have a low threshold for emergent imaging. Diagnosis is made by MRI of the lumbosacral spine.

CES is divided into two categories based on the effect on the bladder: CES-I (incomplete) and CES-R (retention). CES-I patients have urinary issues with reduced bladder sensation and difficulty voiding (decreased desire to void, strained micturition and decreased urinary stream). CES-R patients have complete urinary retention with overflow incontinence. This clinical characterization has important prognostic value. The functional status of patients at the time of presentation is predictive of prognosis. Variable deficits with micturition, defecation, and sexual function, are common residual symptoms irrespective of time to surgical decompression. Due to the nature of these lifelong complications, there is a strong association with CES and medico-legal litigation. Document a thorough history and physical examination, as well as attempts to obtain emergent imaging and consultation.

Acute Transverse Myelitis

Acute transverse myelitis is a rare disorder caused by spinal cord inflammation, rather than a compressive lesion, leading to motor, sensory, and autonomic dysfunction. It is most often idiopathic but can occur as an initial presentation of multiple sclerosis, autoimmune disorders (e.g., lupus), and vasculitis. Associations exist with preceding viral infections (e.g., varicella, herpes, cytomegalovirus) and bacterial infections (e.g., tuberculosis, Lyme disease, syphilis) either related directly to infection or due to post-infectious inflammation. Bimodal peaks exist between ages 10 and 19 years as well as 30 and 39 years. Presentation may be variable based on spinal segment involved, most commonly thoracic followed by lumbosacral, and is often bilateral. Presentation may be similar to other causes of myelopathy, including motor and sensory abnormalities, risk of progressive paralysis, and bladder, bowel, and sexual dysfunction. In an ED population eventually confirmed to have ATM, it was the initial diagnostic impression in fewer than 10% of cases. Diagnosis is made by full spine MRI with and without contrast. If multiple sclerosis is suspected, non-emergent brain MRI can be performed.

Mechanical Back Pain

Pain without a clear origin and not caused by a specific disease or spinal abnormality is defined as "non-specific" or mechanical back pain. This is the most common cause of back pain presenting to the ED but is a diagnosis of exclusion, after excluding other worrisome causes of back pain. Underlying causes are poorly understood and can include muscle strain, ligamentous strain, myofascial pain, facet joint arthritis, and disc disease. These patients report mild-to-moderate pain with an otherwise negative history and benign physical examination. There is an absence of radiculopathy and myelopathy symptoms. Pain is generally unilateral, often described as "aching," "throbbing" and "spasmodic," and is exacerbated by activity and improves with rest. Pain may radiate to the buttocks or posterior thigh but not past the knee. Because most patients with nonspecific back pain experience symptomatic improvement within 6 weeks, only conservative management is needed. No further diagnostic testing is required beyond the history and physical examination.

Chronic Back Pain

In the absence of new findings, chronic back pain (defined as pain lasting over 3 months) is often regarded as one of the most challenging clinical scenarios. One-third of ED patients will report functional impairment and pain three months after an ED visit for acute, non-traumatic, non-radicular back pain.[4] The underlying cause of chronic pain is complex and multifactorial, making proper assessment and treatment nearly impossible in the ED setting. These patients usually require a multidisciplinary treatment approach for the greatest chance for success. For some patients, chronic, recurrent back pain is a long-term issue, and they may visit the ED during an acute exacerbation. These patients still require a thorough examination and review of key clinical findings to stratify based on risk and to guide ED evaluation. Labelling these patients without performing a thorough investigation can have dangerous consequences. For example, CES is often seen in those with a prior history of back pain or sciatica.

Pivotal Findings

While most patients with back pain will be diagnosed with mechanical or non-specific causes, the emergency clinician must consider and confirm or exclude potentially life-threatening and disabling causes of back pain that require urgent treatment (seen in <1% in primary care, but 1% to 7% in the ED).[5] A thorough history and physical examination are invaluable. Technologically sophisticated radiologic and laboratory studies are not a substitute for a detailed history and physical examination. This approach will help separate patients into high- and low-risk groups. Specific findings will guide the additional evaluation of patients with neurologic deficits and more serious spinal or visceral sources (Table 31.1).

Symptoms

As with any patient who complains of pain, symptoms should be characterized by basic historical elements of the episode, such as the rate of onset, duration, severity, location, and quality (dull, aching, shooting, burning), exacerbating or alleviating factors, effects on activities of daily living and the presence of key clinical findings (see Box 31.1). Identify associated characteristics such as weakness, gait abnormalities, clumsiness, loss of fine motor skills, radiation, and/or paresthesias. Inquire specifically about bowel and bladder function, sexual dysfunction, or loss of sensation in the groin, as these indicate more serious pathology. Rather than asking about urinary incontinence, one should ask about difficulty passing urine and retention. Discussing issues related to sexual dysfunction are difficult for both clinicians and patients, but is important in the evaluation of epidural compression. Rather than asking if there are any issues with sexual function, a more direct and informative way would be to ask if the patient has a "change in ability to achieve an erection or ejaculate" or "loss of sensation in genitals during sexual intercourse."[8] Inquire about demographic features and comorbidities such as intravenous (IV) drug use, diabetes, age, immunocompromised states, osteoporosis, history of cancer, and constitutional symptoms (fever, chills and weight loss).

The different causes of acute back pain have distinguishing characteristics. Typical mechanical or non-specific back pain is unilateral, worsened with movement, alleviated with rest, and not associated with complaints of numbness, weakness, bowel or bladder dysfunction (see Table 31.1). Pain may radiate generally to the buttocks or posterior thigh areas, but not past the knee. Radicular (nerve root) pain occurs in a more focal dermatomal distribution, and often radiates distal to the knee toward the foot. There may also be associated numbness or weakness, relieved with recumbent positioning, exacerbated by Valsalva maneuvers (coughing, sneezing), and positions that produce increased pressure on annular fibers (prolonged sitting, standing, and bending postures).

Multi–nerve root pathology or the presence of bilateral symptoms is a potential indicator of a spinal mass lesion or large central disc herniation, which compresses multiple descending nerve roots within the spinal canal. Peripheral nerve pain may be described as "pins and needles" as opposed to nerve root pain (radiculopathy), which is transient and very sharp and "electrical."

Discogenic pain is typically worse with flexion, whereas pain from spondylolysis (defect or stress fracture in the pars interarticularis of the vertebral arch) is aggravated by facet loading, which occurs in extension. Inflammatory pain (spondyloarthritis) is insidious in onset, affects younger patients (under age 40), improves with exercise but not with rest, and causes pain at night with improvement upon arising.

Spinal stenosis is suggested by back pain with unilateral or bilateral radiculopathy that is worsened with back extension (walking and prolonged standing) since erect posture narrows the cross-sectional area of the central canal and neural foramina, most commonly in lumbar spine area. It is relieved by forward flexion (shopping cart sign), which increases spinal canal diameter, temporarily relieving the stenosis. Spinal stenosis can cause diffuse intermittent burning, cramping pain in the back, motor weakness, reflex changes, and pain radiating to the buttocks, thigh, and legs, with associated paresthesias. This symptom constellation is termed neurogenic claudication (also called pseudoclaudication) and is caused by neurologic compression, unlike vascular

TABLE 31.1 Classical Findings in Selected Serious Causes of Acute Back Pain

Findings	Diagnoses	History	Important Physical Examination Findings	Ancillary Testing	Comments
Critical					
Vascular	Aortic dissection	Often sudden-onset, tearing, severe chest and/or back pain; associated nausea, vomiting, acute anxiety common; syncope can occur.	Associated diaphoresis, unstable vital signs; hypertension common; unequal upper extremity blood pressure; new-onset aortic insufficiency murmur; central and peripheral neurologic deficits secondary to ischemia	Choice of CT, transesophageal ECHO, MRI; depends on patient stability and availability of equipment	More common as cause of thoracic back pain.
	AAA, Abdominal aortic aneurysm (ruptured, expanding)	Pain typically noted in the abdomen, but back, flank, or pelvic pain, or radiation to groin may occur; syncope may be present.	Pulsatile abdominal mass, abdominal bruits; hypoperfusion	Bedside US; if stable, abdominal CT with contrast; plain films may show calcified, enlarged, aortic contour	Can also mimic renal colic, GI bleeding, diverticulitis, myocardial infarction; 30% of signs are misdiagnosed.
Infectious	Spinal epidural abscess	At-risk population with diabetes, chronic renal failure, dialysis, IV drug use, HIV/AIDS, immunosuppression, steroid use, alcoholism, cancer, recent spinal surgery, trauma, recent bacterial infection, bacteremia	Fever (50%), back pain (75%); focal neurologic deficits are late findings (<50% of patients); all three (classic triad) present in 15%; localized body tenderness along spine; rare cauda equina–like syndrome	Elevated WBC (66%), ESR/CRP (80%–100%) sensitive but nonspecific; MRI with contrast is modality of choice; CT if MRI contraindicated; search for source of infection; obtain blood cultures; *Staphylococcus aureus* most common cause (>50%)	Manifests as mass- occupying lesion compressing spinal cord; may be mistaken for hematoma, malignancy, herniated disc; abscess drainage may be necessary; start IV antibiotics immediately as 5% will die from sepsis.
Mechanical	Epidural compression syndrome (e.g., cauda equina syndrome, neoplastic cord compression)	Usually history of back pain, cancer; symptoms may develop over hours; sciatica (96%), urinary dysfunction (89%), bowel dysfunction (47%)	Urinary retention, fecal incontinence; saddle anesthesia (81%), bilateral leg pain; lower extremity weakness with hyporeflexia	Evaluate postvoid residual; MRI makes the diagnosis, consider performing with contrast if infection or cancer highly suspected; if contra-indicated, then obtain CT	Emergent condition caused by compression of lumbosacral nerve roots; functional status at diagnosis highly predictive of longer term outcomes.
	Spinal fracture with cord impingement, or unstable fracture	Acute onset, localized pain; usually trauma history; older adults; chronic steroid use; osteoporosis	Bone tenderness, radiculopathy or myelopathy symptoms	Plain films initially, then CT or MRI	Symptoms, signs depend on level
	Epidural hematoma	Usually seen in patients with coagulation disorder, hereditary or acquired (e.g., anticoagulants); may occur after epidural anesthesia	Radiculopathy or myelopathy symptoms	MRI or CT	Can also occur in AV malformations
Emergent					
Infectious	Vertebral osteomyelitis	At-risk group similar to that for epidural abscess; onset may be insidious; back pain, tenderness, and stiffness may precede neurologic findings by significant time period.	May have fever (poorly sensitive or specific), other constitutional symptoms; localized tenderness of two adjacent vertebrae	CBC, blood cultures, generally low yield; ESR/CRP usually elevated but nonspecific; diagnose using MRI with contrast	Biopsy may be necessary for diagnosis; *S. aureus* most common, ideally hold antibiotics until bacteria isolated unless unstable patient; if cultures positive for GPC, consider endocarditis; can lead to pathologic fracture

Continued

TABLE 31.1 Classical Findings in Selected Serious Causes of Acute Back Pain—cont'd

Findings	Diagnoses	History	Important Physical Examination Findings	Ancillary Testing	Comments
Immune	Transverse myelitis	Back pain, neurologic deficits; Almost 50% of patients worsen maximally in 24 h	Presentation similar to other causes of myelopathy, including motor and sensory abnormalities, risk of progressive paralysis; bladder, bowel, sexual dysfunction; most common thoracic followed by lumbosacral; likely bilateral	Goal is to rule out mass lesion compressing the cord; thought to be autoimmune origin; MRI imaging modality of choice; contrast CT if MRI contra-indicated.	May be associated with multiple sclerosis, SLE, sarcoidosis; also associated with Lyme disease, Epstein-Barr virus, other viral (e.g., herpes, enterovirus) or bacterial (e.g., tuberculosis, syphilis) infections
Mechanical	Back pain with neurologic deficits; central disc herniation; spinal stenosis; spinal fractures without cord impingement; malignancy; sciatica with potential for nerve root compression	Search for key clinical findings (see Box 31.1) to rule out serious underlying disease.	Positive straight leg raise test; muscular weakness; sensory deficits; absent or diminished deep tendon reflexes	Plain films not indicated; Perform MRI or CT for complete assessment if infection, mass, cord hematoma, or cord compression is suspected	Perform complete neurologic examination including motor, sensory, reflex, and gait testing.

AV, Arteriovenous; *CBC*, complete blood count; *CRP*, C-reactive protein; *CT*, computed tomography; *ECHO*, echocardiogram; *ESR*, erythrocyte sedimentation rate; *GI*, gastrointestinal; *GPC*, gram positive cocci; *MRI*, magnetic resonance imaging; *SLE*, systemic lupus erythematous; *US*, ultrasound; *WBC*, white blood cell.

claudication, which is caused by arterial insufficiency, may have abnormal pulses, and is relieved by rest.

Pain that is oncologic or infectious in origin is often severe, constant, may occur at night and is associated with constitutional symptoms. Epidural compression syndromes (spinal cord compression, CES) are associated with numbness, weakness, bilateral leg pain, incontinence and saddle anesthesia, or decreased perineal sensation. Ask patients about decreased sensation when wiping to assess for saddle anesthesia.

Back pain associated with pain in other locations should prompt consideration of an extraspinal cause. Association with chest or abdominal symptoms may indicate a visceral cause, such as vascular or solid organ pathology. Unilateral flank symptoms may have a renal or retroperitoneal origin, and thoracic level pain can emanate from the chest or pleura. Because most benign back pain is tolerable, worsened with activity, and improved with rest or lying still, symptoms such as severe night pain (especially deep bony pain) and severe unrelenting pain that is not relieved by rest, recumbency, or appropriate analgesic treatment are concerning for non-musculoskeletal causes, such as malignancy or infection. Other pertinent history considerations include past and present work history (a history of repeated loading would suggest a mechanical cause), medications (anticoagulants are associated with epidural and retroperitoneal hematomas, steroids are associated with infection and compression fractures), hematuria (nephrolithiasis, pyelonephritis, ruptured AAA), and colic (nephrolithiasis, cholelithiasis).

Although AAA as a cause is rare in the overall population of patients with back pain, isolated back pain is one of the classic presentations of a contained ruptured AAA. Vigilance is required to differentiate renal colic from AAA in older patients because both groups may present with back pain associated with nausea, diaphoresis, or syncope, and hematuria may be present in either condition. Previous atherosclerotic or vascular disease may suggest aortic disease, and sudden-onset, severe back pain suggests a vascular cause. Direct trauma may suggest contusion, strain, or fracture. Resulting splenic, hepatic, or retroperitoneal bleeding may lead to referred pain to the back.

Younger patients are at increased risk of spondylolysis and spondylolisthesis. Disc herniation is unusual in those younger than 18 years and is rare in the fibrotic discs of older adults. Prevalence of vertebral compression fractures increase with increasing patient age; they occur in almost a quarter of all postmenopausal women, and up to 30% of women by 80 years of age.

Increased risk of infectious etiology exists for patients with a history of IVDU, diabetes, hepatitis, recent spinal instrumentation, indwelling devices (e.g., epidural catheters, spinal stimulators, vascular access), and recent bacterial infection (e.g., pneumonia, urinary tract infection).[9]

Inquiring about risk factors for cancer is important since spinal epidural metastasis can be the initial presentation of malignancy or may occur in patients with a known primary malignancy. Spinal metastases usually arise in the posterior aspect of the vertebral body, with subsequent invasion of the epidural space.

It is important to note that the presence of an individual key clinical finding may raise suspicion but does not necessarily correspond to a specific pathology. These key clinical findings have traditionally been promoted as "red flags," or signs that predict increased risk of underlying serious spinal pathology. A wide variety of different "red flags" for back pain have been endorsed by many guidelines with a lack of consensus, poor consistency, and limited accuracy or evidence for their support. Examples of findings with poor diagnostic accuracy include night pain and age over 50 years increasing risk of cancer diagnosis.[6] The term "red flags" should be abandoned and we will instead refer to them as "key clinical findings." Many of these key clinical findings have poor or untested diagnostic accuracy and have meaning only in the context of the complete history and findings in an individual patient.[5,10] In addition, the absence of key clinical findings does not necessarily reduce the likelihood of a serious diagnosis.[6] Blindly allowing the presence or absence of these individual findings to guide diagnostic treatment will lead to potentially unnecessary, misleading, and costly investigations in most patients.

TABLE 31.2 Physical Examination for Lumbosacral Nerve Root Compromise

Disk Space	Nerve Root	Sensory Testing	Reflex	Strength and Motor Testing	Pain Location	Screening Exam
L3–4	L4	Test from the medial lower leg and foot down to the medial surface of the great toe (not including the first web space).	Patellar reflex	Test with knee extension (quadriceps), ankle inversion and dorsiflexion.	Back pain radiates to anterior thigh and to anterior leg.	Squat and rise
L4–5	L5	Test from the lateral lower leg, dorsum of the foot, and first web space (between great toe and second toe).	There is no reliable reflex to test L5.	Test with hip abduction, knee flexion, foot/ankle eversion/inversion, great toe dorsiflexion (extensor hallucis longus).	Back pain radiates to buttock, lateral thigh and calf, dorsum of foot, great toe.	Heel walking
L5–S1	S1	Test from the posterior lower leg, lateral/plantar foot and ankle.	Achilles reflex	Test with hip extension, knee flexion, and foot plantar flexion.	Back pain radiates to buttock, posterior-lateral thigh, posterior lower leg, lateral/plantar foot.	Toe walking

Presence of multiple key clinical findings may increase the probability of disease and is often an indication for further investigation, which may be initiated in the ED or on an ambulatory basis, depending on the individual patient. Key clinical findings should supplement (not replace) clinical judgment when selecting appropriate laboratory and radiologic testing. In an ED population, three of the important variables associated with serious outcomes include (1) new urinary retention, (2) disturbance of saddle sensation, and (3) use of anticoagulants.[5] A history of cancer predicts the greatest probability of back pain from bone metastasis. Prolonged use of corticosteroids, significant trauma, older age (>70 years), and presence of contusion or abrasion increase probability of fracture(s).

Signs

Begin by noting vital signs, as abnormal or unstable vital signs may indicate an extraspinal cause of the back pain (e.g., hypotension and tachycardia with ruptured AAA, hypertension with aortic dissection). Presence of a fever may indicate an infectious etiology, though its absence does not exclude diagnosis. Patients with back pain may prefer to lie relatively still as movement worsens pain. Extreme pain or writhing may have an underlying emergent etiology including spinal causes (epidural abscess and osteomyelitis) and extra-spinal causes (intraabdominal, retroperitoneal, or vascular) (See Table 31.1). Perform cardiac and pulmonary auscultation, abdominal examination (for tenderness, bladder distention, aneurysm, or masses), and palpate for symmetry of peripheral pulses. Examine the hips for musculoskeletal tenderness, deformity, or inflammatory focus other than the back.

The patient's neck and back should be fully exposed and inspected for signs of infection, trauma, paraspinal muscle spasm, edema, range of motion. Palpate midline spinous processes for tenderness suggesting fracture or infection. Pain during lumbar flexion suggests discogenic pain, whereas pain on lumbar extension suggests facet disease. Paraspinal muscle spasm should be noted but is not diagnostic of any particular condition. Superficial, non-anatomic, or variable tenderness suggests a non-organic cause.

Perform a complete neurologic examination, including strength, sensory, reflex and gait testing, and evaluation for upper motor deficits. Attempt to distinguish true neurologic weakness from pain-induced weakness. Early and effective treatment of pain will aid in obtaining an accurate physical examination. Lumbar spine pathology is frequently manifested in the lower extremities in the form of altered reflexes, sensation, and muscle strength. The distal neurologic examination targets the three most common locations for disc herniation—L4, L5, and S1. A vast majority of herniated discs affect the L4–5 or L5–S1 interspaces, causing impingement on the L5 (most common) and S1 nerve roots. At each spinal level, the corresponding muscle strength, sensation and reflex needs to be tested and documented (Table 31.2). Muscles may have innervation from multiple roots so patients may have preserved strength despite significant involvement of a single nerve root. True sensory loss is best tested with pinprick rather than light touch. Although the classic teaching is that sensory findings follow a dermatomal distribution, clinical experience suggests otherwise due to dermatomal overlap and individual variation in nerve root dermatomes. Owing to this sensory overlap, it is unusual to have a clearly demarcated sensory loss even in cases of severe radiculopathy due to a single root lesion. In contrast, a sharp line of demarcation is frequently seen in pure peripheral nerve lesions such as in carpal tunnel syndrome. Saddle anesthesia is defined as diminished to absent sensation over the buttocks, posterior-superior thighs and perianal regions and indicates neurologic compromise. Gait disturbance and unsteadiness are common early symptoms of myelopathy, characterized by a spastic, scissoring quality.

See Table 31.2 for nerve root levels and corresponding examination findings. Of note, ankle reflexes decrease with age, lost in nearly 50% of those older than 80 years. This loss is usually symmetric, so unilateral absence may signify pathology. Measurement of post void residual volume (PVR) may help to differentiate true overflow incontinence from urge or stress incontinence. Large PVR (>100 mL) indicates a denervated bladder with resultant overflow incontinence and suggest significant neurologic compromise.

Mid and upper lumbar nerve root impingement likely has a higher prevalence than previously reported and is found with increasing frequency in older adults with spinal stenosis. Pathology at the higher lumbar spine (L1, L2, L3) will cause acute back pain, with radiation to the groin or anterior thigh, weakness with hip flexion (iliopsoas), and anterior thigh sensory changes in the corresponding dermatome. A partial knee bend while bearing weight on one leg and then the other indicates normal hip, buttock, and thigh muscle strength. There are no individual reflexes for the L1–3 lumbar levels. Those with pathology at the lower sacral levels (S2–5) will have sacral or buttock pain that radiates down the posterior leg or into the perineum and can have difficulties with penile erection (S2–4), abnormal perianal sensation (S3–5), anal wink (S2–4), rectal tone (S2–5), and bladder function (S2–4). Assessment of perianal sensation is extremely important for the diagnosis and prognosis of epidural compression syndrome. Sensation changes can be unilateral, mild, or patchy. Specifically assess "pinprick"

sensation, which can be performed using a broken wooden cotton tip applicator, but warn the patient they may feel a sharp sensation. A digital rectal examination is not a routine part of the physical examination but can be performed in those with suspicion of progressive neurologic findings (e.g., epidural compression syndrome). Check the anal wink and bulbocavernosus reflex and perform a Babinski test in high-risk patients. A Babinski sign (positive plantar reflex) is extension of the great toe, with flexion and splaying of the other toes. The presence of clonus, hyperreflexia, or Babinski sign indicates an upper motor neuron lesion. These signs suggest myelopathy.

Straight leg raise (SLR) test for nerve root compression has a sensitivity of 72% to 97% and a specificity of 11% to 66%. In high-risk patients with sciatica or neurologic symptoms the test has a positive predictive value (PPV) of 67% to 89% and a negative predictive value (NPV) of 33% to 57%. To perform this test, the patient is positioned supine, with the legs fully extended. The clinician places one hand under the ankle and the other hand on the knee (to maintain leg extension). With the patient relaxed, the straightened leg is slowly lifted by flexing the leg at the hip until pain is elicited or end range is reached. Each leg is tested separately. A positive test causes or reproduces radicular pain below the knee of the affected leg when the leg is elevated between 30 and 70 degrees. Care should be taken that the patient is not actively helping in lifting the leg and that the knee remains straight throughout the examination.

A further positive finding occurs if radicular symptoms are elicited when the leg is then lowered until pain is eased and the ipsilateral ankle is dorsiflexed (Braggard sign). Pain at less than 30 degrees, more than 70 degrees, or with reproduction of pain only in the back, hamstring, or buttock region, does not constitute a positive test result. Pain referred to the affected leg when the opposite asymptomatic leg is tested, called a positive crossed-SLR, is highly indicative of nerve root irritation from a herniated disc (specificity, 85% to 100%; sensitivity, 29%). In cases where the patient is reluctant or unwilling to lie supine for SLR testing, the seated-SLR or slump test should be attempted. The patient sits at the edge of the examination table and slumps forward while flexing the neck and trunk. This is followed by knee extension and ankle dorsiflexion. A positive test reproduces radicular pain.

Waddell's examination findings can aid in distinguishing between true pathologic back pain and nonorganic back pain; it can be remembered by the mnemonic DORST—distraction, overreaction, regional disturbances, simulation tests, and tenderness). Waddell's signs, especially if three or more are present, correlate with malingering and functional complaints (physical findings without anatomic cause). Superficial, nonanatomic, or variable tenderness during the physical examination suggests a non-organic cause. Provocative maneuvers such as axial loading of the head or passive rotation of the shoulders and pelvis in the same plane should not elicit back pain. There may be a discrepancy between the symptoms reported during the supine and seated SLR tests. The seated version of the test, sometimes termed the distracted SLR, can be performed while distracting the patient or appearing to focus on the knee. Furthermore, radicular pain elicited at a leg elevation of less than 30 degrees is suspicious because the nerve root and surrounding dura do not move in the neural foramen until an elevation of more than 30 degrees is reached. Sensory and motor findings suggestive of a nonorganic cause include stocking, glove, or non-dermatomal sensory loss or weakness that can be characterized as "give-way," jerky, or cogwheel weakness. Finally, gross overreaction is suggested by exaggerated, inconsistent, painful responses to a stimulus. These signs can be used in the evaluation of selected patients and are merely a component of a comprehensive physical examination. They should never be used independently because they lack the sensitivity and specificity to rule out true organic pathology.

ANCILLARY TESTING

Ancillary testing is not indicated in the absence of concerning findings and should only be used to help guide specific management. Routine nonemergent use of laboratory testing, computed tomography (CT), MRI should be discouraged. Blind diagnostic testing may lead to false-positive results and further unnecessary evaluations and interventions.

Laboratory Tests

Laboratory studies are not often indicated in the early evaluation of low back pain. Complete blood counts (CBC) have poor sensitivity and specificity for infection. White blood cell (WBC) counts may be elevated and a left shift may be present and increase suspicion for infection, but lack of these does not rule out infection. Both the ESR and CRP tests are highly sensitive (84% to 100%) for spinal infections and are observed in greater than 80% with vertebral osteomyelitis and epidural abscesses. However, elevated CRP was found in 87% of patients with an epidural abscess as well as in 50% of patients with spinal pain not due to an epidural abscess, making it is not highly specific. CRP levels rise rapidly and decrease rapidly with improvement in disease and may be better used to follow response to treatment. ESR is the most sensitive and specific serum marker of infection. ESR is elevated in 94% to 100% of patients with an epidural abscess compared to only 33% of those without an epidural abscess. Infection is unlikely in patients with an ESR less than 20 mm/h. Although an elevated ESR (>20 mm/h) is the most specific serum test for infection, it also may indicate occult malignancy (sensitivity, 78%; specificity, 67%). Incorporating ESR and CRP values into an ED decision guideline may help identify patients that require imaging in the ED vs. non-emergent basis and decrease the rate of diagnostic delay. If infection is suspected, obtain two sets of blood cultures, as a causative pathogen may be identified in 50% of patients.

Imaging Studies

Imaging, like laboratory testing, is not indicated in the absence of concerns for malignancy, fracture, infection, or epidural compression syndrome. Acute back pain and radiculopathy are generally benign, self-limited conditions that do not warrant imaging studies from the ED. Although the added diagnostic value of modern neuroimaging is significant, unnecessary imaging increases the cost of the ED visit, length of stay and observation admissions, exposes patients to unnecessary radiation, and does not decrease return ED visits.[16]

Abdominal Ultrasound

Bedside ultrasound can aid in the rapid diagnosis of non-spinal conditions such as AAA.

Plain Film Radiographs

Radiographs are rarely helpful in diagnosing the causes of acute back pain or directing therapy in the acute setting. All emergent spine conditions with new or progressive neurologic symptoms presenting to the ED require evaluation with CT or MRI.

Computed Tomography Scan

CT scans are better than plain radiographs for the detection of bone pathology such as vertebral fractures, malalignment, and bony fragments within the spinal canal. CT is preferred in the setting of trauma, but without a trauma history should be performed only if MRI is contraindicated or unavailable. For example, CT with IV contrast is the next best imaging modality for epidural abscess. CT measurement of thecal sac effacement may correlate with MRI findings (98% sensitivity

and 86% specificity) for CES if MRI is contraindicated or not available. CT scanning is not without risks as CT of the lumbar spine carries a radiation level equivalent to 300 chest x-rays.

Magnetic Resonance Imaging

MRI is the imaging modality of choice for evaluating soft tissue, spinal cord, nerve roots, and intervertebral discs. MRI is indicated in the evaluation of progressive radiculopathy and myelopathy caused by malignancy (sensitivity and specificity >90%), infections (sensitivity and specificity >90%), and epidural compression syndromes (sensitivity and specificity >90%). If suspicion exists for metastatic disease, osteomyelitis, abscess, or inflammatory conditions, obtain MRI with contrast. However, the high sensitivity of MRI may identify asymptomatic diagnoses in the spine that may be incorrectly inferred as causative for pain. Disc disease is a component of normal aging and is a very nonspecific finding. In fact, one in four asymptomatic persons less than 60 years and one in three greater than 60 years will have MRI findings of a herniated disc. Similarly, spinal stenosis is seen in 21% of asymptomatic adults over age 60. In a recent study, 30% of MRIs ordered for back pain were inappropriate and ordered without indication, and 24% of the providers were responsible for 74% of inappropriate scans.[17] A primary goal of consensus-based guidelines and international campaigns such as Choosing Wisely has been to eliminate practice variation. MRI should be limited in the ED population to those with clinical concern for progressive or urgent neurologic deficits.

DIAGNOSTIC AND MANAGEMENT ALGORITHMS

Figs. 31.1 and 31.2 provide diagnostic and management algorithms which use key findings from the medical history and physical examination to risk stratify patients for further ancillary testing and subsequent management.

Critical Diagnoses

Back pain may be the major or even sole symptom of patients who present with a dissecting thoracic aneurysm or ruptured AAA. Other life-threatening disorders presenting with back pain are usually identified by their associated symptoms and signs.

Emergent Diagnoses

Spinal infections and tumors, CES, transverse myelitis and disc herniation causing severe neurologic impairment can result in significant morbidity if not recognized and treated appropriately.

EMPIRIC MANAGEMENT

Following the history and physical examination, the minority of patients who have multiple key clinical findings or a moderate to high probability of a critical or emergent condition will require further urgent evaluation and management aimed at identifying and treating the underlying cause. Those disorders are discussed in various chapters throughout the book.

One of the most important goals of treatment is provision of an acceptable level of analgesia until the underlying condition resolves or to ameliorate the suffering of those patients who await definitive therapy. Despite numerous studies and recommendations, few treatments have been proven effective for the management of low back pain. Patients' expectations are known to influence the outcome of treatment, and this process can begin in the ED. Reassurance and information about back pain, carefully selected and presented, can have a positive effect on patients' beliefs and clinical outcomes. Guidelines are shifting their focus from pain to functional status and from pharmacological to non-pharmacological management.[18] Setting a goal of pain improvement instead of complete resolution of pain may be beneficial. Avoid the medicalization of benign conditions by ordering unnecessary tests. This behavior, coupled with the over-prescription of analgesics, particularly opioids, fosters a belief on the part of the patient of the existence of serious pathology for an otherwise benign condition.

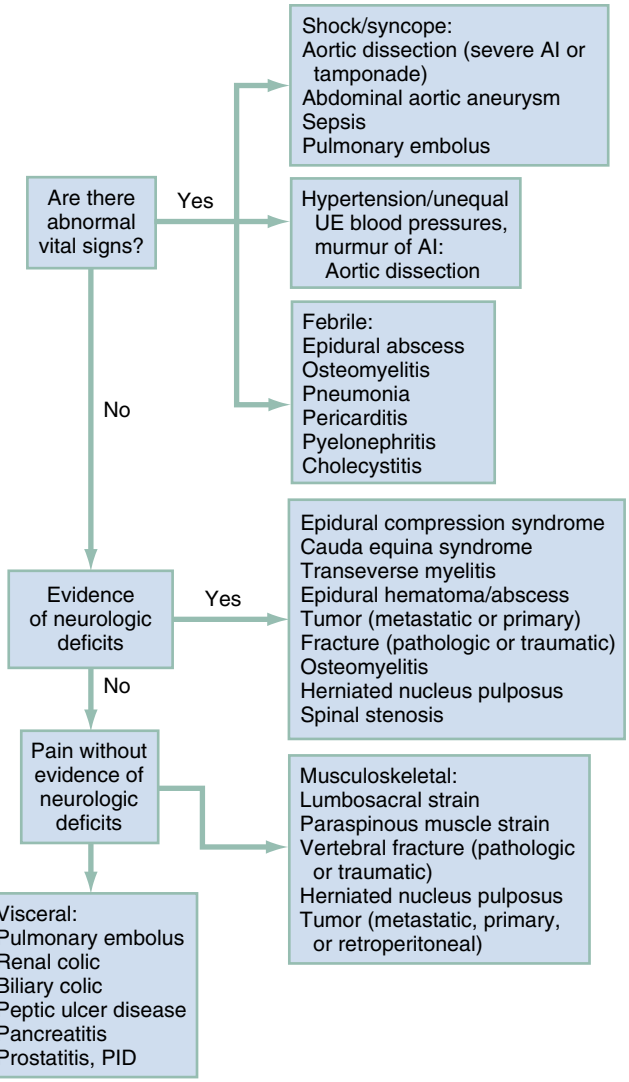

Fig. 31.1 Rapid Assessment of Acute Low Back Pain. *AI,* Aortic insufficiency; *PID,* pelvic inflammatory disease; *UE,* upper extremity.

Mild to Moderate Back Pain

For patients with mild to moderate pain, first-line pharmacologic therapy includes nonopioid analgesics. Enteral nonsteroidal antiinflammatory drugs (NSAIDs) are first line treatment for both acute and chronic back pain, unless contraindicated.[19] Parenteral NSAID analgesia is rarely indicated and is no more effective than an equivalent dose of an oral NSAID. No differences have been found between cyclooxygenase (COX)-2 selective and traditional NSAIDs. When considering NSAIDs, confine dosing to 1 to 2 weeks at most in carefully selected patients with a favorable renovascular and gastrointestinal risk profile. When used alone, acetaminophen has been shown to provide little benefit in the treatment of pain, disability, quality of life, and sleep quality outcomes for patients with back pain.[20] There is little to no benefit of adding acetaminophen to NSAID therapy.

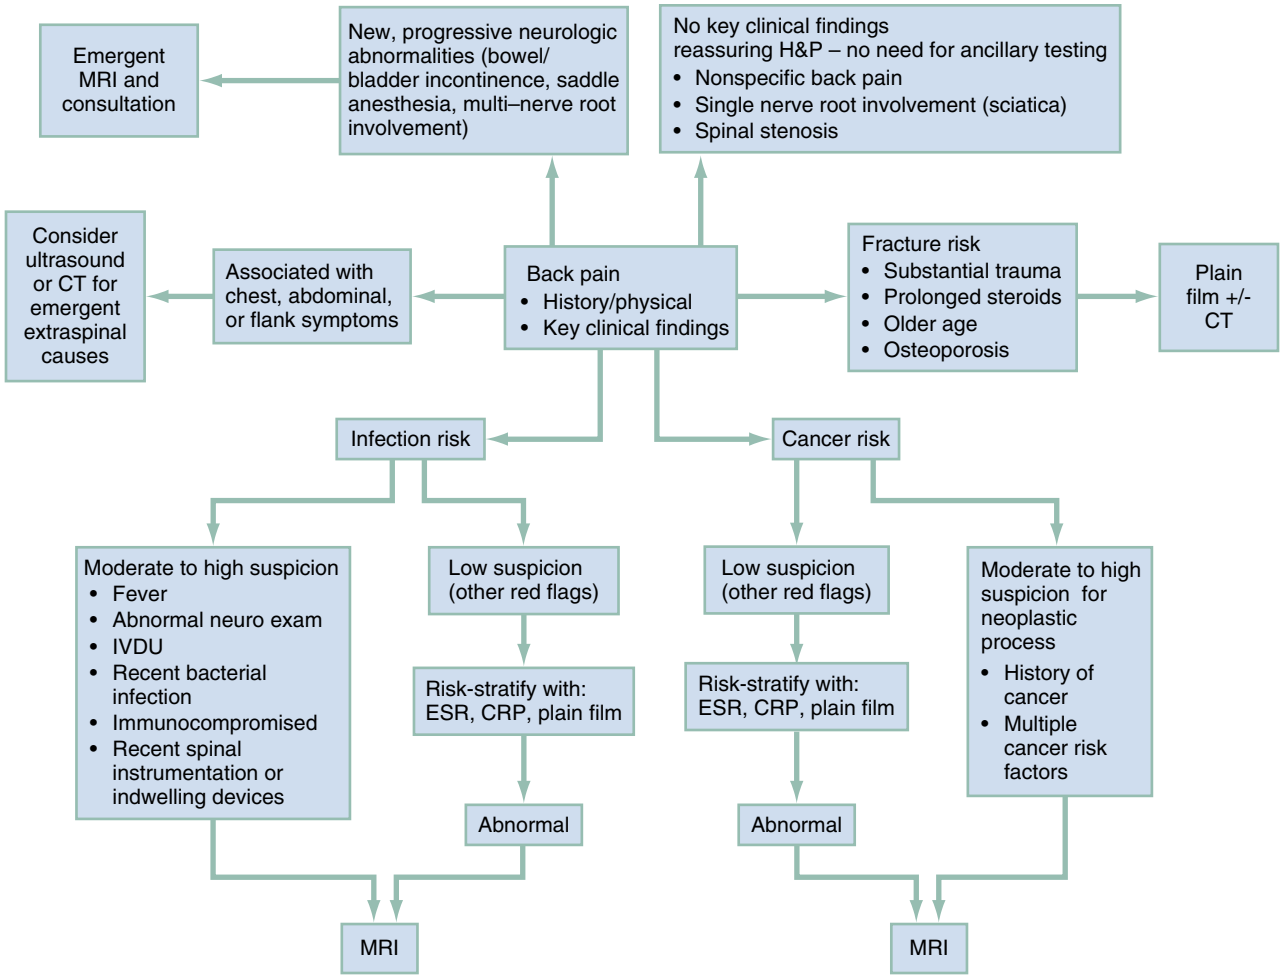

Fig. 31.2 Management of Acute Low Back Pain. *AAA,* Abdominal aortic aneurysm; *ADLs,* activities of daily living; *ASAP,* as soon as possible; *CBC,* complete blood count; *CRP,* C-reactive protein; *CT,* computed tomography; *ECG,* electrocardiogram; *echo,* echocardiogram; *ED,* emergency department; *ESR,* erythrocyte sedimentation rate; *exam,* examination; *H&P,* history and physical examination; *IVDU,* intravenous drug use; *MRI,* magnetic resonance imaging; *neuro,* neurologic; *NSAIDs,* nonsteroidal antiinflammatory drugs.

Lidocaine transdermal patches are a safe, non-sedating, effective treatment option for acute and subacute back pain, especially in patients with paraspinal muscle involvement (spasm).

Muscle relaxants, such as cyclobenzaprine, may provide short term pain-relief for patients with acute low back pain compared to placebo, though results are controversial.[19,21] There is little difference in efficacy among the various muscle relaxants, and data are insufficient to support their use in the treatment of chronic back pain. Evidence for muscle relaxants for back pain is weak compared to NSAIDs, so limit use to patients who have contraindications to NSAIDS and who can tolerate the side effects of muscle relaxants, which include anticholinergic effects, dizziness, and sedation.

Caution and careful consideration should be used when deciding to prescribe muscle relaxants in elderly patients. Decision-making should weigh possible interactions with other medications and the potential for exaggerated adverse effects in this population, including drowsiness and dizziness, which may increase fall risk.

There is no evidence for the efficacy of benzodiazepines for back pain despite frequent prescriptions.[21] Among an ED population with acute back pain, addition of diazepam to naproxen does not improve functional outcome or pain compared to naproxen alone.[22] Their effect, if any, likely is based on their anxiolytic and sedative properties, which may promote sleep and synergize pain relief. Sleep quality is related to subsequent lower back pain intensity, so benzodiazepines may be beneficial, with limited side effects, when taken at bedtime.

Combination therapy with NSAIDs and the addition of muscle relaxants, benzodiazepines, or opiates for acute mechanical back pain does not improve pain or functional outcomes when compared to NSAID monotherapy.[22–25] Benzodiazepines and opioids should never be co-prescribed due to increased risk of overdose death.[26,27] Oral and intramuscular glucocorticoids have not been shown to provide benefit in regard to musculoskeletal low back pain (with or without sciatica), activity level, or ability to return to work for patients in the ED. ED providers' decision to prescribe multiple medications is often related to self-imposed pressure to escalate care or avoid inpatient admission, despite little supporting clinical evidence.[28]

Severe Back Pain

For patients with severe acute back pain, opioid analgesics or tramadol may be considered with caution. Opioids should be considered a second-line alternative and are best used for those experiencing severe or debilitating acute back pain with inadequate or refractory control with first-line non-opioid analgesics. When indicated, parenteral opioids such as morphine or hydromorphone are the preferred analgesic

for severe pain and should be given in a titrated fashion. When administering opioids, frequently reassess the patient until an adequate response is reached, and then transition to oral agents in preparation for discharge. Prescribe the smallest quantity possible for the shortest duration possible and ensure close outpatient follow up. Consider the known side effects of opioids (e.g., constipation, confusion, sedation). Even when accounting for patient clinical characteristics, large variability exists in ED opioid prescribing practices, which highlights the need for greater adherence to established treatment guidelines.[29] Although opioids are effective for relieving pain, they do not improve functional status or health-related quality of life.[30] Early opioid prescriptions in the ED for uncomplicated acute back pain increase long-term opioid use, increase medical costs, and prolong work disability.[31,32]

Chronic Back Pain

For patients with chronic back pain, opioid treatment efficacy is less clear and should be avoided in the ED. For such patients, NSAIDs are still indicated as first-line treatment, and opioids should be considered as an adjunct for short-term pain relief only and should be avoided whenever possible. They should be referred to a pain management center, where epidural glucocorticoid injections and other potential treatments may be provided. Practice guidelines recommend considering non-pharmacologic treatments such as heat, massage, acupuncture, yoga, and mindfulness-based stress reduction, and best coordinated by patients' PCPs.[19] Utilizing ED-based physical therapists for evaluation and treatment of patients with acute and chronic back pain may hold promise for improving clinical outcomes, but is not widely implemented.[33] Combination pharmacotherapy has not been shown to be effective for acute pain, but may be effective in chronic low back pain.[25]

DISPOSITION

Patients with back pain often present to the ED with high expectations of investigations (blood work and imaging) and analgesia making adherence to management guidelines challenging. Throughout the visit, focus on patient education and reassurance of the likely benign etiology of the pain. Educate patients regarding why they are not undergoing laboratory or radiographic studies. Most patients can be convinced by education and an explanation of radiation dosing and associated deleterious effects. This advice is best delivered by the physician and will help avoid misperceptions of substandard care as well as unnecessary return visits when symptoms persist for an expected amount of time. Reassure patients by acknowledging their pain and being supportive, provide reassurance that back pain is very common and that the pain does not indicate ongoing harm or serious pathology. Provide a full explanation of the diagnosis, evaluation, treatment plan, and expected time course for recovery in terms that the patient understands. Patients can be reassured that most will experience spontaneous improvement. Avoid language that may scare the medically naive patient by implying a serious abnormality when none exists (i.e., "ruptured disc"). Consider using the term "common" or "mechanical" back pain, and avoid the term "non-specific," as it may not engender patient confidence.

The final and perhaps most important aspect of ED management of acute back pain involves discharge instructions. All patients should be given clear discharge instructions with unambiguous indications on when to return to the ED. Although patients should avoid vigorous exercise and provocative activities, complete rest should be avoided. Bed rest has been proven to be deleterious to successful recuperation from back pain, leading to decreased functional recovery and slightly increased pain compared to those advised to remain ambulatory. Remaining active will also help with muscle spasm and atrophy. However, patients with severe pain may be able to do little beyond navigating between the bedroom, bathroom, and kitchen. The perception of activity as a trigger may predispose patients to experience additional disability. It should be made clear that ongoing pain does not imply ongoing harm. Recommend continuing daily activities and gradually increasing specific exercises, as tolerated. Clarify that back pain does not need to be totally alleviated before the patient can return to work. Returning to work should be based on consideration of the actual work duties of the patient. Those with jobs involving heavy manual labor may benefit from time away from work if no light duty options are available, and ED work notes should make this distinction clear. Lastly, patients should be told to return to the ED for symptoms such as new or progressive arm or leg weakness, bowel or bladder dysfunction, or saddle anesthesia, since these findings may be absent in early presentations of emergent pathologies.

CHAPTER 31: QUESTIONS & ANSWERS

1. What is the most likely cause of back pain in a 48-year-old patient with bilateral leg pain and weakness, urinary retention, decreased rectal tone, and saddle anesthesia?
   a. Abdominal aortic aneurysm
   b. Bone metastasis
   c. Epidural abscess
   d. Herniated disk
   e. Primary bone tumor

Answer: d. The listed symptoms and signs describe cauda equina syndrome, which is usually caused by a large central herniated disk. Other less common causes include tumor and infection.

2. What percentage of asymptomatic persons less than 60 years old will have herniated disc findings on MRI?
   a. 10%
   b. 25%
   c. 50%
   d. 75%

Answer: b. Disc disease is a component of normal aging and is a very nonspecific finding. In fact, one in four asymptomatic persons <60 years and one in three >60 years will have MRI findings of a herniated disc.

3. A 35-year-old man presents with severe back pain that radiates down his right leg. He reports that while lifting a heavy box at work 2 weeks ago, he felt a "pop" in his lower back. He has not been able to return to work since the injury occurred. The patient spoke with his lawyer and was told to come directly to the emergency department to get an magnetic resonance imaging (MRI). He denies having any other symptoms and reports no significant past medical history. During the physical examination, the patient is asked to lie on his back, with his knees extended. His right leg is elevated and, at 50 degrees, he reports severe pain running down the lateral aspect of his right leg to his foot. The patient is then asked to sit with his knees flexed and legs hanging over the side of the bed. His legs are passively extended, with no production of pain. The remainder of the physical examination is normal. What is the most appropriate next step in managing this patient?
   a. Computed tomography (CT) of the lumbar spine
   b. Discharge home
   c. Emergent neurosurgical consultation
   d. MRI of the lumbar spine
   e. Radiography of the lumbar spine

Answer: b. Several aspects of this scenario point to malingering. The most convincing relates to the physical examination findings. The straight leg raise (SLR) is the classic test for sciatic nerve root irritation. The absence of a positive result generally rules out nerve root irritation. To perform the SLR, the patient is positioned supine, knee extended, and leg elevated until pain is elicited. A positive result is pain radiating down the leg below the knee in a dermatomal distribution when the leg is elevated between 30 and 70 degrees. In a patient who may be malingering, the SLR can be performed with the patient sitting on the side of the bed with knees flexed. Passively straightening the legs in this position should produce equally positive results if true nerve root irritation exists.

4. Disk herniation with involvement of the L5 nerve root will present with which of the following findings?
   a. Decreased or absent ankle jerk
   b. Decreased patellar reflex
   c. Diminished sensation of the lateral small toe
   d. Impaired plantar flexion
   e. Weakness with extension of the great toe

Answer: e. Involvement of the L5 nerve root presents with weakness, with extension of the great toe, decreased sensation in the first web space, and normal reflexes. An S1 radiculopathy is characterized by diminished sensation of the lateral small toe, impaired plantar flexion, and decreased or absent ankle jerk. The patellar reflex is associated with L2–4.

5. A history of IV drug use increases the risk for which of the following causes of acute back pain?
   a. Abdominal aortic aneurysm
   b. Epidural hematoma
   c. Malignancy
   d. Transverse myelitis
   e. Vertebral osteomyelitis

Answer: e. Vertebral osteomyelitis and spinal epidural abscess are diagnosed most frequently in an at-risk population that includes patients with a history of diabetes, chronic renal failure, IV drug use, alcoholism, cancer, AND recent surgery or trauma.

6. Spinal epidural abscess is most commonly caused by which of the following pathogens?
   a. *Mycobacterium tuberculosis*
   b. *Pseudomonas aeruginosa*
   c. *Staphylococcus aureus*
   d. *Staphylococcus epidermidis*
   e. *Streptococcus pyogenes*

Answer: c. *S. aureus* causes 70% of spinal epidural abscesses.

32

Multiple Trauma

Andrea C. Sharp and Leslie V. Simon

KEY CONCEPTS

- Immediately after a trauma patient arrives the emergency department (ED), the primary survey should be performed in a standardized fashion. The goal of the primary survey is to rapidly identify and initiate the treatment of critical, and life-threatening injuries.
- The extended Focused Assessment with Sonography for Trauma (eFAST) examination should be performed early in the evaluation of the trauma patient (ideally as part of the primary survey). Thoracic examination of the trauma patient by ultrasound is more accurate than plain radiography.
- Any patient with potentially life-threatening injuries should have blood typing and screening performed. When transfusion is indicated, blood products should be transfused in a 1:1:1 or 1:1:2 ratio of plasma to platelets to packed red blood cells.
- Tranexamic acid (TXA) is indicated for patients with evidence of significant hemorrhage or shock and is given as a 1-g intravenous bolus followed by a 1-g infusion over 8 h. Results are best if started within an hour of injury but benefit may occur when it is given within 3 h.
- Special consideration should be given to the elderly who demonstrate increased morbidity and mortality in settings where traumatic injury initially appear less concerning. Patients over the age 65 with one or more of the following comorbid conditions (coagulopathy, cirrhosis, COPD, CAD, or DM) have more than twice the mortality risk than younger patients.

FOUNDATIONS

Background and Importance

Unintentional injury remains the leading cause of death in persons 1 to 44 years of age.[1,2] Each day, approximately 9 people are killed and more than 1000 injured by distracted drivers that have led to new laws prohibiting texting while driving. Firearm-related deaths are a significant concern, especially in the United States.[1,3] The economic cost of traumatic injuries and death (medical costs and lost productivity) is estimated in the hundreds of billions of dollars.[1,4]

Stabilization, evaluation, and treatment of trauma patients are central to the practice of emergency medicine. Effective management of critically ill trauma patients requires decisiveness, technical skill, and effective leadership. A methodical, team-based approach is necessary, capitalizing on a strong clinical partnership between emergency medicine and surgery. Coordination with emergency medical services (EMS) providers, nursing, radiology, and other trauma-related specialties is needed to optimize outcomes. Prompt and safe transfer to the operating room requires collaboration and effective communication with other specialists such as surgeons, and anesthesiologists.

Anatomy, Physiology, and Pathophysiology

In blunt trauma victims, the mechanism of injury can be associated with particular injury patterns. These are listed in Table 32.1. Knowledge of these associations can help the clinician evaluate for injuries that may not be readily identified by initial examination.

Older patients commonly sustain extremity, craniofacial, and closed head injuries. Most of these occur as a result of a fall or motor vehicle collision (MVC). Thirty million older adults fall each year, resulting in about 30,000 deaths. Older trauma patients typically have comorbid illnesses, usually on medications (especially anticoagulants), and also have age-related changes in organ-system function. These factors can increase susceptibility to injury, morbidity, and mortality. Obese patients are also at risk for increased morbidity and mortality from trauma.[5]

In penetrating trauma from knife wounds or injuries from low-velocity sharp objects, tissue damage can be expected to occur primarily along the track of the object. However, the type and severity of injuries inflicted by gunshot wounds depend on several factors. The amount of tissue damage is related to the kinetic energy of the bullet, which is a factor of the bullet weight (caliber) and velocity. Gunshot wounds cause trauma to the surrounding tissue by direct laceration, crush injury, shock waves, and cavitation—the displacement of tissue forward and radially. Owing to these dynamic forces, high-velocity weapons, such as rifles, cause more widespread injuries than low-velocity weapons (handguns). Similar to knives, handgun bullets and shotgun pellets (from long range) generally cause injury based on direct laceration and crush generated by the missile along its track. Shotgun wounds from close range are characterized by massive tissue injury.

CLINICAL FEATURES

Primary Survey

A focused and methodical primary survey should be initiated immediately in the emergency department (ED). The goal of the primary survey is to diagnose critical, life-threatening injuries rapidly, and begin treatment at the time of diagnosis. Figs. 32.1, 32.2, and 32.3 show the recommended algorithms for the evaluation of airway, breathing, and circulation. Fig. 32.4 highlights special considerations between blunt

TABLE 32.1 Blunt Trauma Mechanisms and Associated Injuries

Mechanism of Injury	Additional Considerations	Potential Associated Injuries
Motor Vehicle Collisions		
Head-on collision		Facial injuries Lower extremity injuries Aortic injuries
Rear end collision		Hyperextension injuries of cervical spine Cervical spine fractures Central cord syndrome
Lateral (T-bone) collision		Thoracic injuries Abdominal injuries—spleen, liver Pelvic injuries Clavicle, humerus, rib fractures
Rollover	Greater chance of ejection Significant mechanism of injury	Crush injuries Compression fractures of spine
Ejected from vehicle	Likely unrestrained Significant mortality	Spinal injuries
Windshield damage	Likely unrestrained	Closed head injuries, coup and countercoup injuries Facial fractures Skull fractures Cervical spine fractures
Steering wheel damage	Likely unrestrained	Thoracic injuries Sternal and rib fractures, flail chest Cardiac contusion Aortic injuries Hemothorax, pneumothorax
Dashboard involvement or damage		Pelvic and acetabular injuries Dislocated hip
Restraint or seat belt use		
Proper three-point restraint • Lap belt only • Shoulder belt only	Decreased morbidity	Sternal and rib fractures, pulmonary contusions Chance fractures, abdominal injuries, head and facial injuries and fractures Cervical spine injuries and fractures, "submarine" out of restraint devices (possible ejection)
Air bag deployment	Front end collisions Less severe head and upper torso injuries Not effective for lateral impacts More severe injuries in children (improper front seat placement)	Upper extremity soft tissue injuries and fractures Lower extremity injuries and fractures
Pedestrian Versus Automobile		
Low speed (braking automobile)		Tibia and fibula fractures, knee injuries
High speed		Waddel's triad—tibia and fibula or femur fractures, truncal injuries, craniofacial injuries Thrown pedestrians at risk for multisystem injuries
Bicycle		
• Automobile-related		Closed head injuries Handlebar injuries • Spleen or liver lacerations • Additional intra-abdominal injuries • Consider penetrating injuries
• Non–automobile-related		Extremity injuries Handlebar injuries
Falls	LD_{50}, 36–60 ft.	
Vertical impact		Calcaneal and lower extremity fractures

Continued

TABLE 32.1 Blunt Trauma Mechanisms and Associated Injuries—cont'd

Mechanism of Injury	Additional Considerations	Potential Associated Injuries
		Pelvic fractures
		Closed head injuries
		Cervical spine fractures
		Renal and renal vascular injuries
Horizontal impact		Craniofacial fractures
		Hand and wrist fractures
		Abdominal and thoracic visceral injuries
		Aortic injuries

LD_{50}, Height of fall that would be fatal for 50% of those falling.

and penetrating mechanisms that should be considered during the primary survey.

In the absence of obvious direct trauma involving the airway, management decisions are based on the overall patient condition and potential for deterioration. Following initial airway assessment, decisions surrounding airway management should focus on the ability of the patient to protect their airway, adequacy of ventilation and oxygenation, and anticipated clinical course.

Inadequate ventilation, which may lead to respiratory acidosis, can be noted by the rate and quality of respirations and can be monitored using end-tidal carbon dioxide monitoring. Pulse oximetry will detect inadequate oxygenation, which may manifest clinically as agitation and restlessness, as opposed to hypercapnia which usually manifests as somnolence. Assessment of injuries that may compromise oxygenation or ventilation requires careful inspection and auscultation of the chest and may be augmented by use of point-of-care ultrasound. Signs of such compromising injury include increased work of breathing, tachypnea, penetrating wounds, subcutaneous emphysema, chest wall instability, flail segments, tracheal deviation, and distended neck veins. See Fig. 32.2.

Assessment of hemodynamic and circulatory status (see Fig. 32.3) follows evaluation of the airway and ventilation. Clinical indicators of adequate perfusion include normal mental status, skin color and temperature, heart rate, blood pressure, and capillary refill. However, a normal finding for any single sign does not rule out significant hemorrhage or even shock. Mental status changes associated with hypoperfusion can include anxiety, agitation, and depressed consciousness. Cool pale skin or extremities with delayed capillary refill suggest inadequate perfusion and shock. Vital signs can be misleading in well-conditioned athletes and children. Medications may also blunt expected physiologic responses. A normal heart rate, blood pressure, or both can be present, despite significant hemorrhage. Conversely, tachycardia could be seen without significant volume loss.

Traditionally, direct pressure to external bleeding sites was advocated, while the use of tourniquets was discouraged. While direct pressure remains first-line therapy, there is good evidence to support the early use of tourniquets for massive extremity hemorrhage that is not otherwise easily controlled.[6–9] Similarly, studies of newer hemostatic agents have shown potential application in combat and out-of-hospital settings.[6,10]

Early intravenous (IV) access is required in the assessment of circulation. Two short, large-bore (14- or 16-gauge) IV catheters are preferred. Routine IV access may be difficult or unobtainable in certain cases. Intraosseous (IO) vascular access can be obtained rapidly in pediatric and adult patients, and this allows the safe infusion of large amounts of fluid or blood products.[11,12] Battery operated drills are widely available and can facilitate IO placement. Ultrasound-guided peripheral venous access by nurses and emergency clinicians should be considered in patients with challenging peripheral vascular anatomy.[13] Central venous access may also be indicated in the appropriate clinical scenario or based on the emergency clinician's discretion. The use of ultrasound has been shown to increase successful vein cannulation and decrease complications in the placement of central venous lines.[14,15] A straight leg raise test or real-time ultrasound of the vena cava can be performed to determine adequacy or response to resuscitation.[16] An extended, focused, abdominal sonography in trauma (eFAST) examination should be performed on all patients during transition from the primary to secondary survey.[17–19]

Secondary Survey

The secondary survey begins once the primary survey is complete, immediate life threats have been addressed, and resuscitation efforts are in place. The goals of the secondary survey are to: (1) obtain pertinent historical data about the patient and injury; and (2) identify and manage all significant injuries by performing a systematic, complete examination. An AMPLE (***a***llergies, ***m***edications, ***p***ast medical history, ***l***ast meal, ***e***nvironments and events) history should be obtained. Trauma is a dynamic process, requiring frequent reassessment of level of consciousness, airway, circulatory, and pain status throughout the emergency phase of management. If deterioration occurs, a complete reevaluation of the primary survey should be initiated. Features of the secondary survey, with critical and emergent diagnoses, are listed in Table 32.2. Concurrently with the primary and secondary survey, oxygenation is enhanced as necessary, appropriate IV access is established, and volume resuscitation is initiated. On completion of the secondary survey, diagnostic laboratory and a more extensive radiographic evaluations commence.

DIFFERENTIAL DIAGNOSES

The differential diagnoses of injury to the airway or chest that might compromise ventilation or breathing is finite. Circulation problems have a variety of potential causes. Figs. 32.2 and 32.3 outline the approach to emergent diagnoses in the critically ill trauma patient. The early assessment of a trauma patient's circulatory status is crucial and includes hemorrhage control. An algorithmic approach is designed to localize the cause, as well as direct intervention. In victims of blunt trauma, the goal of management often focuses on localizing the injury to: (1) obvious external hemorrhage; (2) long bone fractures; (3) pelvic fractures; or (4) internal hemorrhage.

The goal of the initial assessment in the ED is to determine whether the patient is in shock. If so, the decision making process turns to an assessment of volume status. If the patient is hypovolemic, immediate

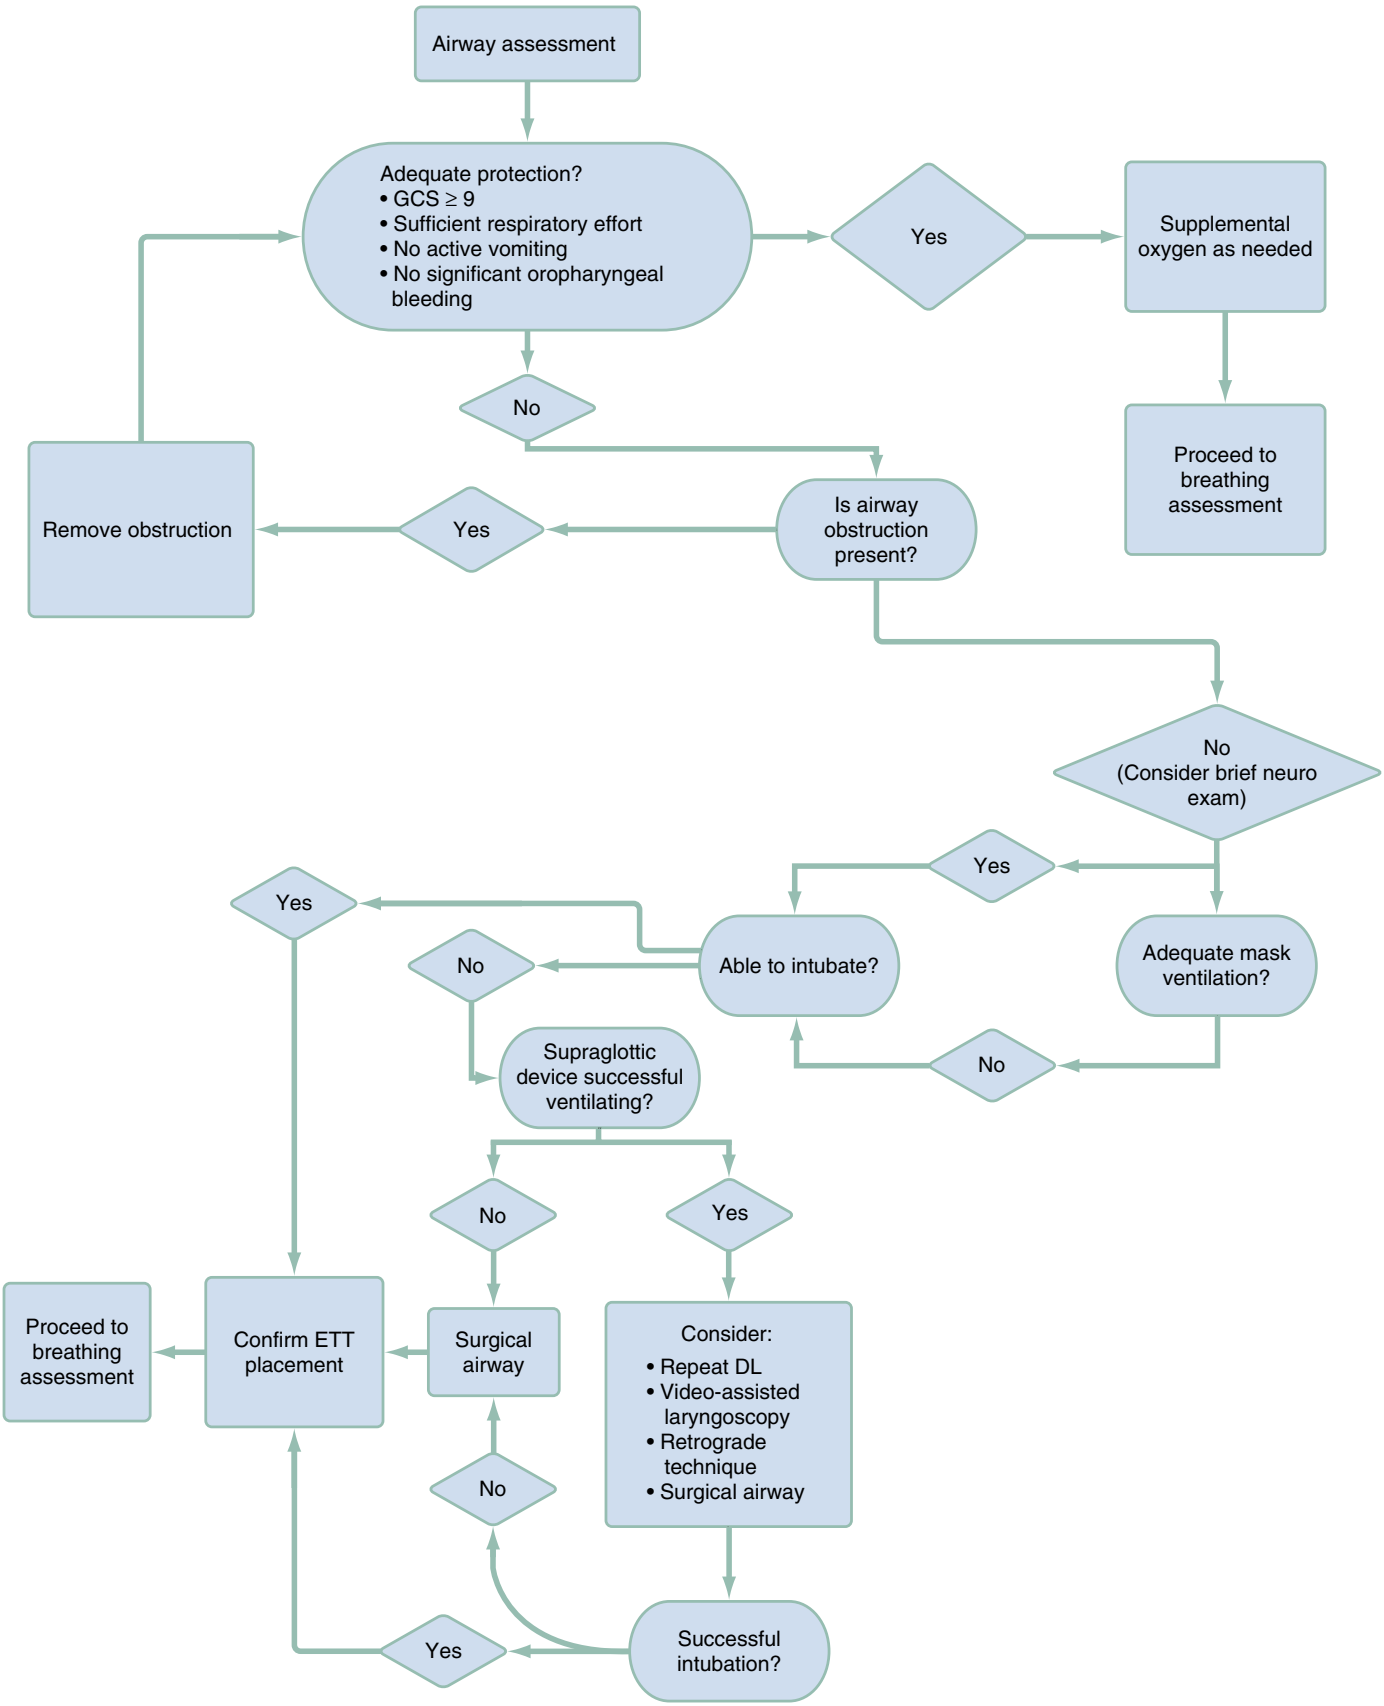

Fig. 32.1 Airway Assessment Algorithm. *DL,* Direct laryngoscopy; *ETT,* Endotracheal tube; *neuro,* neurologic.

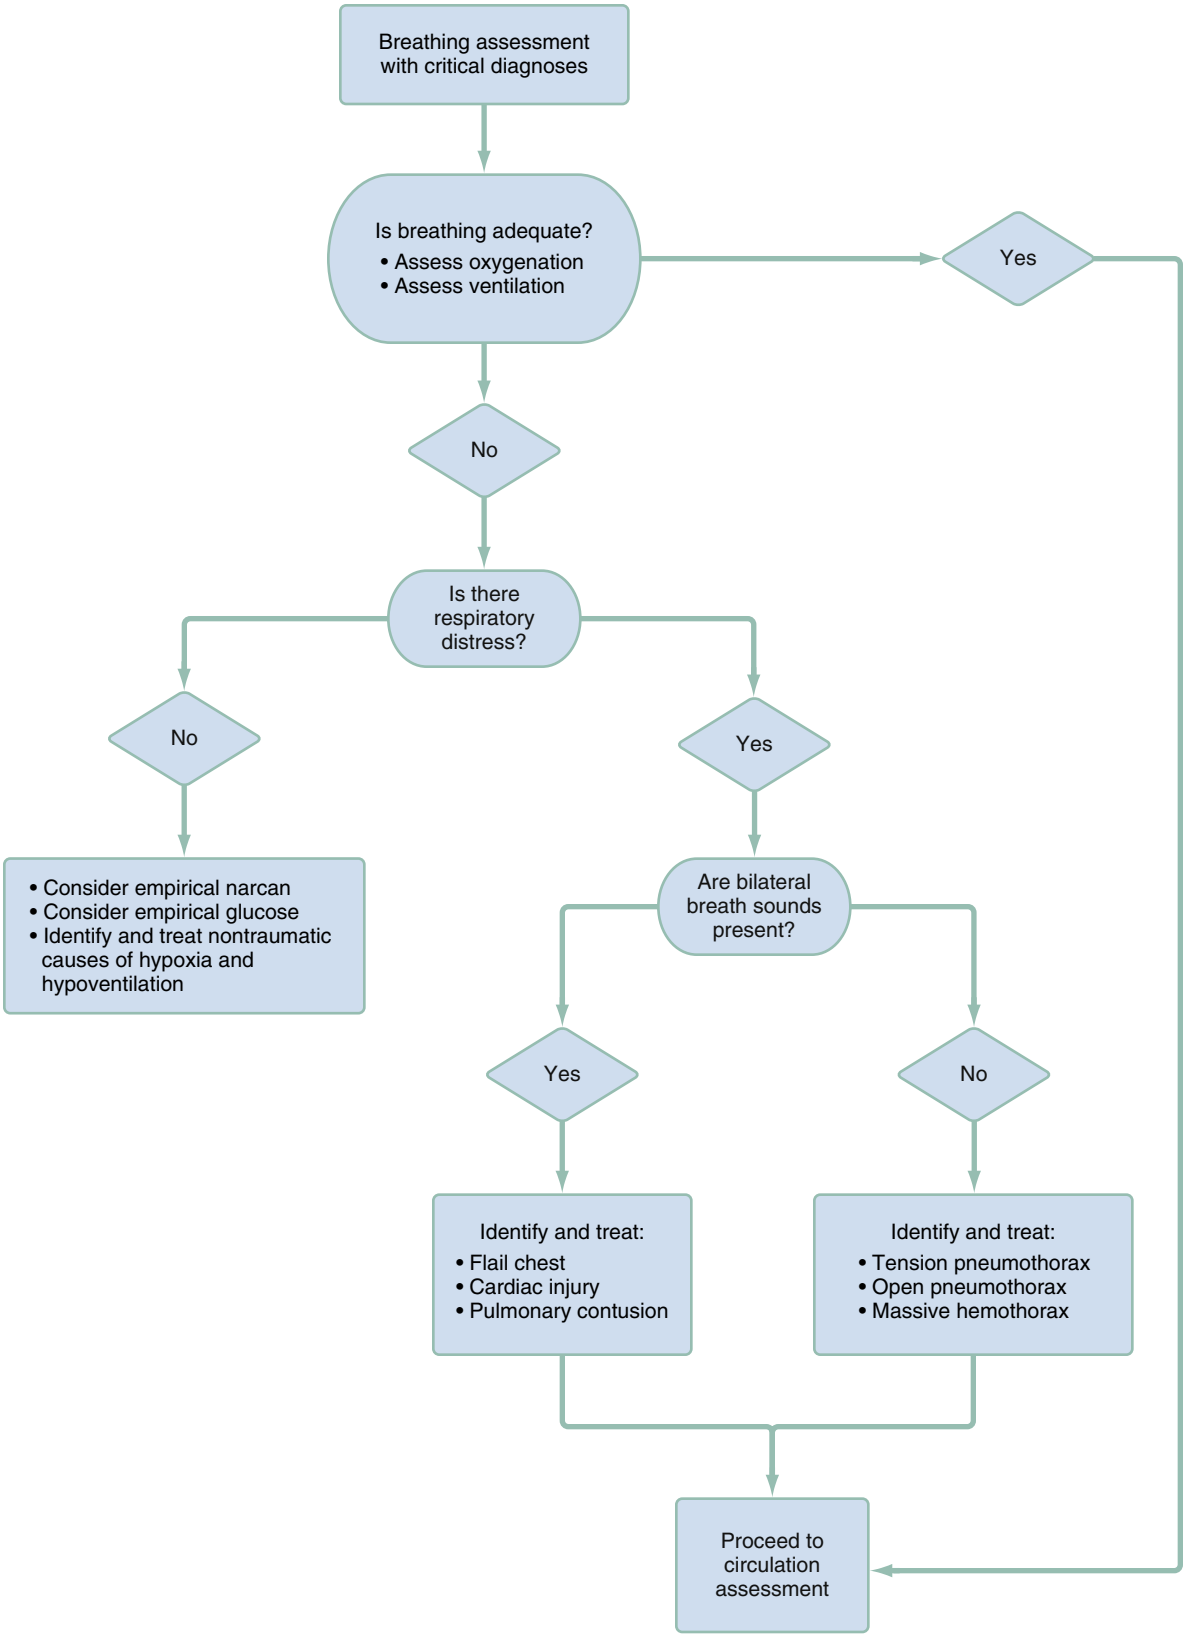

Fig. 32.2 Breathing Assessment Algorithm.

resuscitation is initiated. Hemorrhagic shock prompts the emergency clinician to rapidly locate the source of bleeding and target interventions, with ongoing reassessment.

Although mechanisms of injury alone cannot be relied on to predict all injuries caused by blunt major trauma,[18] common patterns of injuries can be anticipated and specifically assessed in ED patients (see Table 32.1). Although these injuries may be present, there is frequently significant overlap between mechanism and injury. In this section, the differential diagnoses of various presentations are discussed.

TABLE 32.2 Secondary Survey of Trauma Patients

Region or System	Assessment or Examination	Critical Diagnoses	Emergent Diagnoses
General	Level of consciousness	GCS ≤8	
	Glasgow Coma Scale (GCS) score	Focal motor deficit	
	Specific complaints		
Head	Pupils (size, shape, reactivity, visual fields)	Herniation syndrome	Globe rupture
	Contusions		
	Lacerations		
	Evidence of skull fracture (hemotympanum, Battle's sign, raccoon eyes, palpable defects)		Open skull fracture Cerebrospinal fluid leak
Face	Contusions		
	Lacerations		
	Midface instability	Airway obstruction due to bleeding	Facial fractures
	Malocclusion		Mandible fracture
Neck (maintain cervical immobilization)	Penetrating injury, lacerations		
	Tracheal deviation	Carotid injury	
	Jugular venous distention	Pericardial tamponade	
	Subcutaneous emphysema	Tracheal, laryngeal fracture	
	Hematoma	Vascular injury	
	Midline cervical tenderness	Cervical fracture, dislocation	
Chest	Respiratory effort, excursion	Impending respiratory failure	
	Contusions		Cardiopulmonary injury
	Lacerations		Intrathoracic injury
	Focal tenderness, crepitus		Rib fractures
	Subcutaneous emphysema	Flail chest	Pneumothorax
	Heart tones (muffled)	Cardiac tamponade	
	Breath sounds (symmetric)	Tension pneumothorax	Pneumothorax Hemothorax
Abdomen, flank	Contusions		Solid, hollow viscous injury
	Penetrating injury, lacerations	Intra-abdominal hemorrhage	Solid, hollow viscous injury
	Tenderness	Intra-abdominal hemorrhage	Solid, hollow viscous injury
	Peritoneal signs	Abdominal catastrophe	
Pelvis, genitourinary	Contusions	Pelvic hemorrhage	
	Lacerations		Urogenital injury
	Stability, symphyseal tenderness	Unstable pelvic fracture Pelvic hemorrhage	
	Blood (urethral meatus, vaginal bleeding, hematuria)	Unstable pelvic fracture	Urethral injury
	Rectal examination	Colorectal injury (bleeding)	Urethral injury (high-riding prostate)
Neurologic, spinal cord	Midline bony spinal tenderness	Spinal fracture, dislocation	
	Mental status	Epidural hematoma Subdural hematoma	Cerebral contusions Shear injury
	Paresthesias		Spinal cord injury, contusion Nerve root injury
	Sensory level	Spinal fracture, dislocation	
	Motor function, including sphincter tone	Spinal fracture, dislocation	
Extremities	Contusions	Compartment syndrome	Rhabdomyolysis
	Lacerations	Vascular injury	
	Deformity	Neurovascular injury	Fracture
	Focal tenderness		Fracture
	Pulses	Arterial injury	
	Capillary refill	Hemorrhagic shock Arterial injury	
	Evaluation of compartments	Compartment syndrome	

Victims of trauma often present with altered mental status. Underlying medical issues may lead to traumatic injury. These include acute intoxication with pharmaceutical agents, drugs or alcohol, seizures, strokes, cardiac events, and behavioral/mental health conditions. Drug and alcohol testing can be misleading in the setting of altered mental status, and should not delay emergent head computed tomography (CT) when serious head trauma is suspected. Hypoglycemia causes depression of mental status and can be an inciting factor in major trauma. Point of care glucose testing should be assessed in the field and confirmed upon arrival in the ED. Minor mechanisms of injury with significant mental status changes may be a clue to a concomitant nontraumatic cause of altered mental status in these patients. Anticoagulants increase the risk of significant bleeding in patients with traumatic injuries. Therefore, patients on warfarin, other anticoagulants or antiplatelet agents should undergo neuroimaging with even minor mechanisms of injury.[20]

Hypotension is a significant finding in the acute trauma patient and requires a thorough evaluation for hemorrhagic shock. If hypotension persists and no clear source of hemorrhage is identified, other causes of hypotension must be considered. Obstructive shock due to tension pneumothorax, cardiac tamponade, or other causes can be quickly assessed using point of care ultrasound. Neurogenic shock, associated with a spinal cord injury, is less likely in the absence of paralysis but should be considered when other causes of shock have been excluded. If hypotension is present and no clear cause has been identified, diagnoses to be considered include: (1) acute myocardial infarction and cardiogenic shock due to severe myocardial contusion or underlying cardiac abnormalities, or (2) hypotension caused by preexisting sepsis or blood loss (e.g., gastrointestinal [GI] bleed). Multiple causes of shock may coexist simultaneously in the same patient and finding one etiology should not curtail the search for other causes.

Finally, a critical tenet of trauma management is to avoid distraction by what might appear as an obvious injury. Traumatic amputations, gaping wounds, complex open fracture dislocations, and combative patient behavior frequently distract providers from their structured trauma evaluation allowing occult but perhaps more lethal findings to be missed. Approaching every patient in a systematic way, using the primary and secondary surveys, will help prevent overlooking significant acute injuries. Similarly, complete exposure and a head-to-toe examination of the trauma patient will identify otherwise occult injuries, which may be concealed on the back, axilla or perineum of the patient.

DIAGNOSTIC TESTING

Laboratory Evaluation

Laboratory testing in the trauma patient should be guided by clinical assessment and the dynamic needs of the individual patient. Used wisely, these diagnostic studies may provide an objective measure of the adequacy of resuscitation, guide transfusion decisions, assess for coagulopathy, provide baseline information for ongoing assessment, and aid in the management of comorbid conditions, such as renal impairment and diabetes mellitus. Electrolyte levels, liver function studies, international normalized ratio (INR), urinalysis, blood typing and screening (or cross-matching, depending on severity of injury), lactate levels, and base deficit should be determined in all critically ill trauma patients. A pregnancy test should be performed in all female trauma patients of childbearing age. Serum β-human chorionic gonadotropin (β-hCG) testing can avoid the delays in obtaining a urine specimen.

Lactate level, base deficit, and anion gap determinations can help identify subclinical hypoperfusion and track the adequacy of resuscitation.[21,22] Serial serum lactate levels are useful in assessing resuscitative efforts in trauma patients with abnormal vital signs or other findings suggestive of hypovolemia (see Table 32.1).

A type and screen are indicated for those patients with abnormal vital signs thought to be due to injury or mechanisms with risk for occult injury. If transfusion is needed prior to cross-matched blood being available, the provider can temporize with type-specific blood or type O-negative in women of childbearing age or type O-positive in other patient groups.

An INR should be ordered in all patients with critical injuries, with ongoing hemorrhage requiring transfusion, and on anticoagulants. The INR, however, does not provide a rapid comprehensive picture of the clotting process.[23,24] In patients with extensive bleeding or undergoing massive transfusion, thromboelastography (TEG) or thromboelastometry (ROTEM) testing is used to aid the early diagnosis of trauma coagulopathies and direct blood and blood product transfusion.[25] These evaluations are most beneficial for patients undergoing massive transfusion therapy.[26]

Radiographic Evaluation

The initial approach to radiological evaluation of the trauma patient includes selective use of portable plain radiography, bedside ultrasound (eFAST), and CT scanning.

An eFAST examination should be performed on all patients with multisystem trauma or isolated trauma to the torso. Sonographic evidence of free intra-abdominal fluid, pelvic hemorrhage, hemo- or pneumothorax, and pericardial effusions or cardiac tamponade directs surgical management of the patient. An abdominal with relevant findings for free fluid in hypotensive patients can identify those in need of emergent laparotomy, with good sensitivity.[19] Of note, the absence of intraperitoneal fluid on bedside ultrasound does not rule out intra-abdominal or retroperitoneal injury.[27,28]

Cervical spine imaging by plain radiographs in the trauma bay is of limited value and has been largely supplanted by cervical spine imaging by CT. Patients with neurologic deficits are presumed to have spinal cord injury until proven otherwise, and a normal reading on a cervical spine radiograph is not sufficient to rule out injury. In these patients, vigilant spinal precautions should be continued.[29,30] Decision rules such as the Canadian or NEXUS (***N***ational ***E***mergency ***X***-Radiography ***U***tilization ***S***tudy) criteria may be used to reduce unnecessary imaging in selected patients. When a patient is not cleared using these criteria, a CT scan of the head and cervical spine should be obtained. If the neurologic examination is normal, a normal CT scan of the cervical spine is sufficient to exclude injury and further imaging is not necessary.[29]

Imaging of the chest early in the evaluation of the multiple trauma patient can provide important information concerning potentially life-threatening injuries. In the hands of a proficient user, ultrasound is superior to a supine portable chest x-ray as initial screening tool for pneumothorax and hemothorax.[27,31] Thoracic ultrasound should be used early in the evaluation of thoracic trauma; it can be supplemented with chest x-ray.[31] However, a normal chest x-ray does not exclude intrathoracic injury as sensitivity for intrathoracic injury is low.[32] Chest CT imaging should be performed in those with significant chest pain, dyspnea, sternal tenderness, or abnormal thoracic ultrasound or chest x-ray findings. Chest CT is not required in stable, asymptomatic blunt trauma victims with a normal chest x-ray.[33]

There is evidence that thoracic imaging can be avoided altogether in blunt trauma patients with very low risk of thoracic injury. The criteria for obtaining imaging in one large validation study are: (1) age above 60 years, (2) rapid deceleration mechanism, (3) chest pain, (4) drug or alcohol intoxication, (5) abnormal alertness and mental status,

(6) distracting painful injury, and (7) tenderness to chest wall palpation. This rule has a sensitivity of 99.8% and negative predictive value of 98.5%.[33]

In patients with a stab wound to the chest and an initial normal thoracic ultrasound or chest X-ray, routine use of chest CT is not indicated.[34] To exclude significant pathology, asymptomatic patients can undergo a repeat chest x-ray within an hour, rather than the traditional 6 hours after an initial normal chest x-ray.

Pelvic fractures can cause significant hemorrhage, and early recognition of fracture and closure of the pelvic space can mitigate hypotension in these patients. In hemodynamically unstable patients, a portable pelvic x-ray should be obtained in the trauma bay. The sensitivity for an anteroposterior pelvic x-ray to identify all possible fractures is not high; however, an abnormal x-ray showing an obvious open book fracture or vertical displacement of the posterior pelvis should alert the emergency clinician to the need for a pelvic binder and emergent embolization or surgical fixation to control ongoing pelvic hemorrhage. Hemodynamically stable patients with pelvic tenderness or a distracting injury, or those with severe mechanisms of injury and altered mental status, should have their pelvis imaged. If the patient is undergoing CT scanning of the abdomen and pelvis as part of the trauma assessment, we recommend using the bone windows of the CT scan rather than obtaining a pelvic x-ray. Hemodynamically stable patients who are awake, alert, and asymptomatic, with a normal pelvic physical examination, do not require pelvic imaging.[35]. Pelvic injuries in the elderly population presents particular challenges. Even stable injury patterns may require administration of blood products. Pelvic injuries in the elderly result in increased hospital lengths of stays, prolonged immobilization with associated complications, and increased rehabilitation needs. In patients greater than 65 years, a 30% 1-year mortality has been demonstrated with pelvic injuries and 40% after 3 years. This increases significantly to an over 80% 3-year mortality in patients greater that 85 years. Further discussion of pelvic trauma can be found in Chapter 46

In victims of blunt trauma, imaging with an abdominal-pelvic CT scan (AP-CT) is recommended for those with abdominal pain or tenderness, significant mechanism of injury (see Table 32.1), abnormal eFAST examination, gross hematuria, or an unreliable examination (e.g., altered mental status, distracting injury, or head injury). The presence of a seat-belt sign is associated with an internal abdominal injury (IAI) and should prompt CT imaging. Blunt multiple trauma victims who have a Glasgow Coma Scale (GCS) score of 15, normal abdominal physical examination, negative eFAST, and normal laboratory results can forego a CT scan; however, they should have a period of observation, with a repeat eFAST examination, and repeat hemoglobin level determination.

Indications for imaging of the head, spine, and extremities are covered in their respective chapters. Patients with moderate or severe head injury should have their head imaging completed as soon as possible after the primary survey, eFAST examination, and brief secondary survey. Imaging of the thoracic and lumbar spines and extremities can be delayed until other life-threatening injuries have been investigated and managed.

MANAGEMENT

Out-of-Hospital Management

Management of the trauma patient generally begins by first responders before arrival in the ED. The goals of out-of-hospital care include immediate intervention in life-threatening injuries, prevention of additional injury, and rapid transport to designated trauma centers for definitive care.

Most life-threatening injuries that require intervention by out-of-hospital providers are related to airway, breathing, and circulation stabilization. Endotracheal intubation or placement of an extraglottic device may be required for patients with severe trauma, particularly head trauma with coma, and for when transport times may be prolonged. Tension pneumothorax compromises ventilation and perfusion and requires emergent needle or other thoracostomy when suspected. Systemic hypotension with impaired end-organ perfusion necessitates restoration of intravascular volume to a level sufficient to provide perfusion, but not an attempt to restore normal blood pressure.

Preventing additional injury requires an awareness of both clinically evident abnormalities and potentially life-threatening injuries. Coordinated extrication and transport with cervical spine immobilization, spinal precautions, intensive hemodynamic monitoring, and stabilization of fractures to prevent neurovascular compromise are examples of assuming that serious injuries may exist in multiple trauma patients. First responders may treat the patient with IV analgesic medications of sedatives to aid in patient comfort or safety during transport.

Emergency Department Management

As victims of multiple trauma have a variety of injuries from varying mechanisms, the initial focus is directed at overall resuscitative care, with emphasis on performing interventions in a methodical and consistent sequence.

For level 1 trauma centers, the American College of Surgeons (ACS) requires the presence of a board-certified general surgeon to be present in the hospital 24 hours each day. The trauma surgeon is expected to be present in the ED no later than 15 minutes after arrival of trauma patients to the ED (Box 32.1).[4] Most trauma resuscitations in the community are performed by emergency clinicians, with consultation by a surgeon or surgical subspecialist based on specific identified injuries.

As for any other life-threatening condition, the first priorities in the treatment of trauma patients are: securing the airway, maintaining ventilation, controlling hemorrhage, and treating shock.

The goals of airway management are threefold—airway protection, adequate oxygenation, and adequate ventilation. The decision to intubate may go beyond these three tenets because of the potential for deterioration in clinical status. Patients may have an obvious need for early intubation identified during the primary survey. Others will have serious injuries detected later in their evaluation or will have deteriorated and require subsequent intubation and airway management. Still others will require intubation based on their overall clinical course and constellation of traumatic injuries, rather than for any one clear indication.

Airway protection is necessary for many trauma patients. Airway obstruction necessitates immediate intervention. Obstruction from debris, blood, or vomitus may be removed with suction. Neck or facial trauma may cause more complicated scenarios. Swelling, distorted

BOX 32.1 American College of Surgeons Requirements for the Presence of a Surgeon in Major Resuscitations

A surgeon should be present in the emergency department on trauma patient arrival or within 15 min if any of the following major criteria are found:

- Confirmed hypotension (systolic blood pressure <90 mm Hg)
- Gunshot wounds to the neck, chest, abdomen, or proximal extremities
- Intubated patients transferred from the scene
- Respiratory compromise requiring an emergent airway
- Penetrating gunshot wound to the neck, chest, abdomen, or pelvis
- Glasgow Coma Scale score <8 attributed to trauma
- At the discretion of the emergency clinician

anatomy, and hematoma formation may all contribute to impending airway obstruction. Early airway control is safest because these conditions may rapidly worsen. However, there is shift in emphasis from intubation first, to circulation first to prevent peri-intubation hypotension.[36,37] The inability to protect the airway adequately, such as in patients with depressed levels of consciousness, is another indication for intubation. Airway control is recommended for patients with depression of consciousness sufficient to compromise airway protection (usually associated with a GCS score <9).[34] Alcohol intoxication can be an important confounder in the early neurologic assessment of these patients. In patients who do not immediately require airway protection, close observation over time for neurologic recovery to a normal state is recommended.

An attempt to maximize resuscitative efforts should be made prior to administration of RSI medications when possible.

When oxygenation is compromised, face mask oxygen at a high flow rate is required. Restoring adequate oxygenation has a direct effect on the outcome of many trauma patients, particularly head-injured patients. The Brain Trauma Foundation has recommended maintenance of the arterial oxygen concentration (Pao_2) above 60 mm Hg. Certain ventilatory problems, such as pneumothorax or hemothorax, may require tube thoracostomy in addition to intubation. Placement of the chest tube before undertaking intubation, if possible, may improve the patient's hemodynamic status and decrease the risk of serious deterioration related to the use of rapid sequence intubation (RSI) agents and initiation of positive pressure ventilation.

If the patient tolerates, a detailed neurologic examination is important before administering neuromuscular blocking agents, which may confound serial clinical evaluations. Correlation of head CT scan findings with neurologic status is critical to making any decisions regarding operative intervention for intracranial hemorrhage. Also, documentation of neurologic function or deficit is essential in the setting of a potential spine injury. Most patients will not have been cleared of cervical spine injury before intubation, so in-line spine stabilization and video-visualized techniques are important. Videolaryngoscopy with RSI is recommended as the primary method to secure the airway in the severely traumatized patient.[34–39] Videolaryngoscopy has been shown to reduce spine movement, achieve superior laryngeal views and increase likelihood of first-pass success when compared with conventional direct laryngoscopy. When a potentially unstable spine injury has been identified, the use a flexible bronchoscope may be indicated for intubation. Overall, the choice of intubation technique will be based on the clinical scenario and emergency clinician's determination of what is most likely to stabilize the patient as time and expertise allows.

A surgical airway is indicated in cases of difficult airway control, failure to successfully intubate or if there are contraindications to intubation. Cricothyrotomy remains the preferred method, although it is performed in a small minority of all trauma cases requiring airway management. The incidence has been decreasing because of the availability of better alternative rescue devices when intubation fails.[34] When cricothyrotomy is required, we recommend the use of the open technique over the Seldinger technique as the latter may be associated with the creation on a false track. Use of a bougie device has been shown to enhance successful cricothyrotomy.[40]

Control of external hemorrhage and rapidly establishing IV access are essential early steps in the management of the acute trauma patient. This has been discussed earlier (see "Primary Survey"). Volume resuscitation is not a substitute for hemorrhage control. Hypothermia is associated with increased blood loss and IV fluids should be warmed prior to infusion. Current Advanced Trauma Life Support (ATLS) guidelines standardize the ratio of replacement fluids to loss and recommend 1 L of an isotonic solution be infused in all patients in shock. If an adult patient is unresponsive to the initial liter of crystalloid therapy, blood transfusion is indicated. O-positive blood should be used, except in women of childbearing age. Type-specific blood should be used when available, but emergent transfusion should not be delayed pending type and cross-match analysis. Massive transfusion protocols are commonly used for patients with severe hemorrhagic shock. Recent data have suggested that the use of a 1:1:1 ratio of plasma, platelets, and packed red blood cells which may result in earlier hemostasis, although no significant difference in mortality was documented.[6,41] We recommend the use of a 1:1:1 or 1:1:2 ratio of blood products based on specific institutional policies and procedures. Judicious use of fluids will prevent over resuscitation and its associated complications.[42] Calcium should be monitored or empirically administered in patients receiving multiple units of blood products or massive transfusion given risk for severe hypocalcemia, QT prolongation, and death.

The use of the antifibrinolytic agent, tranexamic acid (TXA), has been shown to decrease mortality in trauma patients at risk of major bleeding if given within the first hour following injury.[43,44] Any trauma patient with clinically significant hemorrhage, or those who present in shock, should receive 1 g of TXA intravenously over 10 minutes, followed by a 1-g infusion over 8 hours. TXA infusion should be separated from blood products either temporally or through a separate IV/IO line. Administering TXA up to 3 hours after trauma has shown mortality benefits, but an earlier administration (within one hour) is superior.

In the severely injured, hypotensive trauma patient, restoration of normal blood pressure may be undesirable. The concept of permissive hypotension is based on the premise that resuscitation to a normal blood pressure may increase bleeding from an uncontrolled hemorrhage site or even from a site that is tenuously contained and not actively hemorrhaging. In permissive hypotension, mean arterial pressure (MAP) is restored to a goal of approximately 50 mm Hg. Data have shown that this strategy leads to less blood product use, less bleeding, and lower incidence of coagulopathy.[6,10,45] Permissive hypotension is contraindicated in the management of traumatic brain injury because of the risk of hypoperfusion.[41,46] Rather than any particular MAP target, restoration of adequate tissue perfusion, with normal mentation or normalization of tissue oxygen saturation (Sto_2) monitoring, is the clinically relevant endpoint in the resuscitation of the trauma patient.[10,41,45]

The role of ED thoracotomy (EDT) has become more selective to limit futile resuscitation efforts and minimize risk to providers. Patients with penetrating trauma who undergo cardiac arrest during transportation or in the ED are most likely to benefit from EDT. In contrast, cardiac arrest patients with blunt trauma, prolonged cardiopulmonary resuscitation (CPR), or delayed transportation times generally have poor outcomes that are not altered by EDT.[47] Most institutions have protocols in place outlining criteria regarding when EDT should be performed. The National Association of EMS Physicians and ACS Committee on Trauma have published guidelines for withholding or terminating resuscitation efforts in out-of-hospital traumatic cardiac arrest patients. These guidelines prevent the transport of patients who would not likely benefit from EDT, including any blunt trauma patient without vital signs at the scene, apneic or pulseless penetrating trauma victims without other signs of life, patients undergoing more than 15 minutes of pre-hospital CPR, and patients with transport times of more than 15 minutes after arrest.[47] Suggested algorithms for the application of EDT are outlined in Figs. 32.5, 32.6, and 32.7. EDT is discussed further in Chapter 37. When EDT is performed, the goal is to rapidly manage correctable traumatic injuries and allow for rapid transfer to the operating room for definitive intervention.

To assess disability, a rapid assessment of the patient's neurologic status is necessary early in the ED course. If intubation is necessary early in the patient's treatment, perform a rapid neurologic examination,

including level of consciousness, tone and motor ability for all four extremities (e.g., spontaneous, purposeful, and withdrawal to pain), anal sphincter tone (if obtunded or evidence of paralysis), and any lateralizing signs, prior to administration of the paralytic and induction agent.

DISPOSITION

The decision to admit the patient or to transfer to a tertiary care facility should be coordinated based on available resources, consultation with the trauma surgeon, and consideration of institutional and regional guidelines. The ultimate disposition is dictated by a number of factors, including the patient's condition, nature of the injury, and availability of trauma surgeons, subspecialists, and anesthesiologists. Possible dispositions include transfer to the operating room, admission to the surgical service, observation in the ED, and transfer to another hospital for a more specialized care. The level of care and monitoring established in the ED should be maintained throughout transfer. All equipment and medications needed for resuscitation and maintenance of vital functions should be available during the transfer, as should qualified personnel (such as ALS trained paramedics) to oversee the patient's care.

In cases of interhospital transfers, emergency clinicians at the two institutions should carefully coordinate all arrangements and interventions. Stabilizing measures are begun before the transfer, but decompensation in transit should be anticipated. Qualified personnel and necessary resuscitative equipment should accompany the patient. The compelling reason for transferring a patient with life-threatening trauma is the lack of resources or personnel to care for particular injuries. Transfer should not be delayed for non-essential diagnostic procedures. All documentation and results of diagnostic testing and advanced imaging studies should accompany the patient in transfer.

In certain circumstances, the multiple trauma patient may not need admission or interhospital transfer. The decision to discharge these patients is evaluated carefully because many traumatic injuries may manifest in a delayed manner. When discharge from the ED is considered, thorough evaluation is necessary, with resources in place to ensure optimal surgical consultation (where radiologist image interpretation, and timely scheduled follow-up on an out-patient basis) is carried out.

CHAPTER 32: QUESTIONS AND ANSWERS

1. A 33-year-old mother and her 2-year-old-son are brought in by paramedics after they were both hit by a car moving at 15 mph. Although mother and child had an identical mechanism of injury, the son would be at greater risk for all the following injuries, with the following exception:

a. Head injury
b. Hypothermia
c. Intra-abdominal injury
d. Multisystem injury
e. Posttraumatic stress disorder

Answer: e. Injury patterns can differ significantly between adults and children subjected to similar mechanisms of trauma. The major anatomic distinctions relate to the smaller size and surface area, larger head-to-body ratio, and less protected abdominal cavity of the child.

As a result, children are more vulnerable to multisystem injury in blunt trauma, including significant head and intra-abdominal injuries, as well as being at greater risk for hypothermia.

2. Which of the following is the goal of the primary survey?
   - **a.** Determine which consultations should be obtained.
   - **b.** Do an AMPLE (allergies, medications, past medical history, last meal, environments and events) history.
   - **c.** Obtain pertinent historical data from the paramedics.
   - **d.** Perform a radiographic evaluation.
   - **e.** Rapidly identify critical life-threatening diagnoses and begin treatment at the time of the diagnosis.

Answer: e. The emergency clinician should use a standardized approach to the initial evaluation of these patients. Following the Advanced Trauma Life Support (ATLS) algorithm of ABCs in the primary survey allows the timely identification of critical diagnoses and intervention without delay. The primary survey should be performed in a standardized fashion immediately after the patient arrives in the emergency department. The goal of the primary survey is to identify critical, life-threatening diagnoses rapidly and begin treatment at the time of diagnosis. The goals of the secondary survey are to obtain pertinent historical data about the patient and injury as well as evaluate and treat injuries not found on the primary survey. An AMPLE history should be obtained.

3. An 89-year-old man who was a restrained front seat passenger with a history of hypertension, anxiety disorder, and dementia is being evaluated after a head-on collision. His home medications include an angiotensin-converting enzyme (ACE) inhibitor for the hypertension, lorazepam for the anxiety, and olanzapine (Zyprexa) for the dementia. The patient does not have any complaints but is noted to have a blood pressure of 80/50 mm Hg and heart rate of 100 beats/min. In evaluating the patient, you should suspect that the asymptomatic hypotension is most likely due to which of the following?
   - **a.** Antihypertensive medication use
   - **b.** Antipsychotic medication use
   - **c.** Benzodiazepine use
   - **d.** Blood loss

Answer: d. Lower extremity weakness, gait disturbances, decreased visual acuity, and the use of psychotropics, antihypertensives, and sedatives have been associated with falls in older adults, resulting in major injury. The use of these medications, particularly antihypertensives, should not be considered causative in trauma patients with hypotension until acute hemorrhage has been ruled out. In addition, anticoagulants, antiplatelet drugs, and aspirin are commonly prescribed, and their effects should be suspected and reversed, if warranted.

4. A severely injured, hypotensive trauma patient is being considered for permissive hypotension because she has a contained retroperitoneal hematoma and is not actively hemorrhaging. In permissive hypotension, the mean arterial pressure is restored to a goal of 50 mm Hg. Which of the following should help you decide against using permissive hypotension?
   - **a.** Age >80 years
   - **b.** Age <10 years
   - **c.** Associated traumatic brain injury
   - **d.** Hemoglobin of 10 g/dL
   - **e.** Intoxication

Answer: c. In the severely injured, hypotensive trauma patient, restoration of normal blood pressure may be undesirable. The concept of permissive hypotension is based on the concern that resuscitation to normal blood pressures may increase bleeding from a site that is contained and not actively hemorrhaging. In permissive hypotension, the mean arterial pressure (MAP) is restored to a goal of about 50 mm Hg. Studies have shown that this strategy leads to less blood product use, less bleeding, and lower incidence of coagulopathy. However, the provider should be aware that permissive hypotension is contraindicated in the management of traumatic brain injury because of the risk of hypoperfusion.

5. An 87-year-old male with history of atrial fibrillation on anticoagulation, COPD, hypertension, and hyperlipidemia fell from a standing height sustaining a pelvic fracture requiring blood transfusion. Which of the following should raise concern for increased mortality in geriatric trauma patients?
   - **a.** Anticoagulation
   - **b.** Age >85
   - **c.** Isolated pelvic fracture
   - **d.** COPD
   - **e.** All of the above

Answer: e. All of the above can contribute to both morbidity and mortality of geriatric trauma patients. Often times with less severe injury patterns, this population will have increased transfusion needs, complications due to hospitalizations, immobilization, and prolonged rehabilitation times. Patients with one or more of: coagulopathy, cirrhosis, COPD, CAD, or DM have shown twice the risk of death in the setting of trauma. Additionally, elderly patients who sustain a pelvic ring injury are prone to increased mortality with those >85 years at highest risk.

6. A 52-year-old female involved in a motor vehicle collision (MVC) at 7 pm is transferred to a Level 1 trauma center. She arrives at 11 pm and despite appropriate isotonic resuscitation and remains hypotensive. Transfusion protocol is initiated. What is the next best intervention?
   - **a.** Administer tranexamic acid (TXA) 1 g over 10 minutes
   - **b.** Administer TXA 1 g over next 8 hours
   - **c.** Repeat primary survey
   - **d.** None of the above
   - **e.** All of the above

Answer: c. As with any transferred trauma patient any non-response or change in condition should prompt rapid re-evaluation. Additionally, TXA is indicated in patients with hemorrhagic shock ONLY if given within 3 hours of injury. TXA safely reduces the risk of death in bleeding trauma patients when administered up to 3 hours after trauma but earlier administration within 1 hour is considered superior. Many pre-hospital protocols allow for field use of TXA. Trauma patients with clinically significant hemorrhage, or who present in shock, should receive 1 g of T XA over 10 minutes, followed by 1 g infusion over 8 hours.

Head Trauma

Linda Papa and Scott A. Goldberg

KEY CONCEPTS

- *Head trauma* is a broad term describing an external trauma to the craniofacial area of the body from blunt, penetrating, blast, rotational, or acceleration-deceleration forces. The term *head injury* refers to a clinically evident injury on physical examination, and the term *brain injury* indicates an injury to the brain itself.
- Traumatic brain injury (TBI) is often categorized into mild (Glasgow Coma Scale score, 13–15), moderate (GCS score, 9–12), and severe (GCS score, 3–8), but this actually represents a spectrum of injury. Patients with a presentation GCS score of 13–15 who are stable or improving are unlikely to have CT scan findings that warrant intervention.
- The motor component of the GCS is the strongest predictor of outcome following TBI.
- Secondary systemic insults such as hypoxia and hypotension worsen neurologic outcome and should be corrected as soon as detected.
- A noncontrast head CT scan is the imaging modality of choice when TBI is suspected.
- Anticonvulsant prophylaxis with phenytoin or levetiracetam and broad-spectrum antibiotics should be given to patients with penetrating brain injuries for 7 days postinjury.
- Patients can deteriorate from an expanding intracranial hematoma after a mild traumatic brain injury (MTBI), and should undergo serial evaluations, including GCS scoring.
- An MTBI can be easily overlooked when an alert patient presents with distracting injuries. Specifically, assess for disorientation, confusion, amnesia, or disordered awareness (with or without loss of consciousness).
- Imaging of patients with MTBI should follow a validated guideline, such as the Canadian CT Head Rule and New Orleans Criteria. Emergency clinicians should select the system most applicable for their setting and patient population.
- Intoxicated individuals are high-risk patients. Alcohol and drug use affect the GCS score and may significantly obscure the neurologic examination.
- Most patients with MTBI can be discharged from the emergency department (ED) with a normal examination and after a reasonable period of observation (4–6 h) or following a negative CT scan of the head.
- Patients should be discharged with instructions describing the signs and symptoms of acute and delayed complications of MTBI. All discharge instructions should be relayed to a responsible third party.
- Athletes with a concussive head injury should be immediately removed from play and not return until they have been evaluated by a health care provider with expertise in concussion management. There should be a gradual stepwise increase in physical activity.
- Older adults (age greater than 60 years) may have significant intracranial injuries and not show signs of deterioration, especially if their baseline cognitive functioning is impaired; clinicians should therefore have a low threshold for obtaining CT scans with these patients.
- Falls in older adults, including low-mechanism falls, should prompt emergency clinicians to consider the possibility of brain injury.

FOUNDATIONS

Background and Importance

Head trauma accounts for approximately 2.5 million emergency department (ED) visits annually in the United States , representing an increase of more than 50% from approximately 1.6 million over the previous 6 years.[1] The most common principal mechanisms of injury for all age groups includes falls, being struck by or against an object, and motor-vehicle crashes in the civilian population.[1] Traumatic brain injury (TBI) caused by blasts has resulted in disproportionate morbidity to combatants in the recent wars in Iraq and Afghanistan.[2,3] As veterans return to the United States, the number of patients experiencing the consequences of TBI continues to increase.

Gunshot wounds (GSWs) to the head are particularly lethal; the overall mortality rate is estimated to be 90%, with 70% of deaths occurring at the scene.[4] Overall, TBI-related deaths account for 2.2% of all deaths in the United States.[1]

Head trauma is a broad term describing an external trauma to the craniofacial area of the body from blunt, penetrating, blast, rotational, or acceleration-deceleration forces. *Head injury* refers to a clinically evident injury on physical examination and is recognized by the presence of ecchymosis, lacerations, or deformities. The term *traumatic brain injury* indicates an injury to the brain itself.

The ultimate survival and neurologic outcome of the brain-injured patient depends on the extent of TBI occurring at the time of injury (primary injury) and the subsequent effects of systemic insults (secondary injuries), such as those caused by hypotension and hypoxia. Thus, clinical care of patients with TBI emphasizes early management to minimize the occurrence of secondary brain injury. Emergency clinicians can influence the incidence and severity of primary brain injury through injury prevention programs.

A number of terms describing *mild traumatic brain injury* (MTBI) have been used in the past, including minor, minimal, grade I, class I, and low risk. The term *concussion* is also used to describe a MTBI. However, the diagnosis of MTBI is based on symptoms and clinical assessment. One of the most commonly accepted criteria (from the American Congress of Rehabilitation Medicine together with the Centers for Disease Control and Prevention (CDC) and the World Health Organization) defines a patient with MTBI as one who has a Glasgow Coma Scale (GCS) score of 13 to 15 within 30 minutes of injury or at presentation to the ED, with traumatically induced physiologic disruption of brain function as manifested by at least one of the following: (1) any period of loss of consciousness (less than 30 minutes) or decreased level of consciousness (LOC); (2) any loss of memory for events immediately before or after the accident (posttraumatic amnesia should last <24 hours); (3) any alteration in mental state at the time of the accident (e.g., feeling, dazed, disoriented, foggy, "seeing stars," confused or slowed thinking); and (4) neurologic deficits (weakness,

loss of balance, change in vision, sensory loss) that may or may not be transient (Box 33.1).

Individuals with MTBI are acutely at risk for serious intracranial injuries. Up to 17% of patients with suspected MTBI in the ED have abnormal computed tomography (CT) scans of the head. Although the incidence of life-threatening lesions that require neurosurgical intervention in suspected MTBI is only about 1%, these patients have an important risk of subsequent deterioration from intracranial bleeding. If these cases are recognized and treated early, a full recovery is likely, otherwise, severe disability or death may ensue.

The GCS score was not originally intended for use in MTBI patients, and some authors have suggested that patients with a GCS score of 13 or 14 be excluded from the mild category and placed into the moderate-risk group due to the higher risk of neurosurgical intervention.[5,6] However, patients who may be under the influence of or intoxicated from the use of recreational drugs or alcohol can also present with a GCS score of 13 to 14. Mental status can also be affected by pain, certain medications, and post-traumatic shock. Nonetheless, over 10% of patients who become comatose start with a GCS score of 15. Patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be an MTBI. Among MTBI patients, those with GCS scores trending downward (worsening neurologic status) have a higher rate of neurosurgical interventions and have a less favorable outcome than those with GCS scores trending upward (improving neurologic status).[6,7]

BOX 33.1 Definition of Mild Traumatic Brain Injury

According to the American Congress of Rehabilitation Medicine, a person with mild traumatic brain injury (MTBI) is a patient with a Glasgow Coma Scale (GCS) of 13 to 15 who has had a traumatically induced physiologic disruption of brain function, as manifested by at least one of the following:

1. Any period of loss of consciousness less than 30 min
2. Any loss of memory for events immediately before or after the accident (posttraumatic amnesia should last <24 h)
3. Any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused)
4. Focal neurologic deficit(s) that may or may not be transient

Anatomy and Pathophysiology

Anatomy

Scalp and cranium. The scalp consists of five tissue layers (Fig. 33.1). The skull is comprised of the frontal, ethmoid, sphenoid, and occipital bones and two parietal and two temporal bones. Each bone consists of solid inner and outer layers separated by a layer of cancellous bone tissue (the diploe). In adults, the bones of the skull average 2 to 6 mm in thickness; the bones in the temporal region are usually the thinnest of the skull. The cranial bones form a smooth outer surface of the skull, but within the cranial vault are many bony protrusions and ridges. "*Contrecoup*" *brain injuries*, such as contusions, may occur on the opposite side of the head impact (coup) as the brain shifts to the uninjured side and strikes against uneven bone surfaces. After the first few months of life, the cranial bones begin to fuse, ultimately forming the rigid, nonexpandable cranial vault. The inner aspect of the skull is lined with the periosteal dura, which is a thick connective tissue layer that adheres closely to the bone surface. The inner meningeal layer of the dura is the outermost covering of the brain. This dural membrane reflects back on itself to make folds within the cranial space. These folds serve to protect and compartmentalize different components of the brain. The midline falx cerebri separates the two cerebral hemispheres

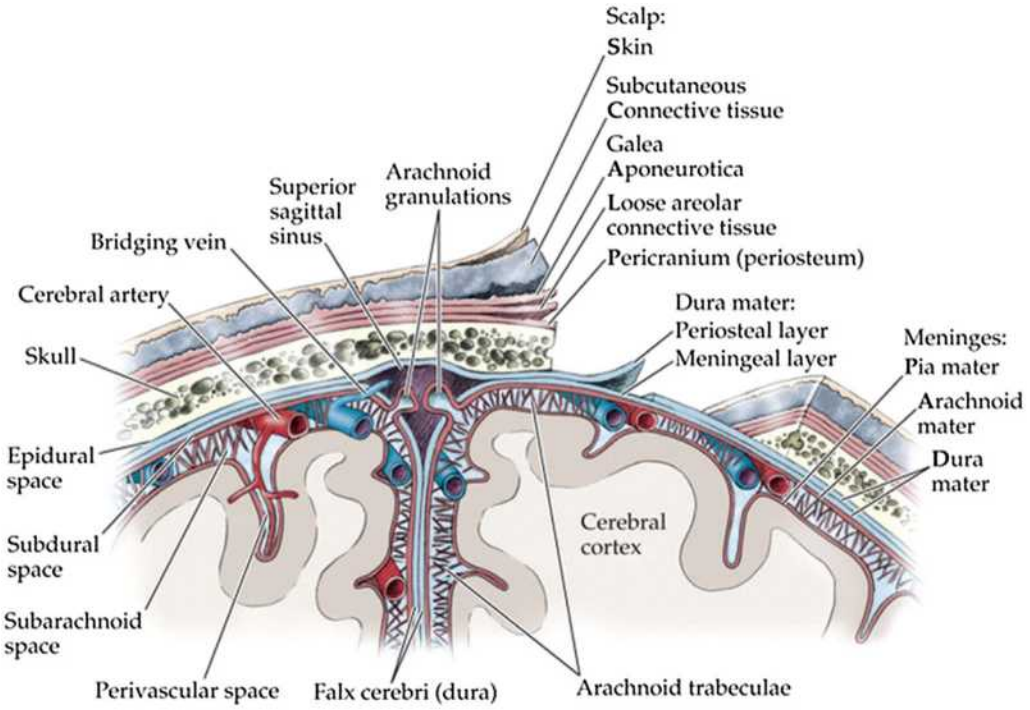

Fig. 33.1 Layers of the Soft Tissues, Skull, and Meninges. The dermis is the outermost layer and is among the thickest layers of skin on the body. The underlying subcutaneous tissue contains the hair follicles and rich blood supply of the scalp. The galea, made of tough fascial tissue, contains the occipitofrontalis and temporoparietalis muscles, which move the scalp backward and forward, elevate the eyebrows, and wrinkle the forehead. Under the galea is a loose areolar tissue layer. The deepest layer of the scalp, the pericranium, is firmly adhered to the skull. (From Blumenfeld H. *Neuroanatomy through clinical cases*. Sunderland: Sinauer Associates, Incorporated; 2002.)

Fig. 33.2 Diffuse axonal injury (DAI), otherwise known as traumatic axonal injury (TAI), is characterized by axonal stretching leading to axolemmal disruption, ionic flux, neurofilament compaction, and microtubule disassembly, resulting in axonal swelling and disconnection. Axonal swelling and disconnection can lead to axon death. **a,** Normal neuron, **b, c,** Axon reaction to increasing stretch. **d,** Retraction balls have formed, and aggregates of axonal material lie along the course of the axon. (From Peerless SJ, Rewcastle NB. Shear injuries of the brain. *CMAJ* 1967;96:577–582.)

from each other. The tentorium cerebelli partitions the cerebellum and brainstem from the cerebral hemispheres. The U-shaped free margin of this dural fold is important in the pathology of the transtentorial herniation syndromes. Within the margins of the dural reflections, the two dural layers separate to form large dural venous sinuses. Injury to the dural sinuses is associated with significant morbidity and mortality because of the potential for uncontrolled hemorrhage.

Brain and cerebrospinal fluid. The brain is a semisolid structure that weighs approximately 1400 g (3 lb.) and occupies approximately 80% of the cranial vault, with the remaining space occupied primarily by vasculature and cerebrospinal fluid (CSF). The brain is covered by three distinct membranes—the meningeal dura, arachnoid layer, and pia (Fig. 33.2). The location of traumatic hematomas relative to these membranes defines the pathologic condition and determines the consequences of the injury.

The brain is suspended in the CSF, which provides some physical buffering for the brain during trauma. CSF is produced by the choroid plexus, located primarily in the lateral ventricles of the brain. CSF passes from the ventricular system into the subarachnoid space that surrounds the brain and spinal cord. The normal pressure exerted by the CSF is 65 to 195 mm H_2O or 5 to 15 mm Hg.

The blood-brain barrier (BBB) maintains the microenvironment of the brain tissue and CSF. Extracellular ion and neurotransmitter concentrations are regulated by movement across this barrier. When the BBB is intact, the ability of neuroactive drugs to penetrate the brain tissue usually depends on their lipid solubility. However, the biomechanics of a brain injury or posttraumatic cerebral edema can cause a disruption of the BBB for up to several hours after the insult. In severe TBI, prolonged disruption of the BBB further contributes to the development of posttraumatic vasogenic cerebral edema and higher maximum intracranial pressure (ICP). Mild TBI patients exposed to repetitive biomechanical forces and those with post-concussive symptoms also appear to have higher BBB permeability on neuroimaging.[8,9]

Pathophysiology

Cerebral hemodynamics and increased intracranial pressure. The brain has an extremely high metabolic rate, accounting for approximately 20% of the entire oxygen consumption of the body and requiring approximately 15% of total cardiac output. In the normal brain, cerebral blood flow (CBF) is maintained at constant levels. Optimal regional CBF is maintained by the ability of the cerebral vessels to alter their diameter in response to changing physiologic conditions. This response protects the brain by increasing the delivery of oxygen to tissue, enhancing the removal of metabolic end products, and allowing nearly instantaneous adjustments to meet changing metabolic demands. Hypertension, alkalosis, and hypocarbia promote cerebral vasoconstriction, whereas hypotension, acidosis, and hypercarbia cause cerebral vasodilation.

Cerebral vasoactivity is also very sensitive to changes in the partial pressures of carbon dioxide and oxygen (P_{CO_2} and P_{O_2}, respectively). The response to changes in P_{CO_2} is nearly linear between P_{CO_2} values of 20 and 60 mm Hg. In this range, lowering P_{CO_2} by as little as 1 mm Hg decreases the diameter of cerebral vessels by 2% to 3%, corresponding to an overall change in CBF of 1.1 mL/100 g of tissue/min. This is the physiologic rationale for intentional hyperventilation in the setting of rapid and marked increases in ICP. Hyperventilation causes P_{CO_2} to fall, resulting in cerebral vasoconstriction. However, this is no longer recommended as a mechanism for reducing ICP.[10] The cerebral vessels also respond to changes in P_{O_2}. As P_{O_2} declines, cerebral vessels dilate to ensure adequate oxygen delivery to brain tissue. When brain injury occurs, increased CBF, vascular dilation, and a disrupted BBB promote vasogenic edema and can further increase ICP. Therefore, avoiding or reversing hypoxia is essential in managing the brain-injured patient.

CBF also depends on the cerebral perfusion pressure (CPP), which is the pressure gradient across the brain. CBF remains fairly constant when CPP is 50 to 160 mm Hg. This is referred to as autoregulation and occurs with a mean arterial pressure (MAP) of 60 to 150 mm Hg. The determinants of CPP are MAP and the resistance to CBF produced by the mean systemic venous pressure and ICP. Because ICP is higher than mean systemic venous pressure, ICP effects predominate, and CPP can be approximated as follows:

$$CPP = MAP - IC$$

If CPP falls below 40 mm Hg, autoregulation is lost and CBF declines, resulting in tissue ischemia and altered cerebral metabolism. Avoidance of hypotension or elevation in ICP in the head-injured patient helps ensure that CPP can be maintained.

The recommended target CPP value is between 60 and 70 mm Hg. However, the risks of aggressive attempts to maintain CPP above 70 mm Hg with fluids and pressors, including the risk of developing adult respiratory failure, should be considered.[10]

Increased intracranial pressure. Increased ICP is defined as a CSF pressure greater than 15 mm Hg (or 195 mm H_2O) and is a frequent consequence of a severe TBI. Initially, as ICP increases as a result of a traumatic mass lesion or edema, CSF is displaced from the cranial vault to the spinal canal, offsetting the increased blood or brain volume. When this compensatory mechanism is overwhelmed, the elastic properties of the brain substance allow tissue compression to provide buffering for the increasing pressure. Depending on the location and rate of mass expansion and edema formation, the intracranial compensatory mechanisms can accommodate an increased volume of 50 to 100 mL. Beyond that, even small changes in intracranial relationships, such as from vasodilation, CSF obstruction, or areas

of focal edema, may increase ICP. If ICP increases to the point at which CPP is compromised, vasoparalysis occurs and autoregulation is impaired. The CBF then depends directly on the systemic MAP. With the loss of autoregulation, massive cerebral vasodilation occurs. Systemic pressure is transmitted to the capillaries, contributes to vasogenic edema, and further increases ICP.

ICP above 22 mm Hg is associated with increased mortality requiring intervention and treatment.[10] If ICP is not controlled, herniation will occur, resulting in brainstem compression and cardiorespiratory arrest. Simple techniques to reduce ICP include head of bed elevation to 30 degrees and keeping the neck in a neutral position. Common therapies include use of osmotic and diuretic agents such as mannitol or hypertonic saline (HTS), and CSF drainage. Therapeutic hyperventilation, once almost universally used, is potentially harmful and is now recommended only as a temporizing measure for a select group of patients for whom other measures are not available or have failed.

Cushing reflex. Progressive hypertension associated with bradycardia and diminished respiratory effort is a specific response to acute, potentially lethal increases in ICP. This response is called Cushing reflex or Cushing phenomenon, and its occurrence indicates that the ICP has reached life-threatening levels. However, only one-third of cases of life-threatening increased ICP manifest the full triad of hypertension, bradycardia, and respiratory irregularity.

Altered Levels of Consciousness

Consciousness is the state of awareness of the self and environment, and it requires intact functioning of the cerebral cortices and reticular activating system (RAS) of the brainstem. With increasing ICP from brain swelling or an expanding mass lesion, brainstem compression and subsequent RAS compression can occur. A patient who has sustained TBI typically has an altered LOC, but reversible conditions that can alter mental status such as hypoxia, hypotension, or hypoglycemia should be corrected as soon as they are identified. Global suppression may result from an intoxicant consumed before the injury, posttraumatic seizure (PTS), or postictal period after a seizure from any cause.

Definitions and Patterns of Injury

Traumatic Brain Injuries: Severe, Moderate, and Mild

Traditionally, TBI has been separated into the three broad categories of mild, moderate, and severe, primarily based on the GCS score following resuscitation and stabilization. Severe brain injury is defined as a TBI with a post-resuscitation GCS score of 8 or lower, moderate as a GCS score of 9 to 12, and mild as a GCS score of 13 to 15. Overall, 80% of patients sustain MTBIs, 10% moderate brain injuries, and 10% severe brain injuries (Table 33.1). An MTBI is often referred to as a concussion.

The degree of brain injury following an MTBI or concussion also depends on the primary mechanism and magnitude of injury, secondary insults, and the patient's genetic and molecular response. Primary damage is caused by the initial impact or force that although not as evident as severe TBI, may lead to smaller contusions, hematomas, axonal damage, and microvascular injury. Following a MTBI without evidence of lesions on CT scans, there is a decrease in CBF over the ensuing hours and days after injury,[11] as well as cortical neurometabolic abnormalities.[12,13] Traumatic axonal injury (TAI) is also an important determinant of outcome.[14]

Increasing evidence has suggested that even a single MTBI can produce long-term gray and white matter atrophy, precipitate or accelerate age-related neurodegeneration, and increase the risk of developing Alzheimer, Parkinson, and motor neuron disease.[15,16] Repeated episodes of MTBI can provoke the development of chronic traumatic encephalopathy (CTE), a term used to describe clinical changes in cognition, mood, personality, behavior, or movement occurring years following concussion.[16,17] CTE has recently been found to occur after other causes of repeated head trauma, suggesting that any repeated blows to the head, such as those that occur in American football, hockey, soccer, and professional wrestling, as well as in military personnel, and in those victims of physical abuse, can also lead to neurodegenerative changes.[18,19]

Direct and Indirect Injuries

Direct injury. Direct head trauma occurs when the head is struck, or its motion is suddenly arrested, by an object. The resulting damage to the skull and brain depends on the consistency, mass, surface area, and velocity of the object striking the head. Direct injury can also be caused by compression of the head. External signs of trauma are frequently noted at the site of impact or compression force where the skull initially bends inward at the point of contact. If the force is sufficient, a skull fracture can occur. The cranium absorbs some of this applied energy, whereas some energy is transmitted to the brain by shock waves that travel distant to the site of impact or compression. With sufficient and prolonged application of a compression force, the ability of the skull to absorb the force is overcome, and multiple linear skull fractures occur. These resulting fractures can be depressed if a high-energy rapid compression force is applied to a small area of the skull. The extent of direct injury depends on the vasoelastic properties of the underlying region of brain tissue, duration of the force applied, magnitude of the force reaching the brain tissue, and surface area of the brain that is affected.

Indirect injury. In indirect brain injury, the cranial contents are set into motion by forces other than the direct contact of the skull with an object. A common example is an acceleration-deceleration injury

TABLE 33.1 Traumatic Brain Injury as a Portion of All Injuries and Emergency Department Visits

		ALL INJURIES		TRAUMATIC BRAIN INJURIES		
Parameter	All Visits	Number	Percent of All Visits	Number	Percent of All Injuries	Percent of All Visits
ED visits[a]	96,839,411	28,697,028	29.6	1,364,797	4.8	1.4
Hospitalizations[b]	36,693,646	1,826,548	5.0	275,146	15.1	0.7
Deaths	2,432,714	169,055	6.9	51,538[c]	30.5	2.1
Total	135,965,771	30,692,631	22.6	1,691,481	5.5	1.2

[a]Persons who were hospitalized, died, or were transferred to another facility were excluded.
[b]In-hospital deaths and patients who transferred from another hospital were excluded.
[c]28 mortality records (from 2002 to 2006) were omitted because of missing age information.
Adapted from Faul M XL, Wald MM, Coronado VG. Traumatic brain injury in the United States: emergency department visits, hospitalizations and deaths 2002–2006. Atlanta: Centers for Disease Control and Prevention, National Center for Injury Prevention and Control; 2010:1–74.

in which no direct mechanical impact is sustained, but the cranial contents are set into vigorous motion. As the bridging subdural vessels are strained, subdural hematomas (SDHs) may result.

In an indirect injury, differential acceleration of the cranial contents occurs, depending on the physical characteristics of the brain region. As one brain region slides past another, shear and strain occur. These movements result in diffuse injuries, such as a concussion or TAI. Additional injury occurs as the movement of the intracranial contents is abruptly arrested, and the brain strikes the skull or a dural structure. Contrecoup contusions are an example of such an injury. In a penetrating injury, the object produces pressure waves that can strike structures distal to the path of the missile.

Neurochemical Cascade

Following a brain injury, secondary insults may be mediated through physiologic events, which can decrease the supply of oxygen and energy to the brain tissue, or a cascade of cytotoxic events, mediated by many molecular and cellular processes. These events include activation of inflammatory responses, imbalances of ion concentrations (e.g., potassium, calcium), an increase in the presence of excitatory amino acids (e.g., glutamate), dysregulation of neurotransmitter synthesis and release, imbalance in mitochondrial functions and energy metabolism, and production of free radicals.[20]

Penetrating Head Trauma

The morbidity and mortality from missile injuries to the head depend on the intracranial path, speed of entry, and size and type of the penetrating object. Projectiles that cross the midline or geographic center of the brain, pass through the ventricles, or come to rest in the posterior fossa are associated with extremely high mortality. High-velocity wounds are associated with greater mortality than low-velocity injuries. Large missiles or missiles that fragment within the cranial vault are usually fatal. The design of the bullet and its fragmentation potential (capacity to deform or fragment) also contribute to final tissue destruction and patients' morbidity and mortality. Important clinical factors associated with mortality include increasing age, suicide attempt, lower GCS score, bilateral mydriasis, dural penetration, and bihemispheric and multi-lobar injury.[21]

Tangential wounds are caused by an impact that occurs at an oblique angle to the skull. If the missile has high velocity but low energy, it can travel around the skull, under the scalp, without passing through the skull. Intracranial damage, primarily cortical contusions, can occur at the initial site of impact secondary to pressure waves generated by the impact. Although many patients with tangential GSWs have a GCS score of 15 on presentation, many have underlying skull fractures and 25% have some degree of underlying intracranial hemorrhage.[22]

Most civilian penetrating brain injuries are penetrating missile wounds, which are produced by moderate- to high-velocity projectiles discharged at close range. The penetrating object may travel through the entire skull, bounce off the opposite inner table of the skull and ricochet within the brain, or stop somewhere within the cranial cavity.

As the bullet passes through the brain, a tissue cavity as much as 10 times the diameter of the missile is created. A percussion shock wave is also created, lasting 2 ms but causing little tissue destruction. The wounding capacity of a firearm is related to the kinetic energy of its missile on impact and how much energy is dissipated. Low-velocity missiles tend to be deflected by intracranial structures. The final track is therefore erratic and occasionally bears no relation to the exit or entrance site of the missile.

Scalp Wounds

The large blood vessels of the scalp do not fully constrict if they are lacerated and can be the source of substantial blood loss. Because the areolar attachments to the rest of the scalp are loose, scalp avulsions frequently occur through this layer. Subgaleal hematomas can become large because blood easily dissects through the loose areolar tissue. Hemostasis may be difficult to achieve, and blood loss may be significant to the point of causing hemodynamic compromise.

Skull Fractures

Skull fractures are local injuries caused by direct impact to the skull. Although the presence of a skull fracture does not always indicate underlying brain injury, the force required to fracture the skull is substantial, and all patients with skull fractures must be carefully evaluated to ensure that no additional injury is present. The pattern, extent, and type of skull fracture depend on the force of the impact applied and ratio of the impact force to the impact area. Clinically significant features of skull fractures include intracranial air, association with an overlying scalp laceration (open skull fracture), depression below the level of the skull's inner table, and location over a major dural venous sinus or middle meningeal artery.

Linear Fractures

A linear skull fracture is a single fracture that goes through the entire thickness of the skull. Linear skull fractures are clinically important if they cross the middle meningeal groove or major venous dural sinuses; they can disrupt these vascular structures and cause the formation of epidural hematomas (EDHs). Most other linear skull fractures are not clinically significant.

Sutural diastasis is the traumatic disruption of a cranial suture. In adults, sutural diastasis often involves the coronal or lambdoid sutures. Sutural diastasis usually occurs when a linear fracture extends into the suture line, and it is rare after sutures have undergone bone fusion. Comminuted skull fractures, which are multiple linear fractures that radiate from the impact site, usually suggest a more severe blow to the head than that producing a single linear fracture. A linear vault fracture substantially increases the risk of intracranial injury.

Depressed Fractures

Depressed skull fractures are usually caused by direct-impact injury with small blunt objects, such as a hammer or baseball bat. Most depressed skull fractures occur over the parietal or temporal regions. These fractures are clinically important because they predispose to significant underlying brain injury and to complications of head trauma, such as infection and seizures.

Basilar Fractures

Basilar fractures are linear fractures at the base of the skull, usually occurring through the temporal bone. Patients with basilar fractures are at risk for extra-axial hematomas because of the proximity of the fracture to the middle cerebral artery. Dural tears, resulting from a basilar skull fracture, may produce a communication among the subarachnoid space, paranasal sinuses, and middle ear. This offers a route for the introduction of infection into the cranial cavity and is suggested by a CSF leak. These fractures are the result of considerable impact force and are highly associated with an underlying brain injury.

Extra-Axial and Intra-Axial Intracranial Injuries

Extra-axial refers to injury or bleeding that occurs within the skull but outside of the brain tissue. Intra-axial injury or bleeding occurs within the brain tissue itself. Extra-axial intracranial lesions include EDH, SDH, traumatic subarachnoid hemorrhage (SAH), and subdural hygroma (SDHG). Intra-axial intracranial lesions include TAI, cerebral and cerebellar contusions, and cerebral and cerebellar hematomas.

Extra-Axial Injury

Epidural hematoma. An EDH is bleeding that occurs between the inner table of the skull and dura. Most EDHs result from a direct-impact injury that causes a forceful deformity of the skull. Often, a fracture occurs across the middle meningeal artery, or vein, or a dural sinus. The temporoparietal region is the most likely site for an EDH. The high arterial pressure of the bleeding vessel dissects the dura away from the skull, permitting hematoma formation. EDHs are rare in older adults and children younger than 2 years because of the close attachment of the dura to the skull in both patient populations.

Subdural hematoma. An SDH is a hemorrhage that occurs between the dura and brain and is usually caused by acceleration-deceleration injuries. SDH occurs most commonly in patients with brain atrophy, such as alcoholic or older patients, because bridging vessels traverse greater distances than in patients with no atrophy. As a result, the vessels are more likely to rupture with rapid movement of the head. Once they are ruptured, blood can fill the potential space between the dura and arachnoid. SDH is much more common than EDH, occurring in up to 30% of patients with severe head trauma. The slow bleeding of venous structures delays the development of clinical signs and symptoms. As a result, the hematoma compresses the underlying brain tissue for prolonged periods and can cause significant tissue ischemia and damage. Approximately 20% of patients will present with a bilateral SDH. The prognosis of SDH does not entirely depend on the size of the hematoma but rather on the degree of brain injury caused by the pressure of the expanding hematoma on underlying tissue or by other intracranial injuries. Mortality is highest in older adults, patients who have a GCS score of 8 or less, and those with signs of acute herniation syndrome on initial ED presentation. Posterior fossa SDHs make up less than 1% of all reported SDHs. They are caused by occipital trauma that tears bridging vessels or venous sinuses and have a very poor prognosis.

Traumatic subarachnoid hemorrhage. A traumatic SAH is blood within the CSF and meningeal intima and probably results from tears of small subarachnoid vessels. Traumatic SAH is detected on the first CT scan in up to one-third of patients with severe TBI and ultimately is identified in almost 50% of patients with severe head trauma. It is therefore the most common CT scan abnormality seen after head trauma. Traumatic intracranial hemorrhage is typically associated with significant morbidity and mortality.[23] Most patients with traumatic SAH and a normal GCS do not require neurosurgical intervention.[24]

Subdural hygroma. A SDHG is a collection of clear, xanthochromic blood-tinged fluid in the dural space. The pathogenesis of an SDHG is not certain. It may result from a tear in the arachnoid that permits CSF to escape into the dural space or effusions from injured vessels through areas of abnormal permeability in the meninges or in the underlying parenchyma. They may accumulate immediately after trauma or in a delayed manner.

Intra-Axial Injury

Diffuse axonal injury and traumatic axonal injury. Prolonged traumatic coma not caused by mass lesions or ischemic insult is thought to result from diffuse axonal injury (DAI). Although the term *diffuse axonal injury* has been widely adopted, the distribution of axonal injury is usually not diffuse but multifocal. Axonal injury occurs on a spectrum, with milder cases primarily localized. Furthermore, DAI has been used to describe axonal injury from nontraumatic causes in other neurologic conditions. Accordingly, the term *traumatic axonal injury* is preferred, particularly in milder cases. In more severe cases, when the axonal injury is more widespread, the term *diffuse traumatic axonal injury* more appropriately describes the condition.

In TAI, axons sustain a primary insult in which they are torn (axotomy) or stretched, resulting in the formation of axon retraction balls that interrupt synaptic connection and normal axonal function. Secondary insult including disruption of the extracellular brain matrix and influx of inflammatory mediators leads to axonal swelling and disconnection and can lead to axon death (see Fig. 33.2). Moreover, acute uncoupling of CBF, metabolism, and apoptosis are thought to be the important factors linked to axonal cell death after TAI.[11,25,26]

Most patients with TAI present with persistent traumatic coma that begins immediately at the time of trauma; however, some patients may recover consciousness briefly before lapsing into prolonged coma. Because diagnostic studies cannot predict the extent of the axonal damage, the severity of the injury is determined by the clinical course. Clinical grades of diffuse TAI have been based on length of coma: (1) grade I (mild)—coma for 6 to 24 hours; (2) grade II (moderate)—coma for longer than 24 hours but not decerebrate; (3) grade III (severe)—coma for longer than 24 hours and decerebrate or flaccid. Currently, no early clinical or biomarker predictor exists that differentiates patients with mild, moderate, or severe diffuse TAI.

Cerebral contusions. Contusions are bruises on the surface of the brain, usually caused by impact injury. Contusions are produced when parenchymal blood vessels are damaged, resulting in scattered areas of petechial hemorrhage and subsequent edema. Contusions develop in the gray matter on the surface of the brain and taper into the white matter. Subarachnoid blood is frequently found overlying the involved gyrus.

Most often, contusions occur at the poles and inferior surfaces of the frontal and temporal lobes, where the brain comes into contact with bone protuberances in the base of the skull. If the contusion occurs on the same side as the impact injury, it is a coup injury; if it occurs on the opposite side, the contusion is a contrecoup injury. Contusions can also develop in the brain tissue that underlies a skull fracture. Multiple areas of contused tissue may be produced with a single impact, often in association with other intracranial injuries. With time, the associated hemorrhages and edema of a contusion can become widespread and serve as a nidus for hemorrhage or swelling, thus producing a local mass effect. Compression of the underlying tissue can cause local areas of ischemia, and tissue infarction is possible if the compression is significant and unrelieved. Eventually, these ischemic areas become necrotic, and cystic cavities form within them.

Intracerebral hematoma. Intracerebral hematomas (ICHs) are formed deep within the brain tissue and are usually caused by shearing or tensile forces that mechanically stretch and tear deep small-caliber arterioles as the brain is propelled against irregular surfaces in the cranial vault. Resulting small petechial hemorrhages coalesce to form ICHs, with 85% in the frontal and temporal lobes. An ICH is often found in the presence of extra-axial hematomas and in many patients multiple ICHs are present. Isolated ICHs may be detected in as many as 12% of all patients with severe head trauma.

Intracerebellar hematoma. Primary traumatic intracerebellar hematomas are rare but can occur after a direct blow to the occipital area. Often, these patients have an associated skull fracture, posterior fossa EDH or SDH, or supratentorial contrecoup hematomas and contusions.

Primary and Secondary Brain Injuries

The acute clinical picture of the patient with TBI is dynamic and represents the sum of primary and secondary injury. A primary brain injury is mechanical damage that occurs at the time of head trauma and includes brain lacerations, hemorrhages, contusions, and tissue avulsions. On the microscopic level, primary injury causes permanent

mechanical cellular disruption and microvascular injury. Other than the evacuation of traumatic hematomas, no specific intervention exists to repair or reverse primary brain injury.

Following the primary injury, a cascade of events occurs at the cellular and molecular level that continues for hours to days and contributes to further brain injury. This secondary brain injury results from intracellular and extracellular derangements that lead to alterations in cell function and propagation of injury through processes such as depolarization, excitotoxicity, disruption of calcium homeostasis, free radical generation, BBB disruption, ischemic injury, edema formation, and intracranial hypertension.[27] Animal and human studies have revealed a complicated series of neurochemical, neuroanatomic, and neurophysiologic reactions after brain injury. The cell has compensatory mechanisms to protect itself from widespread damage, such as endogenous free radical scavengers and antioxidants. However, these systems are quickly overwhelmed, and the functional and structural integrity of the cell is threatened. Investigational agents aimed at specific steps in the destructive processes indicate that some aspects of secondary brain injury may be reversed or modified. Multiple ongoing brain injury trials have been performed with numerous investigational therapeutic interventions; to date, none have proved useful in the clinical setting.[27,28]

Secondary Systemic Insults

The ultimate neurologic outcome after head trauma is influenced by the extent and degree of secondary brain injury. In turn, the amount of secondary brain injury depends on certain premorbid and comorbid conditions, such as the age of the patient and trauma-related systemic events. A primary goal in the emergency care of a head trauma patient is prevention or reduction of systemic conditions that are known to worsen outcome after TBI, such as hypotension, hypoxia, anemia, and hyperpyrexia.[10]

Hypotension. Hypotension, defined as SBP less than 90 mm Hg, has been found to have a negative impact on severe brain injury outcome. Systemic hypotension reduces cerebral perfusion, thereby potentiating ischemia and infarction. Hypotension is associated with a near-doubling of the mortality from TBI and worse outcomes for patients who survive.[10,29]

Hypoxia. Hypoxia, defined as a Po_2 less than 60 mm Hg, is relatively common in the brain-injured patient. Causes include: (1) transient or prolonged apnea caused by brainstem compression or injury after the traumatic event; (2) partial airway obstruction caused by blood, vomitus, or other debris in the airway of the traumatized patient; (3) injury to the chest wall that interferes with normal respiratory excursion; (4) pulmonary injury that reduces effective oxygenation; and (5) ineffective airway management, such as the inability to bag-valve-mask or intubate the patient in an effective or timely manner. When hypoxia is documented, the overall mortality from severe TBI may double.[10,29,30] Significant hyperoxia with resultant oxygen toxicity is also associated with worse outcome after TBI, although this relationship is less clearly defined.[30–32] In TBI, normoxia should be maintained.

Hypocarbia and hypercarbia. $Paco_2$ is one of the most potent drivers of CBF. Hypocarbia ($Paco_2$ ≤35 mm Hg) results in vasodilation, while hypercarbia ($Paco_2$ ≥46 mm Hg) leads to cerebral vasoconstriction. In TBI, both hypocarbia and hypercarbia are associated with increased morbidity. Hypercarbia causes cerebral vasodilatation with a resultant increase in cerebral edema and ICP, and thus is associated with a worsened neurologic outcome.[33] Hypocarbia, generally secondary to hyperventilation, results in reduced CBF and a transient decrease in ICP. For patients with impending brain herniation brief therapeutic hyperventilation may be considered. However, in most patients, hyperventilation should be avoided in favor of maintenance of normal to slightly reduced $Paco_2$ levels.[10]

Anemia. Anemia caused by blood loss can be detrimental to the head-injured patient by reducing the oxygen-carrying capacity of the blood, thus reducing the amount of necessary substrate delivered to the injured brain tissue. When anemia (hematocrit, 30%) occurs in patients with severe brain injury, the mortality rate increases. However, transfusion of red blood cells also has adverse effects in TBI patients.[34–37] At this time, evidence is insufficient to recommend a restrictive or liberal approach to transfusion in the brain-injured patient and transfusion threshold should be tailored to the individual patient.

Hyperpyrexia. Hyperpyrexia (core body temperature >38.5°C [101.3°F]) is also correlated with worse outcomes after TBI, and its magnitude and duration are contributory factors. Pathophysiology likely involves increased metabolism in injured brain areas, thus recruiting blood flow, with a resultant increase in ICP.

Cerebral Herniation Syndromes

Cerebral herniation occurs when increasing cranial volume and ICP overwhelm the natural compensatory capacities of the central nervous system (CNS; Fig. 33.3). When the signs of herniation syndrome are present mortality approaches 100% without rapid implementation of temporizing measures and definitive neurosurgical intervention.

Uncal Herniation

The most common clinically significant traumatic herniation syndrome is *uncal herniation*, a form of transtentorial herniation. Uncal herniation is often associated with traumatic extra-axial hematomas in the lateral middle fossa or the temporal lobe. As compression of the uncus begins, the third cranial nerve (CN) is compressed, which may result in anisocoria, ptosis, impaired extraocular movements, or a sluggish pupillary light reflex on the side ipsilateral to the expanding mass lesion. As the herniation progresses, compression of the ipsilateral oculomotor nerve eventually causes ipsilateral pupillary dilation and nonreactivity.

Initial motor examination findings can be normal, but contralateral Babinski responses develop early. Contralateral hemiparesis develops as the ipsilateral peduncle is compressed against the tentorium. With continued progression of the herniation, bilateral decerebrate posturing eventually occurs; decorticate posturing is not universally seen with the uncal herniation syndrome.

In a certain percentage of TBI patients, the contralateral cerebral peduncle is forced against the opposite edge of the tentorial hiatus. Hemiparesis is then detected ipsilateral to the dilated pupil and mass lesion. This is termed *Kernohan notch syndrome* and causes false-localizing motor findings. As uncal herniation progresses, direct brainstem compression causes additional alterations in the LOC, respiratory pattern, and cardiovascular system. Mental status changes may initially be subtle, such as agitation, restlessness, or confusion, but soon lethargy occurs, with progression to coma. The patient's respiratory pattern may initially be normal, followed by sustained hyperventilation. With continued brainstem compression, an ataxic respiratory pattern develops. The patient's hemodynamic status may change, with rapid fluctuations in blood pressure and cardiac conduction. Herniation that is uncontrolled progresses rapidly to brainstem failure, cardiovascular collapse, and death.

Central Transtentorial Herniation

Less common than uncal transtentorial herniation, the central transtentorial herniation is demonstrated by rostrocaudal neurologic deterioration caused by an expanding lesion at the vertex or frontal

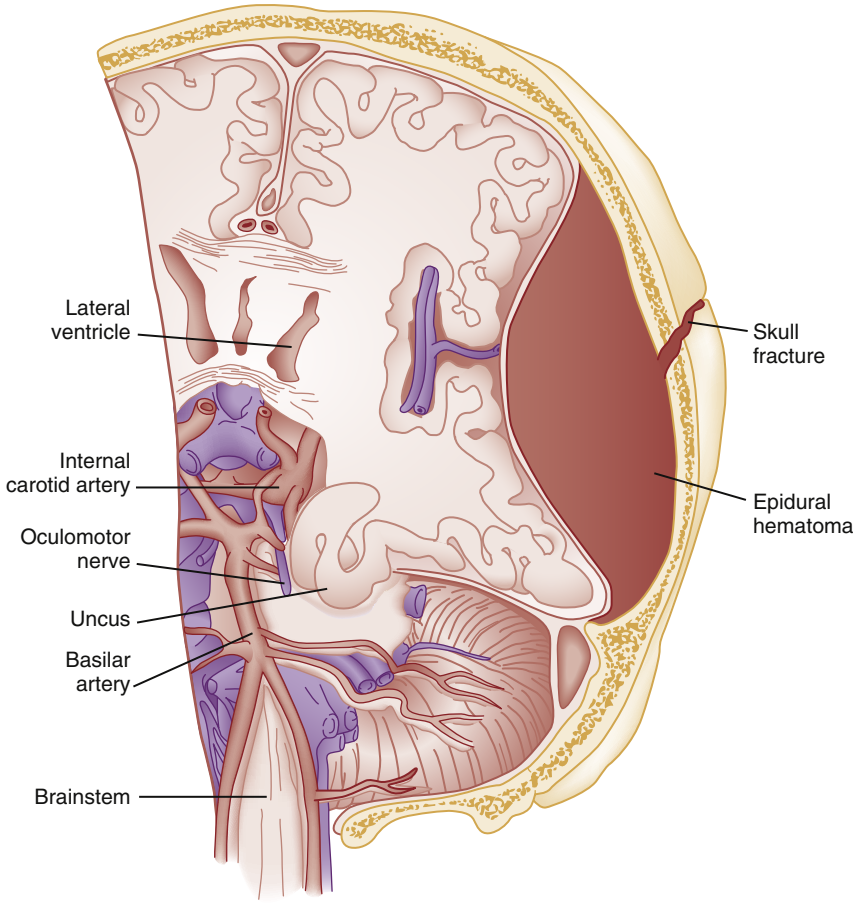

Fig. 33.3 Anterior view of transtentorial herniation caused by large epidural hematoma. A skull fracture overlies the hematoma. (From Rockswold GL. Head injury. In Tintinalli JE, et al., eds. *Emergency medicine*. New York: McGraw-Hill; 1992:915.)

or occipital pole of the brain. Clinical deterioration occurs as bilateral central pressure is exerted on the brain from above. The initial clinical manifestation may be a subtle change in mental status or decreased LOC, bilateral motor weakness, and pinpoint pupils (2 mm). Pupillary light reflexes are still present but are often difficult to detect. Muscle tone is increased bilaterally, and bilateral Babinski signs may be present. As central herniation progresses, both pupils become midpoint and lose light responsiveness. Respiratory patterns are affected, and sustained hyperventilation may occur. Decorticate posturing is elicited by noxious stimuli. This progresses to bilateral decorticate and then spontaneous decerebrate posturing. Respiratory patterns initially include yawns and sighs and progress to sustained tachypnea, followed by shallow slow and irregular breaths immediately before respiratory arrest.

Cerebellotonsillar Herniation

Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate downward through the foramen magnum. This is usually the result of a cerebellar mass or large central vertex mass causing the rapid displacement of the entire brainstem. Clinically, patients demonstrate sudden respiratory and cardiovascular collapse as the medulla is compressed. Pinpoint pupils are noted. Flaccid quadriplegia is the most common motor presentation because of bilateral compression of the corticospinal tracts. Although mortality is high, timely neurointensive care and neurosurgical intervention results in recovery to a minimal or moderate level of disability in over 50% of patients.

Upward Transtentorial Herniation

Upward transtentorial herniation occasionally occurs as a result of an expanding posterior fossa lesion. The LOC declines rapidly. These patients may have pinpoint pupils from compression of the pons. Downward conjugate gaze is accompanied by the absence of vertical eye movements.

MODERATE AND SEVERE TRAUMATIC BRAIN INJURY

Clinical Features

Although the history may be delayed by the need for emergent resuscitation and stabilization, details regarding the mechanism of injury, circumstances surrounding the injury, and any concomitant drug or alcohol use should be solicited. The patient, prehospital providers, or any witnesses should be queried as to loss of consciousness or seizure activity. The patient should be asked about recall of the incident and the time periods and symptoms before including severe headache, nausea, vomiting, or amnesia. The patient's past medical history should be obtained, with particular attention to coagulopathies such as hemophilia. In addition, the patient's medications, particularly anticoagulant or antiplatelet agents, should be noted. If there has been a change in the patient's GCS score, this should also be noted.

The patient's current LOC, as well as that immediately before and after the injury and at the arrival of first responders, should be

noted. Worsening mental status or deteriorating GCS scores since the injury indicate the presence of moderate to severe injury. Witnessed seizures or apnea should be reported. If the patient is now awake but was unconscious at some point, the duration of loss of consciousness should be established, as well as if the patient has returned to baseline mental status.

Physical Examination

In the setting of head trauma and suspected brain injury, management should be guided by the principles of trauma resuscitation. A primary survey focusing on airway, breathing, and hemorrhage control should be performed expeditiously. After immediate life threats are adequately addressed, a secondary survey should evaluate for underlying head injury, brain injury, and neurologic compromise.

The head and neck should be carefully examined for external signs of trauma that may have also produced an underlying TBI. The signs and symptoms of a depressed skull fracture depend on the depth of depression of the free bone piece and the clinical exam may be misleading. A scalp laceration, contusion, abrasion, or avulsion may overlie a depressed skull fracture. The mobility of the scalp can result in nonalignment of the fracture with an overlying scalp laceration. As a result, the skull underlying the laceration may be normal, with the depressed area several centimeters away. Scalp swelling may interfere with physical examination findings and hide otherwise palpable bone defects. In the case of an impalement injury, the penetrating object should be left in place and removed during surgery.

Basilar skull fractures are often diagnosed by the clinical examination (Box 33.2), which should evaluate for hemotympanum, periauricular or periorbital ecchymoses, and clear otorrhea or rhinorrhea. Patients with basilar fractures are at risk for extra-axial hematomas because of the proximity of the fracture to the middle cerebral artery. Basilar fractures can compress and entrap the CNs that pass through the basal foramina, dislocate the bones of the auricular chain, and disrupt the otic canal or cavernous sinuses with subsequent injury to CNs III, IV, and V. Careful evaluation of the facial nerve is important. Fractures of the sphenoid bone can disrupt the intracavernous internal carotid artery, creating the potential for the formation of pseudoaneurysms or carotid venous fistulae.

The percentage of concurrent cervical spine injury in patients with severe head trauma ranges up to nearly 20%.[38] Often, other spinal regions are also injured. The neck should be evaluated for evidence of a cervical spine fracture. Carotid artery dissections caused by a hyperflexion-extension neck injury can occasionally be detected by auscultation of a carotid bruit. In these patients, a careful neurologic examination should assess for subtle asymmetry between the carotid arteries. Finally, all patients should undergo a thorough secondary evaluation after initial stabilization, evaluating for additional injuries, including an evaluation for spinal cord pathology.

Acute Neurologic Examination

General. The goals of the acute neurologic assessment of head trauma patients include detection of life-threatening injuries and identification of neurologic changes in the immediate post-trauma period. An accurate neurologic assessment in this period serves as a basis for comparison in subsequent examinations. An efficient neurologic examination in the emergency setting includes evaluation of mental status, GCS score, pupillary size and responsiveness, and motor strength and symmetry. If a formal GCS measure is not possible or is difficult because of comorbid confounders, the patient's mental status should be described in as much detail as possible. Declining mental status after head trauma suggests increasing ICP from an expanding mass lesion or worsening cerebral edema, which may rapidly become life-threatening. The strongest predictors of outcome following moderate and severe TBI are advanced age, pupillary reactivity, and GCS motor score. Additional predictors include the presence of extracranial injuries, CT characteristics including midline shift and subarachnoid bleeding, hypotension, hypoxia, and specific laboratory parameters (including glucose, hemoglobin, and coagulation profiles).[39,40]

Glasgow Coma Scale. The GCS is a 15-point scale used to quantify the patient's LOC and as an objective method of following the patient's neurologic status (Table 33.2). It was originally developed during a time when CT scanning was not available to communicate changes in neurologic status in comatose patients with TBI (Fig. 33.4). The score

BOX 33.2 Clinical Characteristics of Basilar Skull Fractures

Blood in ear canal
Hemotympanum
Rhinorrhea
Otorrhea
Battle's sign (retroauricular hematoma)
Raccoon sign (periorbital ecchymosis)
Cranial nerve deficits
Facial paralysis
Decreased auditory acuity
Dizziness
Tinnitus
Nystagmus

TABLE 33.2 Glasgow Coma Scale

Response	Score	Significance
Eye Opening		
Spontaneously	4	Reticular activating system intact; patient may not be aware
To verbal command	3	Opens eyes when told to do so
To pain	2	Opens eyes in response to pain
No eye opening	1	Does not open eyes to any stimuli
Verbal Stimuli		
Oriented, converses	5	Relatively intact CNS, aware of self and environment
Disoriented, converses	4	Well-articulated, organized, but disoriented
Inappropriate words	3	Random exclamatory words
Incomprehensible	2	Moaning, no recognizable words
No verbal response	1	No response or intubated
Motor Response		
Obeys verbal commands	6	Readily moves limbs when told to
Localizes to painful stimuli	5	Moves limb in an effort to remove painful stimuli
Flexion withdrawal	4	Pulls away from pain in flexion
Abnormal flexion	3	Decorticate rigidity
Extension	2	Decerebrate rigidity
No motor response	1	Hypotonia, flaccid—suggests loss of medullary function or concomitant spinal cord injury

CNS, Central nervous system.

assigns points based on the patient's best eye opening (spontaneous opening = 4 to no response = 1), motor response (obeys commands = 6 to no response = 1), and verbal response (oriented = 5 to no response = 1). Recent literature has supported the integration of a pupillary component to the GCS score.[41] Due to its ease of use, it has been adopted in the routine assessment of all trauma patients, including those with MTBI who are not comatose. However, the GCS score can reflect impairment from conditions other than brain injury, such as distracting injuries, intoxication from drugs and alcohol, hypoxemia, and sedative medications. Furthermore, patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be a mild brain injury. Although TBI is often categorized into mild, moderate, and severe based on the GCS score, it actually represents a spectrum of injury and the trend in GCS score is more indicative of outcome than any one score in isolation.

Pupillary examination. An evaluation of the patient's pupil size and responsiveness is performed early in the initial assessment of the head-injured patient. Pupillary asymmetry, the loss of the light reflex, or a dilated pupil suggests herniation syndrome as increasing pressure on the CN III resulting in compromise of the parasympathetic fibers and pupillary dilation on the affected side. Of note, use of the pupillary examination for localization of an intracranial lesion is neither sensitive nor specific. Further, traumatic mydriasis, resulting from direct injury to the eye and periorbital structures, may confuse the assessment of the pupillary responsiveness. A pupillometer, though not commonly available, may be of some use in objectively determining pupillary reactivity.[42] As with the GCS score, a change in pupillary response is more indicative of intracranial pathology than the initial findings.

Motor examination. The patient's acute motor examination assesses for strength and symmetry. If the patient is not cooperative or is comatose, motor movement should be elicited by the application of humane external or noxious stimuli (such as a sternal rub). Any movement should be recorded, and voluntary purposeful movement must be distinguished from abnormal motor posturing. If RSI is to be performed, attempts should be made to perform the motor examination before paralytic agents are given as paralysis obscures involuntary reflexes.

Decorticate posturing implies injury above the midbrain and presents as abnormal flexion of the upper extremity and extension of the lower extremity. The arm, wrist, and elbow slowly flex, and the arm is adducted. The leg extends and rotates internally, with plantar flexion of the foot. Decerebrate posturing is the result of a more caudal injury, and therefore is associated with a worse prognosis. The arms extend abnormally and assume an adducted position. The wrist and fingers are flexed, and the entire arm is internally rotated at the shoulder. The neck undergoes abnormal extension, and the teeth may become clenched. The leg is internally rotated and extended, and the feet and toes are plantar-flexed.

Brainstem function. In the acute setting, brainstem activity is assessed by the patient's respiratory pattern, pupillary size, and eye movements. The oculocephalic response ("doll's eyes" maneuver) tests the integrity of the pontine gaze centers. The oculovestibular response (using cold water calorics) also permits assessment of the brainstem. Comatose patients no longer demonstrate nystagmus when cold water is placed in the ear canal; the only response is tonic deviation of the eyes toward the instilled cold water. This response is dampened by cerumen or blood in the patient's ear canal, and the tympanic membrane needs to be intact for this test to be performed. Neither maneuver should be attempted until cervical spine fractures have been ruled out. In patients who are awake and cooperative, a formal CN examination should be performed. In the severely head-injured patient, the CN examination is often limited to the pupillary responses (CN III), gag reflex (CNs IX and X), and corneal reflex (CNs V and VII). Facial symmetry (CN VII) can sometimes be assessed if the patient grimaces with noxious stimuli.

Common Presentations of Specific Lesions

Epidural Hematoma

The classic presentation of an EDH is head trauma producing a decreased LOC followed by a so-called *lucid interval.* Although the patient's LOC is generally normal or only slightly depressed, a completely normal mental status may not return before a second episode of decreased consciousness occurs. While nearly 50% of patients with EDHs present classically, the lucid interval is not pathognomonic for an EDH and may occur in patients with other expanding mass lesions. The development of symptoms and signs of EDH is entirely dependent on how quickly the EDH is developing within the cranial vault. Patients with an EDH often complain of a severe headache, sleepiness, dizziness, nausea, and vomiting. A small EDH may remain asymptomatic, but this is rare.

If the EDH is rapidly detected and evacuated, functional outcome is excellent. Because of their rapid formation, EDHs from arterial bleeding are usually detected within hours after injury and often earlier in children. EDHs that develop from a dural sinus tear develop more slowly, and clinical manifestations may be delayed, with resultant delays in detection.

The usual cause of a posterior fossa EDH is direct occipital trauma resulting in a skull fracture that disrupts a venous sinus, and most patients have external evidence of occipital injury. Most patients become symptomatic within 24 hours after injury, with complaints of headache, nausea, vomiting, and nuchal rigidity. Most patients eventually have a decreased LOC.

Subdural Hematoma

The patient's clinical presentation in SDH depends on the amount of brain injury sustained at the time of trauma and the rate of SDH expansion. If the patient with a SDH was rendered unconscious at the time of trauma, the prognosis is poor; these patients often have concurrent TAI. The signs and symptoms after injury that produce a SDH are initially related to the other intracranial injuries that may have been sustained and then to the slow expansion of the SDH. SDHs are classified by the time to clinical presentation. Acute SDHs are symptomatic within 24 hours after trauma. Patients with acute SDHs often have a decreased LOC and most patients with an acute SDH have a GCS score less than 8. Approximately 12% to 36% of patients will have a lucid period at some point in their presentation. The overall mortality of patients who have an SDH and require surgical intervention is 40% to 60%.

A chronic SDH becomes symptomatic 2 weeks or more after trauma. The signs and symptoms may be very subtle or nonspecific, but many patients demonstrate unilateral weakness or hemiparesis. Most report an altered LOC, but some patients are unable to recall the trauma or describe only a minor injury. A chronic SDH may have initially been a small asymptomatic SDH that eventually expanded owing to a combination of recurrent hemorrhage and escape of plasma into the hematoma. At some point, a critical mass is reached, and the chronic SDH becomes symptomatic.

Clinical manifestations of posterior SDH vary but usually include nausea, vomiting, headache, and decreased LOC. Occasionally, CN palsies may be found, as well as nuchal rigidity, cerebellar signs and symptoms, and papilledema.

Traumatic Subarachnoid Hemorrhage

An increased incidence of skull fractures and contusions is found in patients with a traumatic SAH (tSAH) compared with patients without tSAH. Patients may complain of headache and photophobia. The

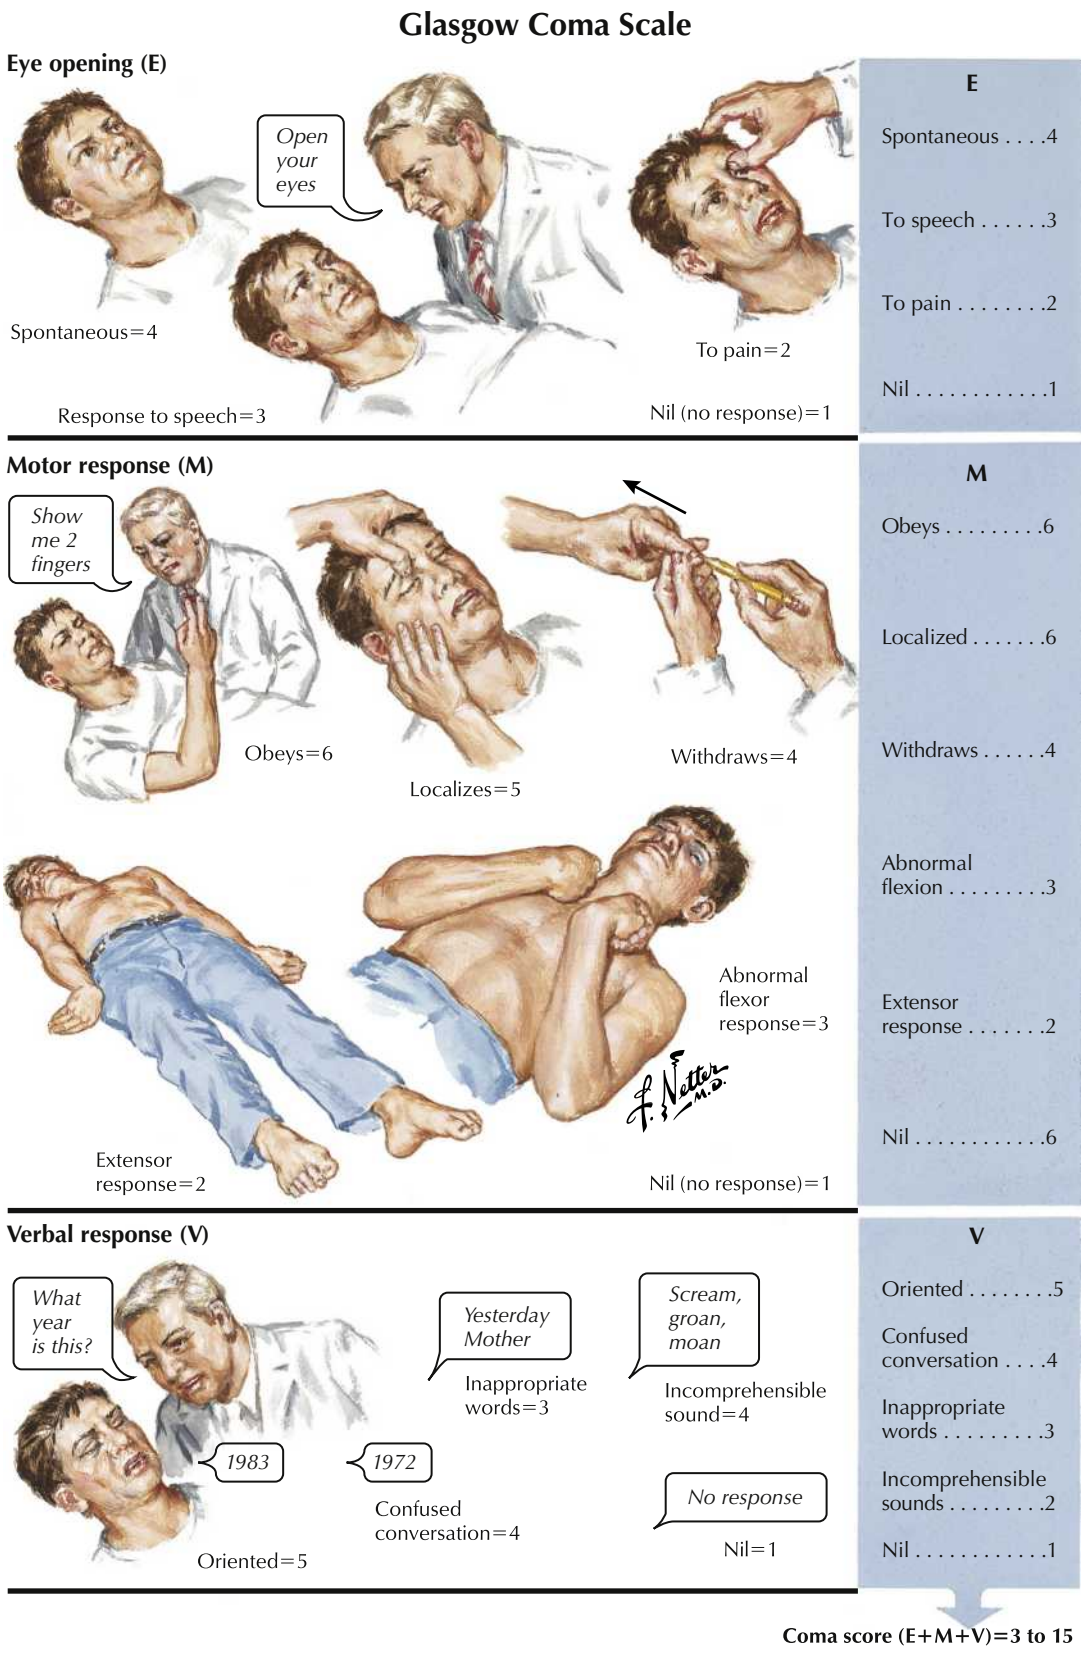

Fig. 33.4 How to calculate a Glasgow Coma Scale (GCS) score. (Copyright 2016 Elsevier Inc. All rights reserved. www.netterimages.com.)

amount of blood within the tSAH correlates directly with the outcome and inversely with the presenting GCS score.

Subdural Hygroma

Clinically, a SDHG cannot be distinguished from other mass lesions. Often, patients have a decreased LOC or focal motor deficits. They may complain of headaches, nausea, and vomiting. The ICP can increase because of the mass effect, and signs of increased ICP may be present.

Traumatic Axonal Injury

The duration of loss of consciousness or coma following injury is directly related to the extent of axonal pathology in the brainstem. Even with extensive axonal pathology in the white matter, there may be little or no loss of consciousness if the brainstem is relatively spared. Therefore, it appears that the distribution, rather than the overall extent, of axonal pathology is important in determining consciousness immediately following TBI.

Cerebral Contusion

The clinical presentation of patients with contusions is frequently delayed. They may have sustained only a brief loss of consciousness, but the duration of posttraumatic confusion and obtundation may be prolonged. If contusions occur near the sensorimotor cortex, focal neurologic deficits may be present. Many patients with significant contusions make uneventful recoveries, but contusions may cause significant neurologic problems, including increased ICP, PTSs, and focal neurologic deficits depending on the location of the contusion.

Intracerebral Hematoma

The clinical effects of ICHs depend on size and location and whether the bleeding is continuing. ICHs have been reported with all degrees of severity of head trauma. More than 50% of patients with ICH sustain loss of consciousness at the time of impact. The patient's subsequent LOC depends on the severity of the impact and coexisting lesions. Combined with contusions, other concurrent lesions, and subsequent perilesion edema, an ICH can produce substantial mass effects and precipitate a herniation syndrome (Fig. 33.5).

Traumatic Intracerebellar Hematoma

The clinical presentation of an isolated traumatic cerebellar hematoma is similar to that of other posterior lesions. When other traumatic lesions are present, the diagnosis may be difficult to make clinically.

Differential Diagnoses

In the context of trauma, conditions presenting with an altered LOC include seizures and associated postictal state, intoxication with alcohol or drugs, and systemic trauma resulting in hypoxemia or hypoperfusion. A patient's mental status may also be impaired by sedatives or motor function may be altered by neuromuscular blocking agents administered prior to ED arrival. Head trauma may result in confounding injuries to other parts of the head or neck, including skull or facial bone fractures, cervical spine or spinal cord injuries, eye injuries, otolaryngeal injuries, and damage to blood vessels within the neck. Although a GCS score of 15 does not exclude the possibility of brain injury, a decreasing GCS score suggests an expanding intracranial lesion. Signs of intracranial injury include worsening headache, focal neurologic signs, confusion, and lethargy, which may progress to coma. Presentation of a subdural hemorrhage may be acute, subacute, or chronic. Epidural or intracerebral hemorrhages have an acute presentation, which may be delayed by minutes to hours from the initial injury. Patients with an epidural hemorrhage may have a lucid interval following a brief loss of consciousness or period of confusion. A skull fracture may be accompanied by underlying traumatic pathology, including brain contusions, dural tears, and vascular trauma. Given the proximity of the middle meningeal artery to the temporal bones, consider extra-axial hematomas (especially EDH) if there are signs of a basilar skull fracture. Decorticate posturing implies injury above the midbrain, whereas decerebrate posturing is suggestive of a midbrain lesion. Pupil inequality and unilateral motor deficits may help localize a lesion. In vulnerable populations, consider nonaccidental trauma in all patients with brain injury. Furthermore, consider TBI in all patients with head trauma and advanced age or those on anticoagulant or antiplatelet agents, regardless of symptoms. With age, the brain atrophies and creates more space within the cranial vault for blood to accumulate, so older adults can have significant hemorrhage and not show signs of deterioration.

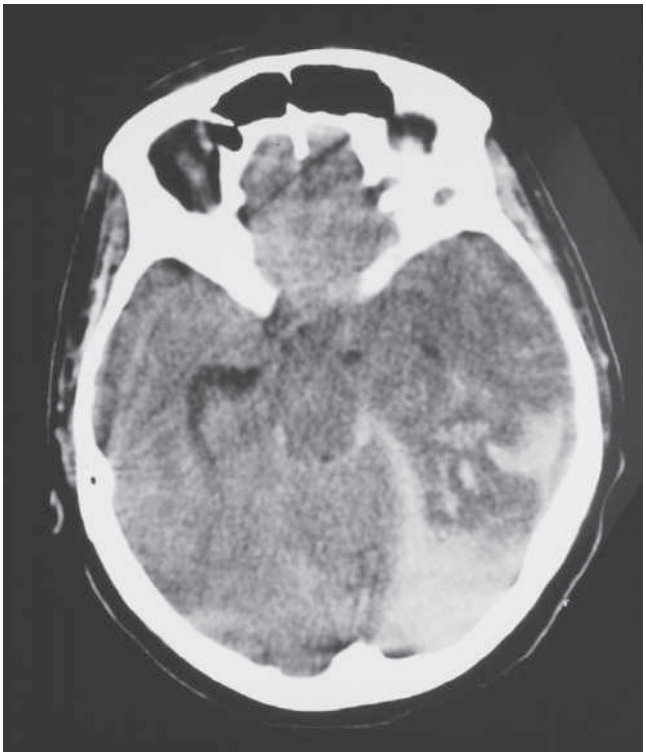

Fig. 33.5 Non–contrast-enhanced computed tomography (CT) scan of intracerebral hematoma and contusion in the left occipital region. The scan also shows layering of a tentorial subdural hematoma. Mass effect and early uncal herniation are visible as well.

Diagnostic Testing

Laboratory Tests

Routine laboratory tests are generally not needed for patients with isolated mild TBI in the acute setting, except for a bedside glucose test in patients with altered mental status and determination of the blood alcohol level in patients suspected of alcohol intoxication and head trauma. Suspicion of systemic pathology as the cause of the head trauma, such as when a diabetic patient sustains an MVC after losing consciousness from hypoglycemia, warrants directed testing for culprit conditions. Coagulation studies are indicated in patients with coagulopathies (e.g., hemophilia, Von Willebrand disease), suspected liver disease, and those on anticoagulants. Ancillary laboratory tests that may provide useful information in the subsequent management of the patient include a complete blood count and electrolyte levels. Routine laboratory testing has limited prognostic value.[43]

Neuroimaging

Skull radiography. Skull radiography after head trauma has long been replaced by cranial CT, which is the cornerstone of imaging for acute head trauma. The bone windows of a CT scan can better define skull pathology, including depressed and basilar fractures, than plain radiographs. Further, patients with clinical signs of skull fracture have a substantially increased incidence of intracranial lesions. When the clinical examination shows evidence of skull fractures, CT should be performed. Although plain skull radiographs were used in the past to localize missile fragments or ascertain penetration of the skull, CT is also the radiologic test of choice for penetrating head trauma. CT defines the precise location of the missile, its intracranial path, the presence of bone or missile fragments, extra-axial or intracerebral blood collections or other traumatic lesions, and pneumocephalus. Skull radiographs for adults with either mild or severe TBI are not recommended.

Computed tomography. Noncontrast CT of the head is the diagnostic standard for identifying intracranial injury in the ED. This scan delineates acute intra-axial and extra-axial bleeding, cerebral swelling, ischemic infarction caused by hypoxia after trauma, evidence of increased ICP, and pneumocephalus. It is sensitive for demonstrating mass effect, ventricular size and configuration, bone injuries, and acute hemorrhage, regardless of location (i.e., parenchymal, subarachnoid, subdural, or epidural spaces). The Rotterdam score was developed to determine the risk for mortality in TBI. It is based on initial noncontrast CT scan findings of basal cistern compression, midline shift, presence of an EDH, and the presence of intraventricular blood or traumatic SAH (Box 33.3). While initial CT scan is sensitive early in the patient's course, any clinical deterioration should prompt repeat scanning.

Pneumocephalus. This is often associated with missile wounds that penetrate the sinuses but can be caused by free air sucked into the penetration cavity behind the projectile. All tangential GSWs should be evaluated with a head CT scan secondary to the high incidence of associated intracranial injury.[25] Angiography may be indicated to better discern location referable to key vascular structures. Pneumocephalus in the setting of TBI should be considered an open fracture.

Epidural hematoma. On CT scan, an EDH appears hyperdense, biconvex, ovoid, and lenticular. The EDH does not usually extend beyond the dural attachments at the suture lines. The margins are sharply defined, and the hematoma usually bulges inward toward the brain (Fig. 33.6). EDHs of mixed density on CT may be actively bleeding. The temporoparietal region is the most likely site for an EDH. An EDH is usually unilateral, and 20% of patients have other intracranial lesions, usually SDHs or contusions. The deterioration of a patient who has an EDH from arterial bleeding can be rapid and dramatic.

A posterior fossa EDH is the most common traumatic mass lesion of the posterior fossa and accounts for 5% of EDHs. On CT scan, a posterior fossa EDH looks similar to other EDHs, but may cross the midline and extend above the tentorium to the supratentorial compartment (Fig. 33.7).

Subdural hematoma. Unlike EDHs, SDHs often extend beyond the suture lines (Fig. 33.8). An SDH may follow the contour of the tentorium and be detected within the interhemispheric fissure (Fig. 33.9). Many patients with an acute SDH also show CT evidence of intracerebral lesions contralateral to the SDH. A subacute SDH is symptomatic between 24 hours and 2 weeks after injury. It may appear hypodense or isodense on CT scans. Contrast increases the detection of isodense lesions. Patients complain of a headache, altered mental status, or focal deficits.

On a CT scan, a chronic SDH may appear isodense or hypodense to brain parenchyma. Indirect evidence of the lesion includes a midline shift, effacement of the ipsilateral cortical sulci, and ventricular compression. Contrast may increase the likelihood of identifying a chronic SDH that has become isodense. On a CT scan, blood of various ages is seen as a mixed-density lesion. On a magnetic resonance imaging (MRI) scan, a chronic SDH appears hyperdense.

Posterior fossa SDHs are caused by occipital trauma and, on a CT scan, they do not cross the midline or extend above the tentorium. The outcome of a posterior SDH is very poor.

BOX 33.3 Rotterdam Score of Initial Noncontrast Computed Tomography for Predicting 6-Month Mortality Following Traumatic Brain Injury[a]

1. Basal cistern effacement
0 = none
1 = partially effaced (compressed)
2 = completely effaced (compressed)
2. Midline shift
0 = no shift or ≥5 mm
1 = >5 mm
3. EDH (epidural hematoma)
0 = EDH present
1 = no EDH
4. IVH (intraventricular hemorrhage) or SAH (subarachnoid hemorrhage)
0 = neither present
1 = either present
2. Add 1 to score
Total score = 1–6 points

[a] Probability of mortality at 6 months postinjury based on score:
1 ≤ 0%
2 ≤ 7%
3 ≤ 16%
4 ≤ 26%
5 ≤ 53%
6 ≤ 61%

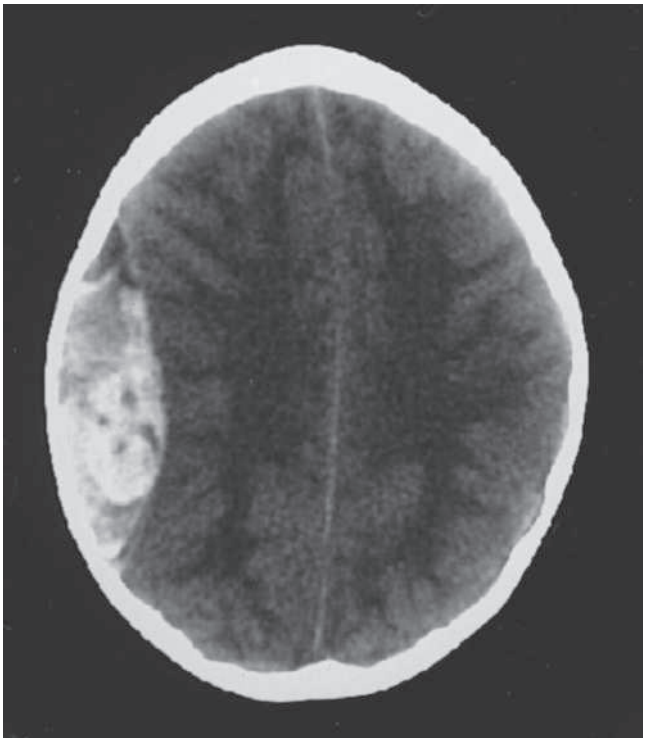

Fig. 33.6 Non–contrast-enhanced CT scan of acute epidural hematoma at the level of right midconvexity. There is an associated mass effect and moderate midline shift.

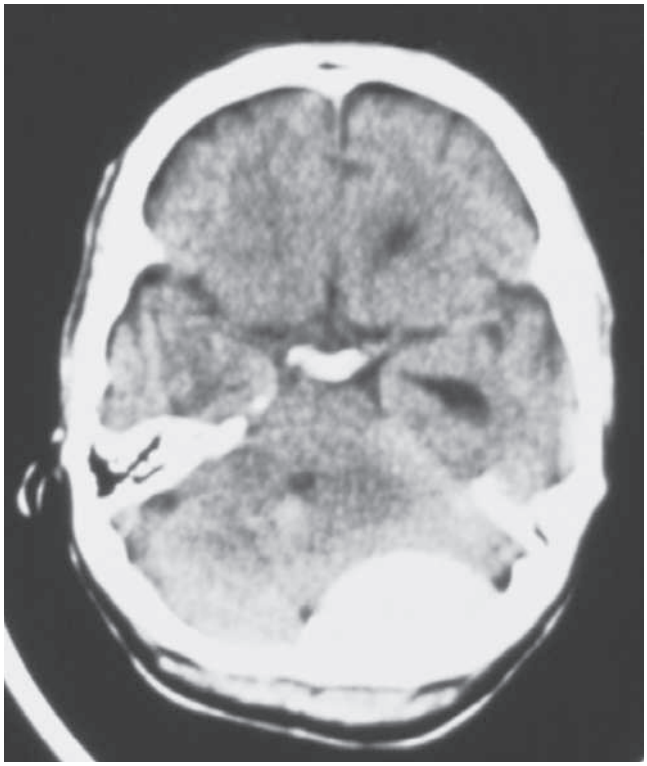

Fig. 33.7 Non–contrast-enhanced CT scan of large left posterior fossa, epidural hematoma. The size of the lesion at this high level suggests that it crosses into the supratentorial compartment. This lesion is often associated with occipital bone fracture that disrupts transverse sinus.

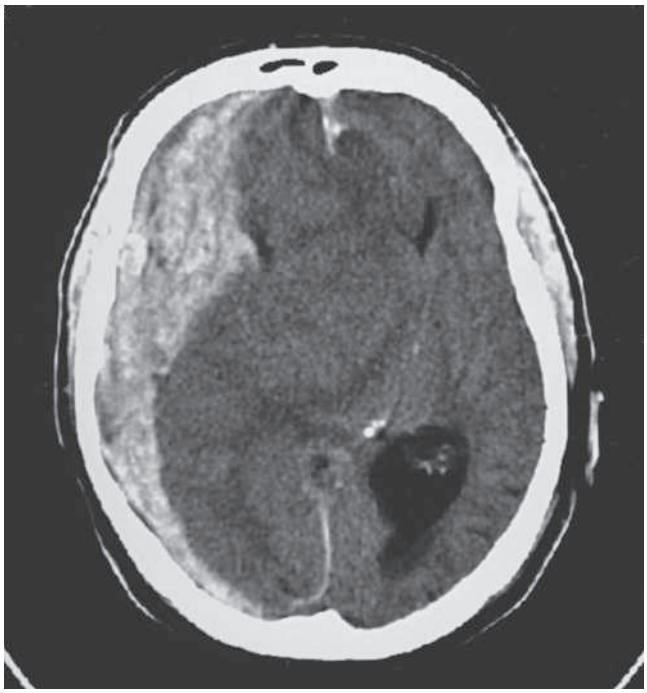

Fig. 33.8 Non–contrast-enhanced CT scan of acute right temporal subdural hematoma. There is acute bleeding and delayed bleeding, which explains the mixed density. Mass effect is large, with a midline shift measuring approximately 2.7 cm right to left. The right lateral ventricle has been obliterated.

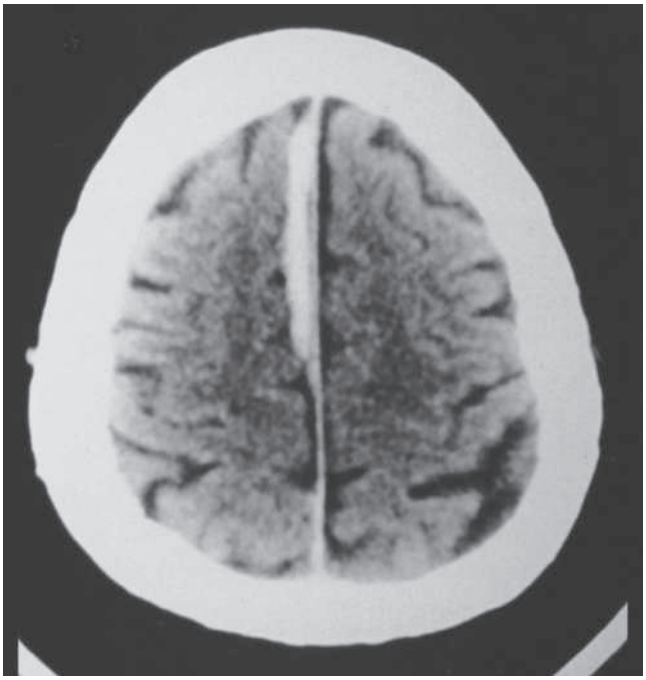

Fig. 33.9 Non–contrast-enhanced CT scan of interhemispheric acute subdural hematoma.

Traumatic subarachnoid hemorrhage. A noncontrast CT scan allows the diagnosis to be made, with increased density noted within the basilar cisterns. Blood can also be seen within the interhemispheric fissures and sulci. The amount of blood within the tSAH correlates directly with the outcome and inversely with the presenting GCS score.

Subdural hygroma. On CT, SDHGs appear crescent shaped in the extra-axial space; the density is the same as that of CSF. Bilateral SDHGs are common.

Traumatic axonal injury. Diffuse TAI is the most common CT finding after severe head trauma, estimated to occur in over 50% of all comatose head injured patients. However, in milder cases, there is no specific acute focal traumatic lesion noted on a head CT scan or on structural MRI scan. Occasionally, small petechial hemorrhages in proximity to the third ventricle and within the white matter of the corpus callosum or internal capsule of the brainstem are detected. Intraventricular hemorrhage and midline SAH have been reported to be an early predictor of TIA.[44,45] Although histopathologic examination of postmortem brain tissue is the gold standard for diagnosing TAI, advanced MRI neuroimaging techniques, such as diffusion tensor imaging (DTI), may help assess white matter integrity (Fig. 33.10).

Cerebral contusions. Non–contrast-enhanced CT is the best diagnostic test to discover contusions in the early posttraumatic period. These appear heterogeneous and irregular because of mixed regions of hemorrhage, necrosis, and infarction. Often, the surrounding edematous tissue appears hypodense. By post-trauma days 3 and 4, the blood located within the contusions has begun to degrade, and structural MRI becomes more diagnostic.

Intracerebral hematoma. An ICH may be detected on the first CT scan immediately after injury but often is not seen for several hours or days. Unlike contusions, ICHs are usually deep in the brain tissue and often become well demarcated over time. On CT scan, an ICH appears as a well-defined hyperdense homogeneous area of hemorrhage (Fig. 33.11).

Traumatic intracerebellar hematoma. Often, these patients have an associated skull fracture, posterior fossa EDH or SDH, or supratentorial contrecoup hematomas and contusions.

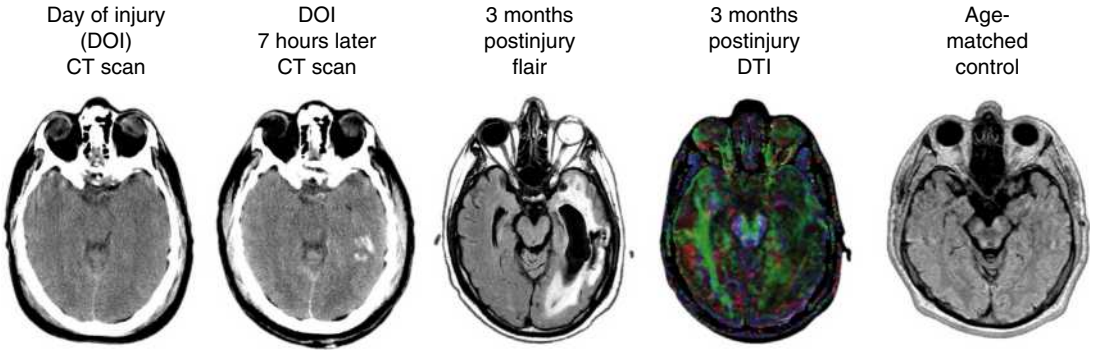

Fig. 33.10 Sequential scan findings in severe traumatic brain injury (TBI) with traumatic axonal injury (TAI). In the emergency department (ED), on initial day of injury (DOI) CT imaging, the scan on the *far left* shows primarily generalized edema but, by 7 hours, distinct intraparenchymal hemorrhages appear, particularly within the left temporal lobe. By 3 months postinjury, TAI and intraparenchymal hemorrhages result in massive degenerative effects, reflected in temporal horn dilation and markedly abnormal white matter signal differences throughout the temporal and occipital lobes on the fluid-attenuated inversion recovery (FLAIR) sequence. Temporal horn dilation is also evident in the right temporal lobe as well, reflective of the generalized atrophy. The loss of white matter integrity is more distinctly observed using diffusion tensor imaging (DTI), where there is no coherent direction noted in the left temporal region; even though the right temporal lobe exhibits atrophic changes, the inferior occipitotemporal fasciculus *(arrow)* is distinctly visible. The control MRI scan is a T1 image showing symmetric temporal lobe morphology with the normal slit-like appearance of the temporal horns. (Adapted from Bigler ED, Maxwell WL. Neuropathology of mild traumatic brain injury: relationship to neuroimaging findings. *Brain Imaging Behav.* 2012;6:108–136.)

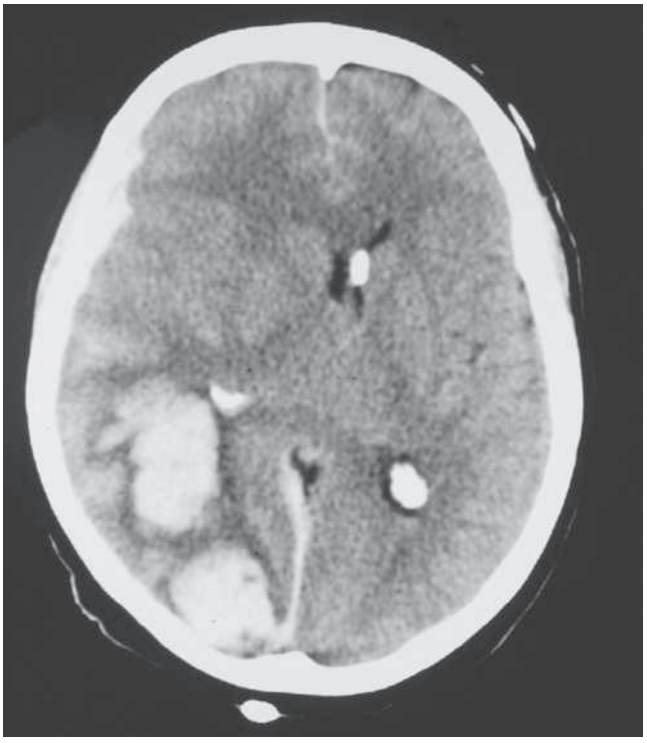

Fig. 33.11 Non–contrast-enhanced CT scan of right occipital and temporal intracerebral hematomas, surrounded by mild edema and hemorrhagic contusion. A small, interhemispheric, subdural hematoma is visible in the posterior interhemispheric fissure. Midline shift is obvious. A ventriculostomy has been placed and is visible as high-density image within the ventricles.

Cerebral edema. On CT scans, diffuse edema manifests as bilateral compression of the ventricles, loss of definition of the cortical sulci, or effacement of the basal cisterns (Fig. 33.12). Focal edema adjacent to traumatic mass lesions demonstrates decreased density on CT scans compared with normal tissue.

Fig. 33.12 Non–contrast-enhanced CT scan showing diffuse cerebral edema. Loss of gray-white differentiation in the brain parenchyma is present. Bilateral compression of the ventricles has occurred, with loss of cortical sulci.

Management

Out-of-Hospital Care

The out-of-hospital management of the head-injured patient should focus on preventing or minimizing secondary brain injury specifically on the major systemic insults of hypotension, hypoxia and hypocarbia. Interventions should be aimed at maintenance of oxygenation and

prevention of hypocarbia through appropriate airway management, supplemental oxygen as needed, and controlled ventilation. Hypotension should be avoided through directed fluid resuscitation and control of hemorrhage.

Airway. The ultimate goal in the field is to prevent or minimize hypoxia. Out-of-hospital airway protocols balance the risks of emergency intubation in an uncontrolled setting with the need to secure an at-risk airway and prevent hypoxia. Controversy exists regarding the benefits of out-of-hospital intubation in patients with brain injuries.[46] In systems with short transport times, and in patients in whom an oxygen saturation more than 90% can be maintained with supplemental oxygen, field intubation is of questionable benefit and may potentially lead to worse outcomes.[47] If oxygenation can be maintained and transport time is short, definitive airway management should be delayed until arrival in the ED.

If endotracheal intubation is undertaken in the field, it should be performed by skilled practitioners with a rigorous quality assurance program and continuous provider training.[48] All advanced airway placement should be confirmed with quantitative end-tidal capnography ($ETCO_2$), which dramatically improves the detection of improperly placed airway devices and inadvertent hyperventilation by field providers.[49] Prehospital endotracheal intubation is associated with poorer prognosis in children and if at all possible, should be avoided in this population (see Chapter 165).

Hypotension. Avoiding and managing hypotension are critical elements of the prehospital treatment of the head-injured patient.[50] The evaluation of the head-injured patient should include a search for external signs of head trauma. Scalp lacerations may bleed a large volume into a bulky dressing, and a less bulky dressing should be used with firm constant manual pressure applied to avoid excessive blood loss. Any other ongoing external hemorrhage should be expeditiously addressed and controlled. Although permissive hypotension may be beneficial in some trauma patients, it is detrimental in the setting of brain injury.[50,51]

Agitation. Many severely head-injured patients are initially combative or agitated. Transporting an agitated patient who is fighting against physical restraints may exacerbate physical injury, cause an increase in ICP, and interfere with appropriate stabilization and management. Management of agitation in the out-of-hospital setting mirrors that used in the ED, as described in the following.

Emergency Department Management

General. In the ED, management of patients with severe head trauma is in accordance with ATLS (Advanced Trauma Life Support) protocols. Monitoring of vital signs should be continuous including oxygenation (pulse oximetry) ventilation (capnography), heart rate, blood pressure, and temperature. Tetanus immunization status should be determined, and prophylaxis given, as appropriate. Pregnancy status in women of childbearing age should be verified.

Airway. Primary airway compromise in the setting of head trauma may result from craniofacial or neck trauma, bleeding, or vomiting. Secondary airway compromise may also result from brain injury, as in the case of loss of brainstem reflexes, patient agitation, severe systemic hypotension, or alterations in mental status. In such cases, the airway should be secured early to protect against aspiration and prevent secondary brain injury as a result of hypoxia or hypercarbia.

If possible, a rapid but detailed neurologic examination should be performed before the patient is given any sedative or neuromuscular blocking agent. This focused examination includes careful recording of the elements of the GCS, characterization of movement of all four extremities (to command, localization or withdrawal to pressure, posturing), tone, and pupillary reflexes. These elements are essential in correlating CT findings with clinical injury and are also useful in following the patient's clinical progression. The rapid sequence intubation (RSI) drug selection and technique of intubation for the head-injured patient is discussed in Chapter 1.

Hypotension. While hypotension can occasionally be attributed to isolated head injury, it is almost always secondary to another systemic insult such as hemorrhage or spinal cord injury. If hypotension is detected at any time in the emergent management of a potentially brain-injured patient, a cause other than the brain injury should be sought (see Chapter 33).

Systemic hypotension has profound implications for neurologic outcomes. As such, fluids or blood transfusion should be delivered to maintain a blood pressure as close to normal as possible, with a SBP of at least 110 mm Hg for those 15 to 49 and over 70 years of age, and at least 100 mm Hg for those 50 to 69 years old.[10] Blood pressure should be corrected early in the patient's course, as not only depth of hypotension but duration as well have an important effect on mortality.[29,50,52]

Brain-directed hyperosmolar therapy. Osmotic therapy should be guided by findings on ICP monitoring. Prior to initiation of such monitoring, brain-directed osmotic therapies should be reserved for patients with signs of transtentorial herniation or progressive neurologic deterioration not attributable to extracranial causes.[10] If there are signs of impending herniation syndrome, such as deepening coma, a newly asymmetric pupil, or other substantially diminishing neurologic parameters, we recommend the use of osmotic diuretics, such as mannitol or HTS.

Osmolar therapy can draw water across an intact BBB and thereby lower ICP. Mannitol, 0.25 to 1 g/kg, is given every 6 hours up to a serum osmolality of 320 mOsm/kg. HTS (23.4%), 30 to 60 mL, can be given every 6 hours, up to a maximum serum sodium level of 160 mEq/L. Treatment with 30 mL of 23.4% HTS appears to be at least as effective as mannitol at lowering ICP rapidly and reversing herniation, although a central line is necessary for safe administration. Peripheral administration of 3% sodium chloride has a low complication rate and may be an acceptable alternative.[53,54] Peripheral administration of 250 mL of 3% sodium chloride (which is comparable to 23.4%) has a low complication rate and may be an acceptable alternative.

Mannitol is the time-honored mainstay for the control of elevated ICP in acute severe TBI effectively reducing cerebral edema by producing an osmotic gradient that reduces brain volume and provides increased space for an expanding hematoma or brain swelling. The osmotic effects of mannitol occur within minutes and peak approximately 60 minutes after bolus administration. The ICP-lowering effects of a single bolus may last for 6 to 8 hours. It also promotes CBF by reducing blood viscosity and microcirculatory resistance. It is an effective free radical scavenger, reducing the concentration of oxygen free radicals that may promote cell membrane lipid peroxidation. Proposed benefits of HTS include reducing secondary injury through effects on cellular modulation, decreasing cerebral edema, improving peripheral perfusion, decreasing ICP through vasoregulatory mechanisms, and upregulation of proinflammatory and prothrombotic mediators. Because it is a potent diuretic, mannitol is preferred in cases of fluid overload, whereas HTS can be used as a resuscitative fluid.

Mannitol can precipitate renal failure or hypotension if given in large doses. It may also induce a paradoxical effect of increased bleeding into a traumatic lesion by decompressing the tamponade effect of a hematoma. Potential adverse events associated with HTS include renal failure, central pontine myelinolysis, and rebound ICP elevation.

Few comparative data exist on brain-directed osmotic therapy.[55] Selection of mannitol versus HTS should be made on an institutional basis, so that providers across various specialties (e.g., emergency medicine, trauma surgery, neurosurgery, anesthesiology) provide consistent care.[10,56] Further, while guidelines highlight the utility of

hyperosmolar therapy in the care of patients with severe TBI,[10] there is limited high-quality evidence demonstrating improvements in mortality or functional outcomes.[57]

Hyperventilation. Under normal conditions, $Paco_2$ is the most powerful determinant of CBF and, between a range of 20 and 80 mm Hg, CBF is linearly responsive to $Paco_2$. Formerly, so-called therapeutic hyperventilation was recommended as a method to reduce ICP. However, this reduction in ICP is accomplished by reducing CBF, which is important in meeting the brain's metabolic demands. A low $Paco_2$, and the resulting lower CBF, may result in cerebral ischemia, whereas high $Paco_2$ levels can result in cerebral hyperemia and high ICP. Normal ventilation is currently the goal for severe TBI patients in the absence of cerebral herniation, and $Paco_2$ should be maintained in the normal range of 35 to 45 mm Hg.[10] Additional care should be taken to avoid hyperventilation during the first 24 hours after injury when CBF is often critically reduced.

In the case of life-threatening cerebral herniation or significant ICP elevation, therapeutic hyperventilation is appropriate only as a short-term intervention, bridging to more definitive therapy (such as craniectomy). If hyperventilation is to be used, jugular venous oxygen saturation (Sjo_2) or brain tissue O_2 partial pressure ($Btpo_2$) measurements are recommended to monitor oxygen delivery, although these modalities are not commonly available in the ED.[10,58] The neurologic effects of hypocapnia are illustrated in Fig. 33.13.

Cranial decompression. In patients with impending herniation who do not respond to first-line therapies, cranial decompression may temporarily reverse or arrest the herniation syndrome and emergency trephination may allow enough time for a patient to undergo a formal

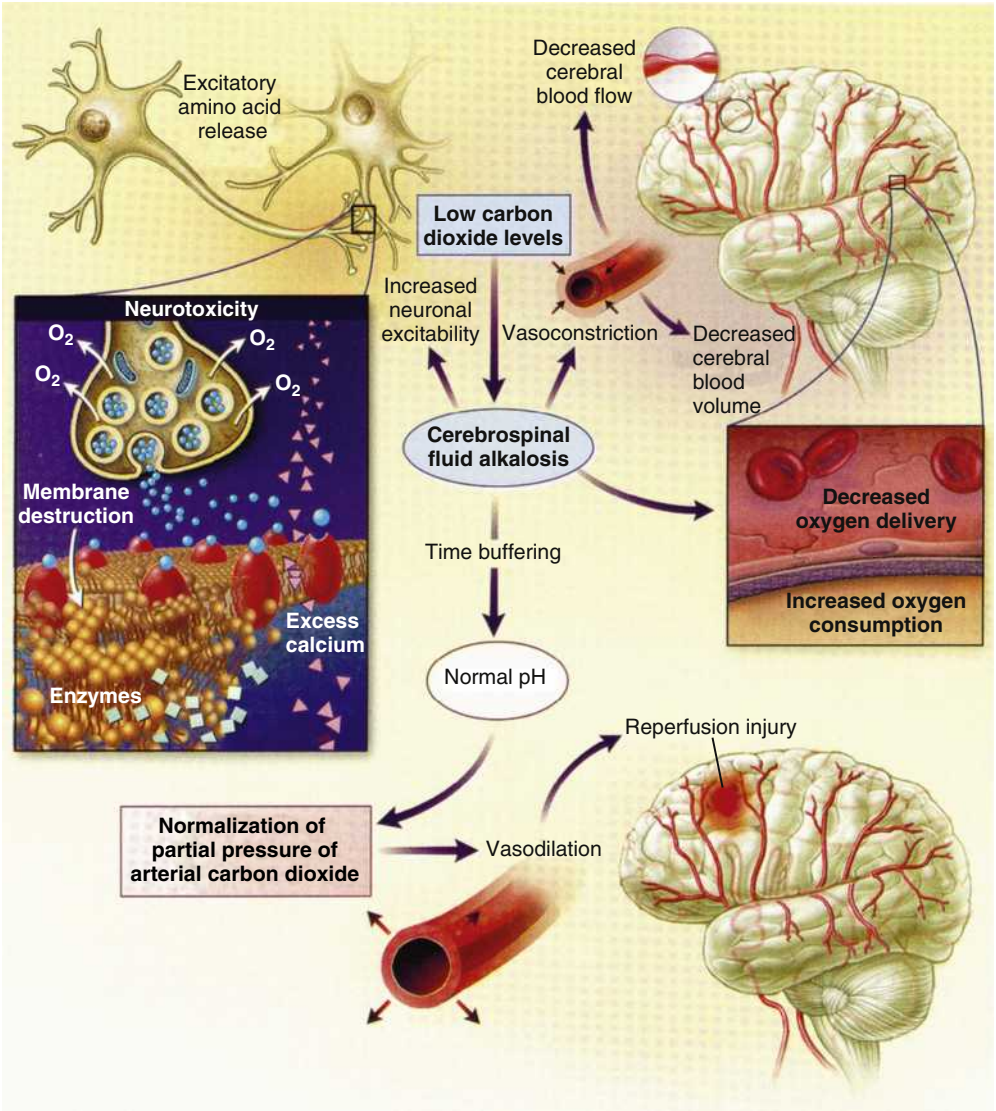

Fig. 33.13 **Neurologic Effects of Hypocapnia.** Systemic hypocapnia results in cerebrospinal fluid alkalosis, which decreases cerebral blood flow, cerebral oxygen delivery and, to a lesser extent, cerebral blood volume. The reduction in intracranial pressure may be lifesaving in patients in whom the pressure is severely elevated. However, hypocapnia-induced brain ischemia may occur because of vasoconstriction (impairing cerebral perfusion), reduced oxygen release from hemoglobin, and increased neuronal excitability, with the possible release of excitotoxins, such as glutamate. Over time, cerebrospinal fluid pH and hence cerebral blood flow gradually return to normal. Subsequent normalization of the partial pressure of arterial carbon dioxide can then result in cerebral hyperemia, causing reperfusion injury to previously ischemic brain regions. (From Laffey JG, Kavanagh BP. Hypocapnia. *N Engl J Med.* 2002;347:43–53.)

craniotomy in the operating room. However, most patients presenting unconscious have sustained diffuse massive brain injury, without focal lesion amenable to emergency decompression. Patients with erratic or absent respiratory effort, bilateral fixed and dilated pupils, no spontaneous eye movements, and decerebrate posturing do not benefit from emergent "burr holes." Outcomes in other patient populations are of questionable benefit.[59] Trephination should be undertaken only after confirmation of an extradural collection by neuroimaging and only by, or under the guidance of, an emergency clinician with specific training.

Decompressive craniectomy (DC) is the surgical removal of a portion of the skull bone and has been performed for the purpose of relieving elevated ICP. Bifrontal DC for severe TBI patients with diffuse injury (without mass lesions) who have ICP elevation refractory to first-tier therapies does not result in improved outcome, as measured by the Glasgow Outcome Scale-Extended (GOS-E) score, at 6 months postinjury.[10] DC for severe and refractory intracranial hypertension following brain injury results in improved mortality at the cost of worse neurologic outcomes at 6 months post injury.[60] As such, there is still ongoing debate as to the optimal timing, technique, and population for DC following TBI.[61,62]

Reversal of anticoagulation. Patients taking warfarin anticoagulants should have these medications reversed in the case of ongoing intracranial bleeding. Vitamin K antagonists may be managed with intravenous (IV) vitamin K, fresh frozen plasma, or 3-factor or 4-factor prothrombin complex concentrate (PCC). While specific international normalized ratio (INR) thresholds will vary depending on injury type and patient factors, a target of an INR less than 1.5 is recommended.[63] Vitamin K 10 mg IV administered slowly and 3-factor or 4-factor PCC is preferred over fresh-frozen plasma.[64] Reversal of warfarin-associated anticoagulation is discussed in Chapter 111.

Idarucizumab is a Fab fragment of a monoclonal antibody that binds to and inactivates dabigatran and serves as an emergency reversal agent for dabigatran.[65] The recommended dose for idarucizumab is 5 g (2.5 g/vial), administered as 2.5 g IV infusion or bolus injection. Each 2.5 g vial should be administered in a dedicated line over 5 to 10 minutes with the second vial administered in succession not more than 15 minutes after the first. If idarucizumab is not available, clotting factor products such as PCCs or fresh-frozen plasma can be used.[66] Idarucizumab should not be combined with other clotting factor products. Patients requiring emergent reversal of Factor Xa inhibitors (e.g. rivaroxaban, apixaban, and edoxaban) can be treated with andexanet alfa, 4-factor PCCs, or FFP.[67] Andexanet alfa is a class-specific antidote targeted to competitively inhibit Factor Xa inhibitors.[68] The initial dose depends on the dose of the Factor Xa inhibitor and the interval since the last dose. Andexanet should not be combined with other clotting factor products.[63] Data in this population are limited, and the decision to reverse the patient's anticoagulation must take into account the specific injury pattern and the risk of reversal.

Although common in practice, there is inadequate evidence to support the routine use of platelet transfusion for intracranial hemorrhage for patients taking preinjury antiplatelet medications (e.g., aspirin, clopidogrel).[69] The transfusion of platelets in patients on antiplatelet medications does not reduce mortality.[70,71] Likewise, while desmopressin has been proposed as a means to improve platelet adhesion in patients taking antiplatelet medications, the available data is insufficient to recommend its routine use.

Hemostatic agents. Recombinant factor VIIa (rFVIIa) is a hemostatic agent that was originally developed to treat bleeding in hemophiliacs. Limited military experience led to interest in the use of rFVIIa for traumatic intracerebral hemorrhage as well. However, results of clinical trials are mixed, and there has been no convincing evidence of benefit for this agent in traumatic intracranial hemorrhage in the absence of preexisting coagulopathy. The routine use of rFVIIa for patients with traumatic intracranial hemorrhage is not currently recommended.

When given early after injury (within 3 hours), tranexamic acid (TXA) has demonstrated benefit in trauma with hemorrhage without increasing the risk of adverse events.[72] The use of TXA is discussed in Chapter 32. While further studies are needed, recent studies have shown TXA to be promising in improving outcomes for TBI patients, particularly those with a less substantial injury burden.[73]

Induced hypothermia. Hyperpyrexia has been suggested to worsen outcomes after severe TBI. Induced therapeutic hypothermia decreases ICP and has been proposed to reduce proinflammatory cytokines and stabilize the BBB. Yet while induced hypothermia remains a significant area of research for patients with severe and moderate TBI, the available scientific evidence does not support its use to decrease morbidity or mortality. While early studies did demonstrate the potential for benefit, recent randomized trials have shown that therapeutic hypothermia for severe TBI does not improve the neurologic outcomes or risk of mortality compared with strict temperature control.[74,75] The routine use of therapeutic hypothermia for the treatment of TBI is not currently recommended.

Seizure prophylaxis. Though rare, acute symptomatic seizures may occur as a result of severe TBI.[76] Such posttraumatic seizures (PTSs) are classified as early when they occur within 7 days of injury or late when they occur after 7 days following injury. Posttraumatic epilepsy (PTE) is defined as recurrent seizures more than 7 days following injury. Up to 12% of all patients who sustain blunt head trauma and 50% of those with penetrating head trauma develop early PTSs. Although the occurrence of seizures in the immediate post-trauma period is not predictive of future epilepsy, early seizures can cause hypoxia, hypercarbia, release of excitatory neurotransmitters, and increased ICP, potentially worsening secondary brain injury.

Prophylactic use of antiepileptic medications is not recommended for preventing late PTS.[77] However, while early PTS have not been associated with worse outcomes, antiepileptics are recommended to decrease the incidence of early PTS (within 7 days of injury) when the overall benefit is thought to outweigh the risk of complications associated with such treatment.[10] Levetiracetam's use for early PTS is increasing, however, the evidence insufficiently demonstrates its effect is equal to phenytoin.[10]

If the patient is actively seizing, benzodiazepines are administered as effective, rapid-acting, first-line anticonvulsants. If an IV is available, administer lorazepam (0.05–0.1 mg/kg IV up to 4 mg at a maximum rate of 2 mg/minute; may repeat at 3 to 5 minutes if seizures continue). Lorazepam is the preferred agent for aborting seizures because of its high effectiveness and prolonged duration of action. An effective alternative is IV diazepam (0.15 mg/kg IV, up to 10 mg per dose at a maximum infusion rate of 5 mg/minute; may repeat at 3 to 5 minutes if seizures continue, up to a total dose of 30 mg). If an IV is not available, IM midazolam (0.2 mg/kg up to 10 mg) can be used.[77]

Antibiotic prophylaxis. Although the practice was once widespread, there is no evidence to support the use of antibiotic prophylaxis for the prevention of meningitis or other infection in patients with blunt basilar skull fractures, with or without evidence of CSF leakage.[78] In the case of penetrating brain injury, however, contamination with skin, bone, hair, and tissue occurs and may be widespread when there is cavitation caused by the missile as it passes through the brain. While evidence is mixed, guidelines support the use of IV prophylactic, broad-spectrum antibiotics to cover for staphylococci, gram-negative bacilli, and anaerobes for penetrating craniocerebral trauma. Although there are several potential antibiotic regimens, a combination of vancomycin, 1 g q12hr, gentamycin, 80 mg q8hr, and metronidazole, 500 mg q6hr, will provide adequate coverage.[79–81]

Patients undergoing ICP monitoring are reported to have related infection rates as high as 27%.[82] For external ventricular drains (EVDs), routine catheter exchanges have been replaced by attention to proper care during insertion, CSF sampling techniques and, in some cases, prophylactic IV antibiotics. We recommend training and situational awareness of best practices for infection control, assisted by protocol checklists. Antibiotic-impregnated EVDs should be considered for minimizing infection.[10]

Other therapies

Corticosteroids. Corticosteroids have no benefit for patients with head trauma, and in fact demonstrate an increase in adverse events, including infection, gastrointestinal bleeding, and mortality. In patients with severe TBI, high-dose methylprednisolone is associated with increased mortality and is contraindicated.[10]

Barbiturates. Barbiturate therapy has historically been used in severely brain-injured patients to reduce cerebral metabolic demands of the injured brain tissue and reduce elevated ICP. However, barbiturates also can cause a decrease in SBP. Compared with placebo, barbiturates offer no mortality benefit; furthermore, any benefit of decrease in ICP is offset by the risk of hypotension. The only remaining value of barbiturates in TBI is the use of high-dose barbiturate therapy to control elevated ICP refractory to maximum standard medical and surgical treatment.[10] Hemodynamic stability is essential before and during barbiturate therapy. Prophylactic administration of barbiturates to induce burst suppression measured by electroencephalography is not recommended. Decreasing the rate of administration for barbiturates may decrease the risk for hypotension.

Monitoring of intracranial pressure and cerebral spinal fluid drainage. Invasive ICP monitoring has been a mainstay of management for severe TBI, although its utility has recently been called into question. Nevertheless, ICP monitoring is recommended to reduce in-hospital and 2-week postinjury mortality.[10] An EVD in a closed position allows for monitoring of ICP, whereas in an open position drainage of CSF can occur. Practice patterns regarding whether the EVD should be maintained in a closed or open position vary widely based on a number of variables, including patient age, institutional resources, and neurosurgical preferences.[10]

Continuous CSF drainage is a relatively common practice in the pediatric population. In adults, there is more variability in practice. Guidelines state that the use of CSF drainage to lower ICP in patients with an initial GCS less than 6 during the first 12 hours after injury may be considered,[10] Further, an EVD system zeroed at the midbrain with continuous drainage of CSF may be more effective than intermittent drainage in lowering ICP burden.[10]

Erythropoietin. In randomized trials of patients with moderate to severe TBI, erythropoietin did not reduce severe neurologic dysfunction or improve mortality. While there may be some utility in an undefined population,[83–85] it is not recommended for use at this time.[86]

Progesterone. Progesterone has been shown to improve neurologic outcome in early-phase trials involving patients with TBI. In a double-blind, multicenter clinical trial, progesterone was administered to TBI patients with moderate to severe TBI within 4 hours of injury. Progesterone did not improve outcomes in patients with TBI over placebo. These findings are consistent with a recent meta-analysis.[87,88] Progesterone is not recommended for treatment of TBI.

Hyperbaric oxygen therapy. Hyperbaric oxygen therapy following severe, acute TBI provides the injured brain with an increased partial pressure of oxygen and theoretically reduces cerebral edema. Although the pooled results of several small studies have suggested some benefit,[82] the clinical significance is questionable and the use of hyperbaric oxygen therapy for the treatment of TBI cannot be recommended.[89] Clinical trials are ongoing.

Management of Specific Injuries

Scalp wounds. For briskly bleeding scalp wounds, rapid hemostasis is a priority. Initially, hemostasis may be achieved by the application of a temporary, tight pressure dressing, allowing prompt attention to other priorities. Alternatively, a skin stapler may be used to rapidly staple the scalp laceration to control bleeding. The wound later can be reopened for proper irrigation and reclosure.

While the best approach is repair with sutures or staples because the closure will assist in tamponade, other methods to achieve hemostasis include direct digital compression of the bleeding vessel against the skull, infiltration of the wound edges with lidocaine plus epinephrine, and clamping or ligation of identified bleeding vessels.

Once hemostasis is obtained, the wound should be irrigated to rinse away any debris. The emissary vessels of the subgaleal layer of the scalp drain directly into the diploe veins of the skull which in turn drain into the venous sinuses. As such, contaminated or infected scalp wounds have the potential to cause serious intracranial infections. Blood clots and other debris should be removed and the galea and underlying cranium palpated to detect any remaining debris, disruptions, or bone step-offs, understanding that shear injuries to the scalp may deposit contaminants at sites distant from the apparent injury. The complexity of stellate lacerations often interferes with thorough inspection and debridement, making them particularly susceptible to infection. Digital exploration of a scalp wound should be performed gently; if done too vigorously, comminuted or depressed bone pieces may dislodge and be depressed further.

It is easy to confuse a disruption in the galea or tear in the periosteum with a skull fracture. The base of the laceration should therefore be directly visualized if at all possible. Clipping away a small area of hair parallel to the edges of the wound may facilitate this. Alternatively, an antibiotic ointment can be applied to the hair immediately surrounding the wound and used to plaster the hair away from the injury site. If hair is accidentally embedded within the repaired laceration, it can delay healing by producing an inflammatory reaction or by serving as a nidus of infection. If the laceration begins on the forehead and extends upward beyond the hairline, surrounding hair should not be removed as removal obliterates a useful landmark for cosmetic closure and may result in malalignment of the two laceration edges.

Several studies have evaluated the use of staples versus sutures to close scalp lacerations that do not involve the galea. For adult and pediatric scalp lacerations that begin beyond the hairline, staples have been shown to be cheaper, take less time, and have the same outcome as sutures if used in the appropriate manner. However, staples cannot be used to close the galea and may not be effective alone when hemostasis is a problem. Large lacerations of the galea are closed to prevent the edges of the wound from pulling apart as the muscles within the galea contract. The skin, dermis, and galea can usually be repaired in a single layer with interrupted or vertical mattress sutures of 3-0 nylon or polypropylene. An alternative method of scalp laceration closure, the "hair apposition technique," is to twist together bundles of the patient's hair on each side of the wound and then secure these with tissue glue. This may provide another method of effective repair and prevent the need to remove the closure material after the wound has healed, particularly in the pediatric population. Because of the rich blood supply of the scalp, even very large scalp avulsions may remain viable. If the avulsion remains attached to the rest of the scalp by a tissue bridge, it should be reattached to the surrounding tissue. If the avulsion is completely detached from the scalp, it should be treated as any other amputated part and reimplanted as soon as possible.

Scalp abrasions are often contaminated with pieces of dirt or other debris. The wound should be cleaned as thoroughly as possible and inspected for puncture wounds or other areas that penetrate beyond

the superficial layers of the skin to ensure the removal of unsuspected foreign bodies. A careful inspection often reveals a small scalp laceration within the abraded area.

Systemic antibiotics are not needed for carefully managed scalp wounds because rapid healing is facilitated by the rich blood supply of the scalp. However, special consideration may be given to large or highly contaminated wounds, bite wounds, and for immunocompromised patients.

Skull fractures. A noncontrast head CT scan with bone windows is the imaging modality of choice for patients with suspected skull fractures or to identify intracranial foreign bodies. Plain radiographs can be useful when CT scanning is not available.

Linear fractures. Linear skull fractures are clinically important if they cross the middle meningeal groove or major venous dural sinuses; they can disrupt these vascular structures and cause the formation of EDHs. No specific intervention is necessary for linear skull fractures if a noncontrast CT scan reveals no underlying brain injury. Patients with no evidence of intracranial injury on CT and no other significant extracranial injuries should be observed in the ED for 4 to 6 hours prior to discharge. If there is any suspicion or clinical evidence of brain injury, patients should be admitted for observation. Those with intracranial injuries should have an emergent neurosurgical consultation. Patients with simple linear skull fractures may demonstrate concussive symptoms or other evidence of mild TBI and should be provided appropriate discharge instructions (see later, "Mild Traumatic Brain Injury: Disposition").

Depressed fractures. When a depressed fracture occurs, traumatic impact drives the bone piece below the plane of the skull. The edges of the depressed portion of skull may become locked underneath the adjacent intact bone and fail to reduce into their anatomic position. As a result, the depressed piece of bone can penetrate tissue and lacerate the dura. Fractures in which the free piece of bone is depressed deeper than the adjacent inner table of the skull require surgical elevation.

Depressed skull fractures are usually open fractures with disruption of the galea, which can often be felt with palpation of the skull. However, this examination should be done cautiously to avoid driving a depressed bone fragment deeper into the cranium. The clinical examination for a depressed skull fracture may be misleading as the mobility of the scalp can result in nonalignment of the fracture with an overlying scalp laceration. As a result, the skull underlying laceration may be normal, with depressed area several centimeters away. Additionally, scalp swelling may interfere with the physical examination findings and hide any palpable bone defects.

CT scanning with bone windows is the imaging modality of choice, as depressed fractures may be difficult to visualize on plain skull radiographs. The free piece of bone demonstrates increased or double density because it often overlaps the nonfractured bone, or it is rotated from the rest of the adjacent cranium. Tangential views of the skull may increase the ability to visualize the fracture.

An open depressed skull fracture, as well as any type of penetrating skull injury, increases the risk for developing intracranial and meningeal infection. We suggest that prophylactic antibiotics be given for 5 to 7 days to prevent the risk of subsequent CNS infection. Suggested antibiotics are identical to those for penetrating head trauma. Development of seizures is also common after this type of injury and prophylaxis may be considered.[90] Patients with depressed skull fractures should be admitted for continued observation. Patients with open (compound) cranial fractures depressed greater than the thickness of the cranium may be treated nonoperatively if there is no clinical or radiographic evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination.

Basilar skull fractures. Basilar fractures are the result of considerable impact force and are highly associated with underlying brain injury. Emergency clinicians should be suspicious of an EDH in patients with a temporal bone basilar skull fracture. All patients with basilar skull fractures should be admitted for observation, regardless of the need for surgical intervention. Routine prophylaxis is not supported by the available evidence, whether or not there is evidence of CSF leakage, unless the patient is immunocompromised.[78] Most CSF leaks resolve spontaneously within 1 week, with no complications. If the leak persists beyond 7 days, the incidence of bacterial meningitis increases significantly; prophylactic antibiotics should be given in such cases and surgical intervention may be warranted.[91] Antibiotic selection is identical to that for penetrating head trauma. If a patient with a previously diagnosed CSF leak returns to the ED later with fever, the diagnosis of meningitis should be strongly suspected and appropriate evaluation (i.e., lumbar puncture) and appropriate antibiotic treatment initiated immediately. Treatment of posttraumatic meningitis is discussed in Chapter 95.

Extra-axial lesions

Epidural hematoma. Consensus guidelines support rapid surgical evacuation for any patient who has mass effect on a CT scan or progressive neurologic deterioration. Indications for urgent surgical evacuation include EDHs larger than 30 cm^3, regardless of the patient's GCS score, as well as comatose patients with an acute EDH and anisocoria on pupillary examination. For patients with acute EDH who are awake and have no focal neurologic deficits, nonsurgical management is based on the size of the hematoma (<30 cm^3), thickness of the clot (<15 mm), and degree of midline shift (<5 mm). In those managed nonoperatively, close neurologic observation in a neurosurgical center is recommended, with a first repeat CT scan obtained within 6 to 8 hours postinjury.

Subdural hematoma. SDH is often associated with significant brain injury. Further, delays in clinical signs and symptoms and the older mean age of the at-risk population lead to a higher mortality rate than EDH. While a small SDH (only a few millimeters thick at its widest point on CT scan) often is amenable to serial observations of the patient's status and appearance of the SDH on CT scan, even a small SDH may be accompanied by extensive brain tissue damage that can cause an increase in ICP sufficient to precipitate a herniation syndrome. If the patient is deeply comatose at presentation, with flaccidity and without signs of brainstem activity, they may best be served by providing supportive care alone. Subsequent management and advanced directive decisions should be discussed with the patient's family and neurosurgeon.

Most patients with subacute SDH require surgical evacuation of the lesion. Indications for surgical evacuation include acute SDHs with a thickness more than 10 mm or a midline shift of more than 5 mm on a CT scan, regardless of the patient's GCS score. Other parameters for surgical evacuation include a worsening GCS score (≥2 points from the time of injury to hospital admission) in comatose patients, asymmetric or fixed and dilated pupils, and persistent elevation in ICP.

The treatment of chronic SDHs is controversial. Symptomatic chronic SDHs require surgical evacuation. Most patients have a good outcome after surgery. Overall, the mortality from surgically drained chronic SDH approaches 5%, with decreased survival in older adults.[92]

Traumatic subarachnoid hemorrhage. In the absence of other brain injury, tSAH generally carries a favorable prognosis. The most serious complication of tSAH is worsening of cerebral vasospasm, which may be severe enough to induce cerebral ischemia. Posttraumatic vasospasm is common, occurring approximately 48 hours after injury and persisting for up to 2 weeks. While commonly used to prevent or reduce cerebral vasospasm following aneurysmal SAH,

calcium channel blockers such as nimodipine and nicardipine are of questionable benefit in tSAH and are not routinely recommended.[93] Patients with severe TBI and large amounts of SAH may benefit from serial noninvasive monitoring and institution of therapy in the setting of radiographic or clinical deterioration.

Subdural hygroma. If SDHGs are asymptomatic, observation is a reasonable approach. Otherwise, they are surgically evacuated. Mortality approaches 20% and appears to depend on the severity of other intracranial injuries.

Intra-axial lesions

Cerebral contusion. Patients with brain contusions can often be treated conservatively, although almost half will have significant progression on CT and 20% will require surgical intervention. Patients with lower GCS scores and larger cerebral contusions are at higher risk for hemorrhagic progression and the need for delayed surgical decompression. Hemorrhagic progression of a contusion generally occurs within the first 12 hours but may occur as late as 3 to 4 days after head trauma.

Intracerebral hematoma. Many patients with an ICH require emergent intervention or surgery to lower elevated ICP. Mortality is low in patients who are conscious before surgery, whereas in unconscious patients, mortality approaches 45%. Bleeding into the ventricles or cerebellum carries a high mortality rate.

Intracerebellar hematoma. Mortality from isolated traumatic intracerebellar hematoma is very high. Emergent neurosurgical consultation is indicated.

Complications and Outcome

In the 24 to 48 hours after trauma, seizures are caused by worsening cerebral edema, small hemorrhages, or penetrating injuries. In patients with severe TBI, the rate of a clinical PTS may be as high as 12%, whereas that of subclinical seizures detected on electroencephalography may be as high as 20% to 25%.[10] Early PTS, within 24 hours of injury, are usually brief and are most likely caused by transient mechanical and neurochemical changes within the brain. PTSs are common in children and can be precipitated by MTBI but are more common in moderate and severe TBI.

Risk factors for early PTS include GCS score of 10 or lower, immediate seizures, posttraumatic amnesia lasting longer than 30 minutes, linear or depressed skull fracture, penetrating head injury, SDH, EDH, ICH, cortical contusion, age 65 years or younger, or chronic alcoholism. The risk factors for PTE include severe TBI, early PTS prior to discharge, acute ICH or cortical contusion, posttraumatic amnesia lasting longer than 24 hours, age older than 65 years, and premorbid history of depression. In addition, location of the lesion plays a role, with higher rates of PTE in patients with temporal lobe bleeding.[94]

Central Nervous System Infections

Meningitis after basilar fractures. Posttraumatic meningitis can be caused by a variety of microbes, depending on the portal of bacterial entry. Patients have typical signs and symptoms of meningitis, including fever, altered mental status, and occasional focal neurologic signs. In patients with a CSF leak after basilar fracture, early meningitis (i.e., within 3 days of injury) is usually caused by pneumococci. Treatment of posttraumatic meningitis is discussed in Chapter 95.

Brain abscess. Brain abscesses develop infrequently after penetrating missile injuries to the head. Abscesses can also develop after open depressed skull fractures if bone fragments are not removed or as a postoperative complication. Posttraumatic CSF fistulae and fractures that disrupt air-filled sinuses predispose to the formation of brain abscesses. Clinical manifestations include headaches, nausea, vomiting, declining mental status, signs of increased ICP, and new focal neurologic findings in patients who had been improving after trauma. Evaluation and treatment of brain abscess are discussed in Chapter 99.

Cranial osteomyelitis. Cranial osteomyelitis can occur after penetrating injury to the skull. The clinical manifestations include pain, tenderness, swelling, and warmth at the infected site. While more than 50% of cases are obvious on plain skull radiographs, plain radiographs lack sufficient sensitivity for routine use. Contrasted CT imaging has reasonable sensitivity, although MRI is the diagnostic test of choice for early identification of cranial osteomyelitis.[95] Patients with posttraumatic cranial osteomyelitis require surgical debridement and removal of the infected bone. Antibiotic choice is determined by culture results. If systemic symptoms are present, an underlying subdural or epidural empyema should be suspected.

Medical Complications

There are several systemic manifestations of TBI that can occur in the absence of any specific organ injury or systemic infection. The nature and severity of these manifestations depend mainly on the severity of the brain injury.

Disseminated intravascular coagulation. The injured brain is a source of tissue thromboplastin that activates the extrinsic clotting system. Disseminated intravascular coagulation (DIC) can develop within hours after any injury disrupting brain tissue. Cerebral intravascular coagulation is a universal response to TBI and is found in tissues from surgical specimens of human cerebral contusions. Coagulation abnormalities, including systemic DIC, are detected in over 50% of severe TBI patients and isolated severe TBI patients who develop coagulopathy have higher mortality rates than isolated severe TBI patients without coagulopathy.[96] DIC not only increases morbidity and mortality after severe TBI, it increases the risk of delayed intracranial hemorrhage. If a stable patient with DIC suddenly deteriorates, a repeat CT scan should be obtained to rule out hemorrhage.

The extent of tissue destruction determines the degree of DIC that develops. The diagnosis is based on abnormalities in the INR, prothrombin time (PT), partial thromboplastin time (PTT), platelets, plasma fibrinogen levels, and fibrin degradation products. Patients with coagulopathy or abnormal platelet function require interventions to correct these.

Patients with moderate or severe head trauma are at extremely high risk to experience venous thromboembolic events (VTEs) after admission to the hospital. The existing literature is insufficient to recommend a particular agent or dose, or timing of anticoagulation.[10] However, in those patients with stable CT scans after 24 to 72 hours, initiation of anticoagulation reduces the incidence of VTE without a corresponding exacerbation of intracranial hemorrhage.[97–99]

Respiratory complications. Pulmonary complications in the hours to days following TBI are common. Acute lung injury has been theorized to occur from a variety of pathologic processes, including a systemic inflammatory response, infection, induced hypertension in an effort to maintain cerebral perfusion, and neurogenic pulmonary edema.[100] Neurogenic pulmonary edema can develop minutes to days after head trauma, leading to extravascular fluid in the lungs, hypoxia, and decreased lung compliance. The catecholamine surge that often follows TBI can result in increased intravascular pressure, increased capillary permeability, and hydrostatic edema. Additionally, a systematic inflammatory reaction leads to endothelial damage and vasogenic edema. Treatment of acute lung injury in TBI is challenging because traditional treatment measures, including hypercapnia, fluid restriction, and prone ventilation (which raises ICP), are contraindicated in TBI.[100] Positive end-expiratory pressure (PEEP) may be beneficial, and although PEEP increases ICP by reducing

venous return, studies have shown that with adequate intravascular volume and MAP PEEP does not adversely affect ICP. Furthermore, controlling ICP also appears to reduce the neurogenic stimulation that may contribute to pulmonary edema. Close ICP and ventilator management are essential to improved outcomes in patients with acute lung injury secondary to TBI.

Cardiac dysfunction. Cushing noted a connection between cardiac dysrhythmias and intracranial bleeding in the early 20th century, and a variety of cardiac rhythm, rate, and conduction abnormalities may be detected after TBI. Catecholamine release following brain injury is common, which may lead to tachycardia, hypertension, or coronary vasoconstriction. Myocardial ischemia, particularly in patients with pre-existing coronary artery disease, results in the ECG changes frequently seen in the head-injured patient.[100] Further, cardiac rhythm abnormalities have been reported in up to 50% of all patients with traumatic intracranial hemorrhage and up to 70% of all patients with tSAH. The most common cardiac dysrhythmia after TBI is supraventricular tachycardia, but many other rhythms have been observed. Findings on the electrocardiogram include diffuse large upright or inverted T waves, prolonged QT intervals, ST segment depression or elevation, and U waves. The primary goal in the emergency management of cardiac dysfunction after head trauma is ensuring adequate tissue perfusion and avoiding hypoxia. Dysrhythmias in head-injured patients often resolve as ICP is reduced.

Disposition

All patients with moderate to severe head trauma require imaging to determine the extent and nature of the brain injury and necessity of neurosurgical intervention. Neurosurgical consultation should be obtained as soon as possible to help direct the patient's subsequent management. Moderate and severely head-injured patients require admission to an institution capable of intensive neurosurgical care and acute neurosurgical intervention. If this is not available at the receiving hospital, the patient should be transferred to an appropriate institution.

All patients with moderate TBI should be admitted for a period of observation, even with an initial, apparently normal CT scan. Frequent neurologic checks should be initiated, and a repeat CT scan is indicated if the patient's condition deteriorates or fails to improve over the first 48 hours after trauma. In patients with persistent symptoms of headache, confusion, or memory difficulties, delayed MRI may define lesions in the regions related to cognition that cannot be seen on CT. Although not useful in the emergency setting, MRI has prognostic value during subsequent care and assists in directing the future rehabilitation of these patients.

MILD TRAUMATIC BRAIN INJURY (ALSO KNOWN AS CONCUSSION)

Clinical Features

Signs and symptoms of MTBI can be subtle and easily overlooked, especially in the setting of polytrauma. A high index of suspicion and systematic diagnostic approach are necessary to ensure identification.[101] A two-question screen administered during triage could potentially improve identification by alerting the emergency clinician to the presence of an MTBI or concussion: (1) Did the patient sustain a blunt force mechanism or whiplash type acceleration-deceleration event, and, (2) At any point after injury, was there alteration in mental status, such as confusion or disordered awareness (feeling dazed, disoriented, foggy, "seeing stars," slowed thinking), amnesia (retrograde or anterograde), or loss of consciousness?[101,102] It is not uncommon for MTBI symptoms to dissipate by the time patients reach the ED. However, not having symptoms on arrival to the ED does not preclude diagnosis of a MTBI. If the answer to both screening questions is yes, a focused neurologic assessment for MTBI should follow.[102]

As with moderate and severe TBI, a comprehensive history includes information from the patient, prehospital personnel, family members, and witnesses about the mechanism of injury, including events before and after the injury. In addition, age, comorbidities, coagulopathies (e.g., hemophilia, Von Willebrand disease, hepatic insufficiency, use of anticoagulants), consumption of alcohol or drugs, changes in mental status or deteriorating GCS scores, previous TBI or concussion, symptoms of other potential injuries, and TBI symptoms (including postconcussive symptoms) should be taken into account. It is important to ask patients specifically about symptoms of disorientation, confusion, amnesia, or disordered awareness, with or without loss of consciousness. The majority of MTBI patients do not experience a loss of consciousness and, if they do, it is difficult to quantify unless there are witnesses.

MTBI symptoms fall into four broad domains: somatic, cognitive, sleep, and emotional.[103] Somatic symptoms include headache, dizziness, diminished balance, vertigo, tinnitus, sensitivity to light and noise, nausea, and vomiting. Cognitive symptoms include impaired memory or concentration, delayed language comprehension, and slowed or repetitive speech. Emotional disturbances include irritability, sadness, anxiety, and depression. Sleep-related disturbances include the spectrum between insomnia and fatigue. Using a validated concussion symptom checklist can facilitate quick determination of the current concussion symptom burden (e.g., Rivermead Post-Concussion Symptom Questionnaire, Post-Concussion Symptom Scale, SCAT5). The greater the number and severity of acute symptoms, the higher the risk of prolonged recovery.[104]

Physical Examination

As described earlier, the general trauma examination is as for the patient with moderate or severe head injury. A more detailed neurologic examination is often possible in MTBI patients who can cooperate with the examination. Although the physical examination for MTBI has not been standardized, it is important to assess MTBI patients consistently in the ED.[105] Recent ACEP guidelines suggests a framework for ED physicians to follow.[102]

Head and Neck

Alert patients are questioned regarding cervical spine pain. Immobilization is indicated until cervical spine injury is excluded. Validated decision guidelines such as the NEXUS or Canadian C-spine criteria may be applied in select alert patients to guide imaging.[106] Assess for scalp trauma, facial, skull, and basilar skull fractures and auscultate for bruits in the rare event of carotid or vertebral artery dissection.

Neck injuries, such as whiplash-induced neck injuries, can occur simultaneously with MTBI and have overlapping symptoms such as headaches, balance difficulties, dizziness, visual disturbances, and poor postural control.[105]

Mental Status and Alertness

Reassess the GCS score while the patient is in the ED and document changes. Patients with GCS scores trending downward (worsening neurologic status) are at higher risk of requiring neurosurgical intervention and having poor outcome.[107] Although the MTBI patient may be alert, they may exhibit signs of impairment, such as repetitive questions, intermittent bouts of confusion, and difficulty paying attention. Note if the patient displays a peculiar flat affect, appears devoid of emotion, and speaks in a slow monotone voice without inflection, which may indicate damage to the prefrontal cortex or frontal lobes.[108]

Cranial Nerves

CN injuries following MTBI are more common with fractures at the base of the skull.[109–111] Assess for anosmia and hyposmia, because the olfactory nerve (CN I) is one of the most common CNs affected after MTBI. This may be done by having the patient smell ground coffee or a citrus-scented beverage. The facial nerve (CN VII) and oculomotor nerves (CNs III, IV, and VI) are also frequently injured, so assess for facial paralysis, change in taste, or diplopia. In MTBI, CNs IV and VI are more commonly injured than CN III. CN VII palsy may indicate a fracture of the temporal bone, particularly if it occurs in association with decreased hearing (CN VIII). Hearing impairment can be one of the more subtle deficits seen after TBI. Facial pain (CN V) and occipital neuralgia may also occur in association with MTBI. CN IX and X palsies can present with dysphagia and may be associated with fractures of the occipital condyles.[110,111]

Cognitive Function (Attention, Memory, Concentration)

Performing a cognitive examination can be challenging in the ED setting. Brief assessment tools include the Mini-Mental State Exam (MMSE) and the Standardized Assessment of Concussion (SAC) can be used.[112] The SAC is embedded in the Sport Concussion Assessment Tool 5 (SCAT5) which can also be used.[113] Serial subtraction exercises, such as serial 7s beginning at 100, can be completed quickly and only require 4 or 5 rounds (down to 65) to ascertain if the patient can concentrate and adequately use working memory. Serial 3s from 100 can be used for adolescents ages 14 to 18 years, and serial 1s from 10 for children ages 7 to 14 years. Baseline cognitive status should be considered.

Vestibular Function (Balance, Gait, and Eye Movements)

A growing body of evidence suggests MTBI disrupts the vestibular system, including balance, gait, and eye movements.[114] Balance relies on visual, vestibular, and proprioception input from cortical networks. Balance is tested in a graduated way, with an initial test of simply standing with the examiner nearby for safety. Next, a formal Romberg test can be performed. Balance can also be quantified using the modified Balance Error Scoring System (mBESS) which counts errors with double leg, single leg, and tandem leg stances.

Gait is then assessed by having the patient walk several steps and then return back to the examiner. For younger individuals, tandem stance and tandem gait can be performed, initially with eyes open and then with eyes closed. Significant sway, missteps, arms extended for balance, and broad-based or abnormally slow gait are considered errors.

The vestibular system controls eye movements, such as smooth pursuits, saccades, and vestibulo-ocular reflex. These can be assessed using the Vestibular/Ocular-Motor Screening Exam (VOMS) screening tool. Although it is not currently routine practice to perform VOMS in the ED, it has been shown to be feasible following provider education along with the use of clinical support tools.[115] It should be considered for patients at high risk for ongoing symptoms.

MTBI disrupts neural pathways controlling ocular accommodation and convergence. Ocular near vision (accommodation and convergence) can also be assessed using the VOMS.[116] Moreover, MTBI patients often can have difficulty with the finger-nose-finger test and will use slow purposeful movements to complete the task.

Differential Diagnoses

MTBI (GCS score of 13 to 15) is characterized by symptoms of confusion and amnesia, with or without preceding loss of consciousness. The differential diagnosis, in the context of trauma, includes intoxication (drugs, alcohol, medications), PTSs and postictal state, hypoglycemia, and other injuries that may impair a patient's ability to communicate. These include facial bone fractures, hypoxemia or hypoperfusion (from extracranial injuries), cervical spine or spinal cord injuries, injuries to the eyes or tympanic membranes, laryngeal or vocal cord injuries, and vascular injuries of the neck. Patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be an MTBI, even if the patient initially presents with a GCS score of 15. In such a case, the injury would be reclassified as moderate or severe TBI.

Prior to the trauma, patients may have experienced a syncopal episode, seizure, or cardiac event that produced a loss of consciousness that led to the subsequent trauma. For example, an MVC may have resulted from the driver becoming distracted or incapacitated by important symptoms suggestive of an unrelated disorder. Therefore, potential precipitants to the trauma should also be considered in the differential diagnoses.

An MTBI or concussion may go unrecognized in the ED, especially if symptoms are transient or if more visible injuries dominate the assessment. An underlying dementia or psychiatric illness make it challenging to distinguish an MTBI from baseline cognitive or mental dysfunction. Other conditions that could cofound the diagnosis include stroke, encephalopathies (e.g., hepatic, uremic), delirium from alcohol or drug withdrawal, neurologic conditions (e.g., Parkinson or Alzheimer disease, autism), and infection or sepsis. Even low-mechanism trauma should alert the emergency clinician to the possibility of brain injury in susceptible populations.

Diagnostic Testing

Neuroimaging in the Emergency Department with Computed Tomography

Traumatic intracranial injuries requiring prompt intervention occur in approximately 7% of patients with MTBI.[117] Intracranial injuries leading to death or requiring neurosurgical intervention is about 0.9%.[117] CT scan of the head is the diagnostic standard for acute evaluation of suspected traumatic intracranial injuries in the ED. However, CT is associated with exposure to ionizing radiation and higher health care costs. Several clinical decision rules have been prospectively derived and validated to reduce the need for CT scanning and identify MTBI patients at risk for intracranial lesions and neurosurgical intervention. These include the New Orleans Criteria (NOC), Canadian Computed Tomography Head Rule (CCHR), and National Emergency X-Radiography Utilization Study II (NEXUS-II; Box 33.4). Others have developed guidelines based on available evidence, including the American College of Emergency Physicians clinical policy on neuroimaging of adult ED patients with MTBI (ACEP), National Institute for Health and Clinical Excellence (NICE), Neurotraumatology Committee of the World Federation of Neurosurgical Societies (WFNS), Scandinavian Neurotrauma Committee, and Scottish Intercollegiate Guidelines Network (SIGN). Although most of the rules and guidelines produce high sensitivities for detecting neurosurgical intervention and intracranial lesions, the specificities are variable. Additional clinical decision rules have been developed for the pediatric population (see Chapter 160).

The most widely researched clinical decision rules for MTBI are the CCHR and NOC, with external validation studies in the United States and internationally. The CCHR was developed for use in patients with a GCS score of 13 to 15; it divides clinical variables into high- and medium-risk categories. The NOC was developed for use in patients with a GCS score of 15 only and is composed of seven clinical variables. For injuries requiring neurosurgical intervention, both the CCHR and NOC have a high sensitivity (99% to 100%) but the CCHR has a much higher specificity (CCHR, 48% to 77%; NOC, 3% to 31%). For identification of traumatic intracranial lesions on CT, the CCHR and NOC have a high sensitivity (CCHR, 80% to 100%; NOC, 95% to 100%)

BOX 33.4 Clinical Decision Rules for Neuroimaging in Adults with Mild Traumatic Brain Injury

Canadian Computed Tomography Head Rule (CCHR)

High-Risk Injury (May Require Neurologic Intervention)

1. GCS score <15 at 2 h after injury
2. Suspected open or depressed skull fracture
3. Any sign of basal skull fracture (hemotympanum, raccoon eyes, CSF otorrhea or rhinorrhea, Battle's sign)
4. Vomiting >2 episodes
5. Age >65 years

Medium-Risk Injury (May Have Important Brain Injury on CT)

6. Amnesia before impact ≤30 min
7. Dangerous mechanism (pedestrian struck by vehicle, occupant ejected from vehicle, fall from elevation >3 feet [five stairs])

New Orleans Criteria (NOC)

1. Headache
2. Vomiting
3. Age >60 years
4. Drug or alcohol intoxication
5. Persistent anterograde amnesia
6. Trauma above the clavicle
7. Seizure

NEXUS II Criteria

1. Evidence of significant skull fracture
2. Scalp hematoma
3. Neurologic deficit
4. Altered level of alertness
5. Abnormal behavior
6. Coagulopathy
7. Persistent vomiting
8. Age >65 years

CSF, Cerebrospinal fluid; *GCS,* Glasgow Coma Scale.

but specificity is higher with the CCHR. In terms of potential for CT reduction, adherence to the NOC results in an increase in head CT use; adherence to the CCHR results in a decrease in head CT use compared to current practice. Imaging of patients in this population should follow a validated guideline. Clinicians in emergency medicine, trauma surgery, neurosurgery, and neurology should review the relevant guidelines (CCHR, NOC) and select the system thought to be most applicable for their setting and patient population. Oversight should ensure that cases not following the adopted guidelines are reviewed and feedback is provided to emergency clinicians.

Of note, CT scanning detects the presence of intracranial bleeding but does not exclude the existence of underlying brain injury and is not diagnostic of an MTBI.

Other Neuroimaging Modalities

Structural magnetic resonance imaging. CT is the imaging modality of choice for initial screening to exclude serious traumatic intracranial lesions in MTBI. However, many patients who develop persistent symptoms and cognitive deficits have no detectable abnormalities on initial CT screening. About a quarter of concussion patients with normal CT scans have been shown on MRI to have traumatic abnormalities such as micro-hemorrhages.[118] MRI is better than CT in detecting posttraumatic ischemic infarctions, subacute nonhemorrhagic lesions and contusions, axonal shear injury, and lesions in the brainstem or posterior fossa. Structural MRI, particularly at a 3-T strength, improves structural sensitivity, can be performed when neurologic findings cannot be explained by CT, and is particularly valuable in assessing the brainstem, posterior fossa, and brain parenchyma adjacent to the calvaria. Structural MRI (without contrast) can also be used for the evaluation of TBI-related symptoms in the subacute and chronic phases of injury.

Susceptibility-weighted imaging. A significant advancement in the imaging of MTBI has been the development of susceptibility-weighted imaging (SWI). This technique is an imaging method that grew out of and is part of MRI. It uses differences in magnetic susceptibility between tissues and is particularly helpful for the evaluation of TAI and punctate hemorrhages (microhemorrhages) in the deep subcortical white matter not visible on CT or structural MRI scans. It takes about 4 minutes to image the entire brain and, in the ED, SWI detects additional lesions 30% of the time compared to CT and structural MRI.[118] The number and volume of SWI microhemorrhages correlate with clinical outcome.[119]

Diffusion tensor imaging. DTI uses MRI technology to analyze the movement of water molecules in the white matter of the brain and provides the opportunity to perform tractography—visualization of major white matter pathways—to assess damaged nerve fiber tracts. DTI can detect white matter abnormalities when conventional imaging is normal. These abnormalities may be a marker of TAI and are associated with cognitive dysfunction.[120] Continuing loss of structural integrity in certain tracts may contribute to persistent post-concussion symptoms and is associated with recovery.[121,122]

Computed tomography angiography and magnetic resonance angiography. Vascular imaging such as CT angiography and MR angiography are not recommended routinely for patients with MTBI unless there is suspicion of a traumatic vascular injury, such as pseudoaneurysm, dissection, or uncontrolled hemorrhage.[123] Typically, vascular injuries occur with penetrating trauma, skull base fractures, blunt neck trauma, or skull base or cervical spine fractures. Independent predictors of arterial injury in blunt trauma include cervical facet subluxation or dislocation, fracture lines approaching an artery, and high-impact injury mechanisms.

Ancillary Studies

Laboratory testing. Laboratory tests are not needed for patients with isolated MTBI except for a bedside glucose level in those with a GCS score less than 15. Coagulation parameters such as INR, PT, and PTT are indicated for those with inherent coagulopathies or suspected liver disease and those on anticoagulants.

Glial Fibrillary Acidic Protein (GFAP) and Ubiquitin C-terminal hydrolase (UCH-L1) have been evaluated in several studies to determine the need for CT scan and neurosurgical intervention in adults with mild to moderate TBI[124–127]and more recently in children.[125,128–130] In early 2018, GFAP and UCH-L1 were FDA-approved for clinical use in adult patients with mild to moderate TBI to help determine need for CT scan within 12 hours of injury (Fig. 33.14).[131] The approval was based on the ability to find lesions on CT scan but was not approved to diagnose a concussion. Moreover, it was not approved for use in children.

Neuropsychological testing. Neuropsychological testing is used to assess cognitive function after MTBI and includes in-depth testing of memory, attention, and concentration that may reveal cognitive abnormalities not detected on the initial physical exam. Several studies have reported an association between cognitive deficits detected in the

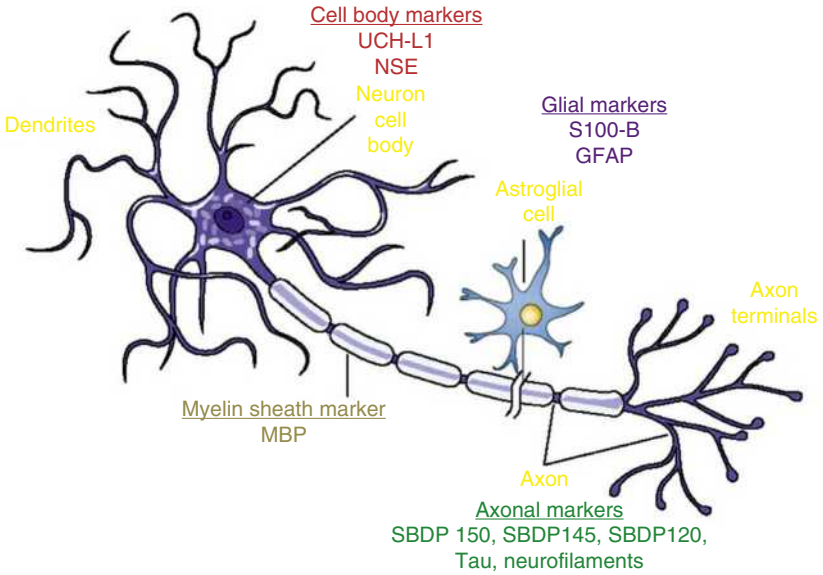

Fig. 33.14 Neuron and Neuroanatomic Locations of Potential Traumatic Brain Injury Biomarkers. S100β is the major low-affinity calcium binding protein in astrocytes that helps regulate intracellular levels of calcium. Glial fibrillary acidic protein (GFAP) is a monomeric intermediate protein found in the astroglial skeleton and in white and gray brain matter and is strongly upregulated during astrogliosis. Neuron-specific enolase (NSE) is one of the five isozymes of the glycolytic enzyme enolase found in central and peripheral neuronal cell bodies. UCH-L1 is highly abundant in neurons and was previously used as a histologic marker for neurons. Alpha II-spectrin is the major structural component of the cortical membrane cytoskeleton and is particularly abundant in axons and presynaptic terminals. Tau is an intracellular, microtubule-associated protein that is highly enriched in axons. Neurofilaments are heteropolymeric components of the neuron cytoskeleton. (From Papa L. Exploring serum biomarkers for mild traumatic brain injury. In Kobeissy F, ed. *Brain neurotrauma: molecular, neuropsychological, and rehabilitation aspects in brain injury models.* London: CRC Press; 2015: 303.)

ED and prolonged recovery.[104,132] Although commercially available computerized testing platforms can simplify and standardize test administration, testing still requires 20 to 25 minutes and the assistance of ancillary staff. Although not routinely done in the ED, referral to a neuropsychologist is warranted for patients having persistent symptoms following a concussion.

Disposition

Most patients with MTBI can be discharged from the ED with a normal examination and after a reasonable period of ED observation (4 to 6 hours) or following a negative head CT scan, except in the presence of therapeutic anticoagulation; in these cases, a more prolonged observation period of up to 24 hours, with repeat head CT scan, may be warranted.[63] If the emergency clinician decides that the patient with MTBI can be sent home, an appropriate early follow-up should be arranged. Providing patients and families with educational information about postconcussive syndrome and what to expect after injury helps improve outcome. Patients should also be given contact information for the brain injury association in their region. State brain injury associations can connect patients and families with support groups, programs, and professionals who understand the injury (www.biausa.org/mild-brain-injury.htm).

Patients should be discharged with instructions describing the signs and symptoms of acute and delayed complications of MTBI, have access to a telephone, and be monitored in the acute post-trauma period by a responsible adult. All discharge instructions should be printed and verbally described to a responsible third party. Warning signs for acute deterioration, such as inability to waken the patient, severe or worsening headaches, somnolence or confusion, restlessness, unsteadiness, or seizures, difficulties with vision, vomiting, fever, or stiff neck, urinary or bowel incontinence, and weakness or numbness involving any part of the body, should prompt the caregiver to seek immediate medical help. If any doubt exists regarding the safety of the discharged patient with MTBI, a brief inpatient observation period (12 to 24 hours) is advisable. Additionally, patients with persistent postconcussion symptoms, such as intractable headache or vomiting requiring parenteral medication, that are not amenable to outpatient treatment might require hospital admission.[102]

If resources allow, prolonged ED observation may be practical in some circumstances.[133] For example, intoxicated patients with MTBI who otherwise fulfill low-risk criteria should undergo serial evaluations in the ED until clinical sobriety is achieved. In these patients, a CT scan may be unnecessary, and ED observation is beneficial.

If a patient with MTBI returns to the ED because of persistent symptoms, delayed complications of injury should be sought. If a CT scan was not initially obtained, the intensity of symptoms may guide the decision to obtain a CT scan at the second ED visit. If a negative scan was initially obtained, the likelihood of the subsequent development of an intracranial lesion is exceedingly low. The decision to rescan is more complex in patients from certain subgroups who may be considered more likely to develop delayed complications. These include patients on anticoagulation therapy, those with preexisting neurologic injuries that may obscure an examination, and those with previous neurosurgical procedures (e.g., ventriculoperitoneal shunts). The literature about repeat CT scanning in MTBI suggests that patients who are unchanged or improving neurologically do not benefit from a repeat CT, but repeat imaging is indicated to assess a deteriorating patient.

Complications

In addition to being at risk for serious intracranial injuries, patients with a suspected MTBI can have elusive axonal injuries and microbleeds and over the long term, can suffer impairment of physical, cognitive,

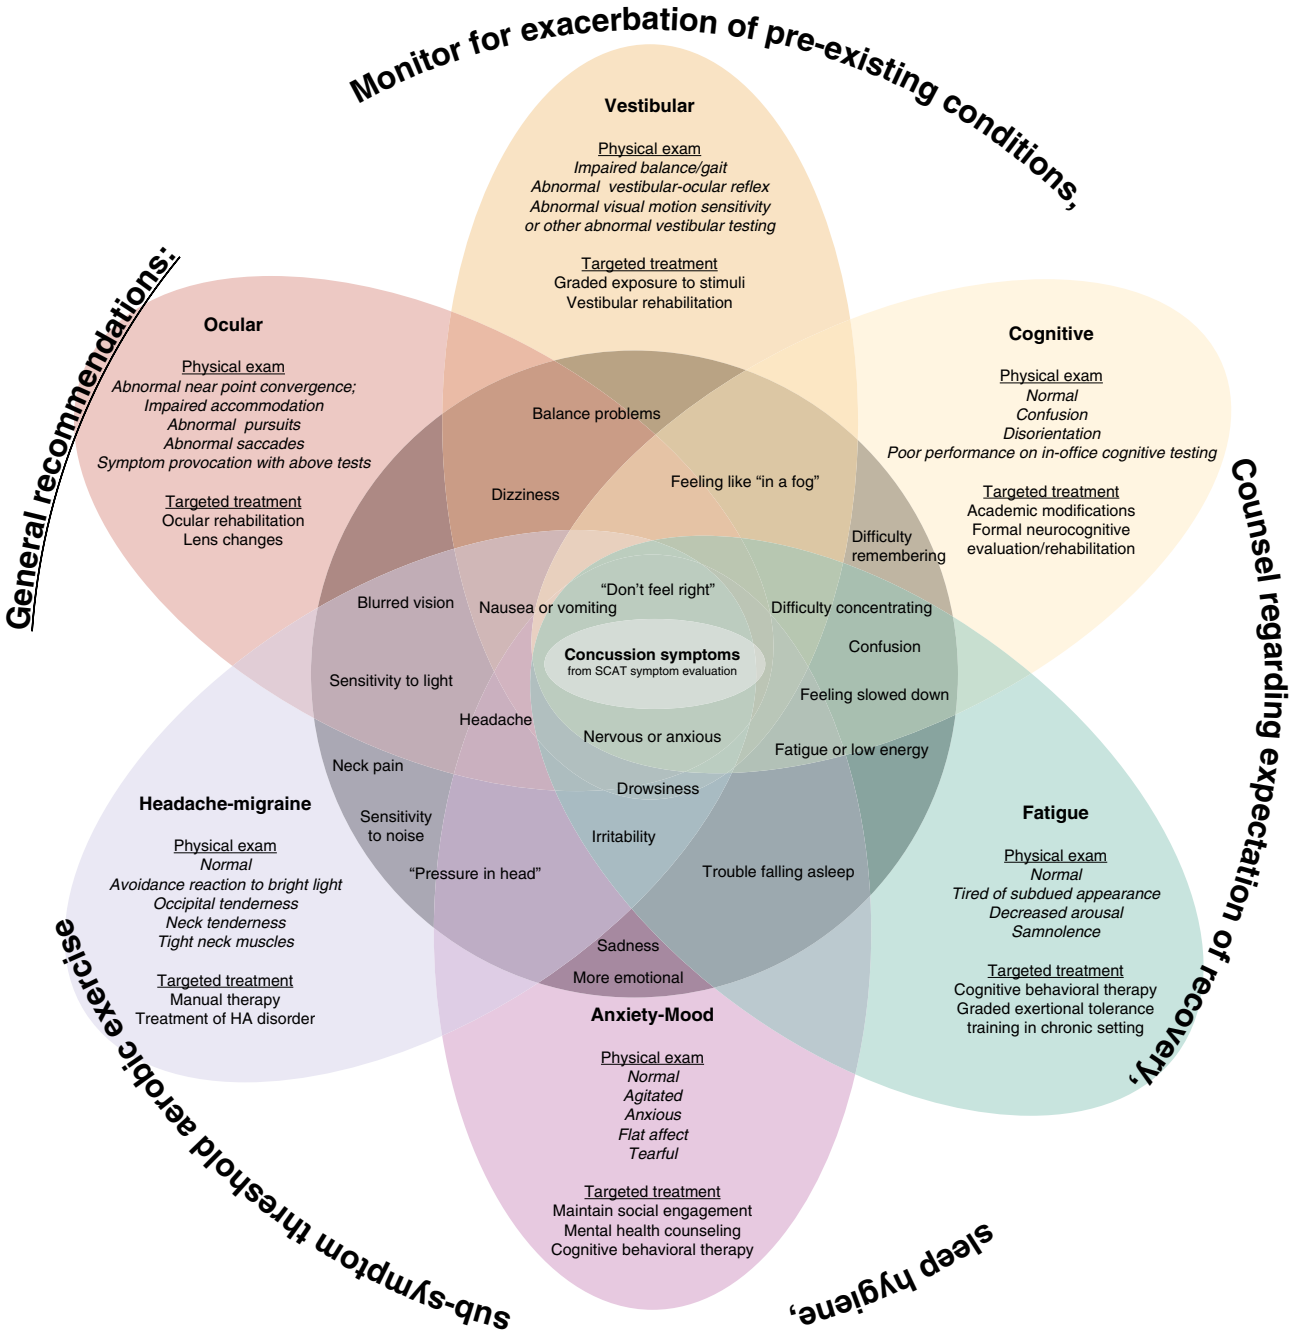

Fig. 33.15 Constellation of Symptoms Following Concussion. Overlapping clinical profiles is an emerging concept to facilitate individualized management after concussion. (From Harmon KG, Clugston JR, Dec K, et al. American Medical Society for Sports Medicine position statement on concussion in sport. *Br J Sports Med.* 2019;53(4):213–225.)

and psychosocial functioning (Fig. 33.15).[118,119] It has been reported that more than one-third of MTBI patients do not resume work until 1 to 3 months after their injury, and lingering cognitive complaints are reported by as many as 15% of patients 1 year postinjury.[134] Recovery can also be complicated by psychiatric or substance abuse problems, health problems, concurrent orthopedic or traumatic injuries, chronic pain, lack of family and social support, unemployment, and litigation.[135,136]

Postconcussive Syndrome

Postconcussive syndrome (PCS) refers to a constellation of symptoms that include somatic (headache, dizziness, vertigo, nausea, fatigue, sensitivity to noise and light), cognitive (difficulties with attention, concentration, and memory) and affective complaints (irritability, anxiety, depression, emotional lability) that occur following an MTBI or concussion and persist beyond the expected recovery period. Affected patients commonly report headache, dizziness, memory or concentration difficulties, irritability, sleep disturbances, dizziness, and depression. There appears to be psychological and structural components to postconcussive syndrome, because patients with a history of migraines, depression, or anxiety are more likely to experience postconcussive syndrome.[136] The severity and duration of postconcussive symptoms may correlate with the abnormalities found with early functional

imaging.[119] Studies of ED patients have indicated that as many as 30% of patients with a discharge diagnosis of MTBI will have symptoms at 3 months postinjury, and up to 15% will continue to be symptomatic at 1 year postinjury.[119] In the ED, patients with more severe symptoms, such as prolonged amnesia, dizziness, headache, anxiety, noise sensitivity, or trouble with verbal recall have been shown to be at a higher risk of developing postconcussive syndrome (see Fig. 33.15). Other factors that have been identified as conferring an increased risk for the development of PCS symptoms include prior MTBI, history of depression or anxiety, multiple injuries, forgetfulness or poor memory, noise or light sensitivity, and history of migraine.[137] There are a wide range of treatments being studied, including cognitive and behavioral therapies, medications, devices, dietary supplements, return to activity and rest.[138]

Seizures

PTSs occur in fewer than 1% of MTBI patients, and acute antiepileptic prophylaxis is not indicated. The cumulative incidence of PTE in the first 3 to 5 years after discharge is about 4% for patients with MTBI.[139] PTE usually develops within the first 2 years after injury. Prophylactic treatment with anticonvulsants does not prevent delayed-onset PTE and is not recommended.[140]

Posttraumatic Transient Cortical Blindness

Posttraumatic transient cortical blindness syndrome is characterized by transient visual loss, normal pupillary response, and normal funduscopic examination within hours following MTBI. This syndrome has been reported mainly in children. In most cases, vision returns to normal within minutes to hours (usually within 24 hours) following injury and leaves no neurologic sequelae. Headache, confusion, irritability, anxiety, nausea, and vomiting are common related symptoms. Although the mechanism for the transient blindness is unknown, it has been suggested that it is an abnormal vascular response to trauma, with resultant transient hypoxia and cerebral dysfunction.

Special Populations with Mild Traumatic Brain Injury

Mild Traumatic Brain Injury and Sports-Related Concussion

In the United States, the nearly 8 million students who currently participate in high school athletics and the greater than 480,000 who compete as National Collegiate Athletic Association (NCAA) athletes are at risk for concussion. Between 1.1 and 1.9 million concussions occur annually in children in the United States annually from organized and recreational sports.[141] Football, ice hockey, soccer, and lacrosse tend to have the highest concussion incidence rates when calculated by athlete exposure.[142] A concussion is mild TBI; the term sport-related concussion refers to the subset of concussive injuries occurring during sport activities.[102] It has been suggested that sports-related concussions are associated with less disability and more rapid recovery than concussions in nonathletes. However, neuroimaging has suggested similar patterns of neuronal disruption for sports- and nonsports-related MTBI.[143] Athletes are more vulnerable to the deleterious long-term effects of MTBI because they are often subjected to repetitive trauma and greater levels of physical exertion during recovery. Only recently has CTE come to public attention due to autopsy findings in high-profile athletes.[144] Originally identified in boxers, CTE has recently been found to occur after other organized sports, including US football, hockey, soccer, and professional wrestling.[18,145] Meta-analyses of neuropsychological outcomes following MTBI have suggested that recovery from impairments in the general population takes longer (weeks to months) than in athletes who tend to show recovery within 2 to 14 days following concussion. Among athletes there is a tremendous motivation to return to play. As a result, athletes often underreport symptoms, return to their regular activities prematurely, and may create the impression that they recover more quickly than they actually do.[146,147]

Second-impact syndrome is thought to be an exceedingly rare yet potentially fatal consequence of repeated MTBI in sports occurring within a short period of time (hours to days). It confers a mortality of 50% and permanent disability in the rest.[148] It is defined as occurring when an athlete who has sustained an initial head trauma, most often a concussion, sustains a second head trauma before symptoms associated with the first have fully cleared, leading to diffuse cerebral swelling.[148] The second impact could be smaller in magnitude and does not necessarily have to be a direct blow to the head.[149] Some debate whether a repeated head trauma is required or whether the brain swelling is the result of a single blow to the head or whether underreporting of symptoms could be a contributing factor.[149] Based on the published case studies, athletes at a highest risk include playing American football, male gender, and young age.[149] Accordingly, the CDC has developed the HEADS UP Concussion in Youth Sports initiative to offer information about preventing, recognizing, and responding to a concussion to coaches, parents, and athletes involved in youth sports.

Several new or updated clinical practice guidelines and position statements have been recently published on the diagnosis, treatment, and management of sports-related concussion including the American College of Emergency Physicians Sport-Related Head Injury Prevention Task Force,[102] the American Medical Society for Sports Medicine,[150] and the Zurich Consensus working group.[113] There is consensus that concussion is a clinical diagnosis that is ideally made by a licensed health care provider with experience in the evaluation and management of patients with a concussion. Any athlete suspected of having a concussion should be immediately removed from play. Graded symptom and clinical sign checklists can be useful, particularly if they can be compared to preseason data. The Sport Concussion Assessment Tool, fifth edition (SCAT5), is a standardized tool for evaluating injured athletes for concussion and can be used in athletes 13 years and older (https://bjsm.bmj.com/content/bjsports/51/11/851.full.pdf) and the Child SCAT5 can be used for children 5 to 12 years old (https://bjsm.bmj.com/content/bjsports/51/11/862.full.pdf).[151] The SCAT5 takes 15 to 20 minutes to complete and computes a composite score comprised of post-concussive symptoms, cognitive screening, and a screen of coordination, gait, and balance. The SCAT5 (Child and Adult versions) also includes a page of information to be given to the athlete and parents after discharge. This tool has been used successfully in the ED setting to evaluate sports-related concussion.[152]

When evaluating an athlete with sports-related concussion in the ED, follow the principles for MTBI evaluation including comprehensive history, details of injury mechanism, symptom trajectory, emphasis on mental status and alertness, head and neck, neurologic exam, vestibular exam (ocular, gait, and balance), and cognitive function.[102,150] As with all MTBI patients, monitoring of the injured athlete with serial assessments is crucial, because signs and symptoms may evolve over hours after injury. A head CT scans is not routinely recommended but should be considered if there is clinical suspicion of a traumatic intracranial lesion (see diagnostic imaging previously).

Before return to play, a gradual, stepwise increase in general physical activity, followed by sports-specific activities, is recommended. Progression to more strenuous steps is only recommended if the athlete is asymptomatic at the current level of activity (Table 33.3). Ideally, a multidisciplinary approach to assessment and management is used, with the inclusion of sports medicine specialists from various subspecialties, as appropriate for the athlete's symptoms and signs.[150] Because many

TABLE 33.3 Graduated Return to Play Protocol: Graduated Return-to-Sport (RTS) Strategy

Stage	Aim	Activity	Goal of Each Step
1	Symptom-limited activity	Daily activities that do not provoke symptoms	Gradual reintroduction of work/school activities
2	Light aerobic exercise	Walking or stationary cycling at slow to medium pace. No resistance training	Increase heart rate
3	Sport-specific exercise	Running or skating drills. No head impact activities	Add movement
4	Non-contact training drills	Harder training drills, e.g., passing drills. May start progressive resistance training	Exercise, coordination, and increased thinking
5	Full contact practice	Following medical clearance, participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6	Return to sport	Normal game play	

NOTE: An initial period of 24 to 48 hours of both relative physical rest and cognitive rest is recommended before beginning the RTS progression. There should be at least 24 hours (or longer) for each step of the progression. If any symptoms worsen during exercise, the athlete should go back to the previous step. Resistance training should be added only in the later stages (stage 3 or 4 at the earliest). If symptoms are persistent (e.g., more than 10 to 14 days in adults or more than 1 month in children), the athlete should be referred to a healthcare professional who is an expert in the management of concussion.

Adapted from McCrory P, Meeuwisse W, Dvorak J, et al. Consensus statement on concussion in sport-the 5(th) international conference on concussion in sport held in Berlin, October 2016. *Br J Sports Med.* 2017;51(11):838–847.

states have passed laws regarding concussion management in organized youth sports, it is good practice for emergency clinicians to familiarize themselves with the laws of the state in which they are practicing.

Key recommendations of recent position statements have stated that any athlete suspected of having a concussion should not be allowed to return to play on the day of the injury. Athletes with concussion should not return to play until they have been evaluated by a licensed health care provider with expertise in concussion management. A head CT should only be considered if intracranial lesions are suspected. Furthermore, there should be a gradual stepwise increase in physical activity.[102,113,150]

Military Personnel and Blast Injury

Mild TBI is also a common injury among soldiers who have participated in combat. Explosive blast brain injury is becoming recognized as a distinct entity from the penetrating form of blast injury and closed brain injury.[153] In recent US conflicts in Iraq and Afghanistan, over 60% of combat casualties were from explosive blast, mostly from improvised explosive devices (IEDs).[154] Other mechanisms included falls, motor vehicle accidents, fragment shrapnel, and bullet wounds. In an explosive blast, the primary injury to the brain occurs when the physical forces emanating from a detonation impart loading on the head and consequently the brain. The definition of MTBI from the American Congress of Rehabilitation Medicine is currently being applied to explosive blast TBI (including loss of consciousness, amnesia, altered mental status, and focal neurologic deficit).[153] A soldier who has been exposed to a blast may lack overt evidence of a head injury, such as lacerations, bruising, or hematomas. Recognizing an MTBI acutely is important so that the soldier can receive appropriate medical attention and be removed from combat-related duty to avoid another TBI.[154] After the first blast exposure, many soldiers do not recognize that they may have been injured, and thus will not seek medical care. The first indication of injury may be persistent postconcussive symptoms, such as headaches, vertigo, short-term memory loss, and difficulty concentrating and multitasking.[154] The clinical presentation of explosive blast MTBI can be confounded by the considerable overlap between the symptoms of MTBI and posttraumatic stress disorder (PTSD), such as mood fluctuations, sleep disturbances, and difficulty concentrating.[155] Both may occur in the same individual. PTSD symptoms usually include bursts of anger, irritability, hypervigilance, and increased startle response.[153,155] Additionally, military service members are frequently subjected to subconcussive blast events during training and deployment that may also have long-term consequences on cognitive functioning.[156]

Anticoagulated Patients

Patients on anticoagulant medications. Most clinical decision guidelines for determining need for CT scan exclude patients who are taking anticoagulants such as warfarin (vitamin K antagonists), antiplatelet medications (aspirin, clopidogrel, prasugrel, ticagrelor), and non–vitamin K antagonists known as direct oral anticoagulants (DOACs) such as Factor IIa inhibitors (dabigatran) or Factor Xa inhibitors (rivaroxaban, apixaban, edoxaban, betrixaban, darexaban). Overall, there is a higher incidence of intracranial bleeding in TBI patients on anticoagulants following head trauma, with an incidence of up to 22% in patients with MTBI.[157,158] As a result, most practice guidelines propose that patients who sustain head trauma and are on anticoagulation treatment should undergo a CT scan without contrast.[63] For those on warfarin, an INR should be determined because an initial INR greater than 3 confers a much higher risk of intracranial bleeding.

Some guidelines advocate observation for the first 24 hours following MTBI, along with a second CT scan for those with an initially negative CT.[63,159] However, intracranial bleeding can be delayed beyond the first 24 hours in 1% to 3% of anticoagulated patients and can present as late as 6 weeks following injury.[160] This underscores the importance of detailed patient instructions on discharge from the hospital. In anticoagulated patients with a negative CT scan and a normal neurologic examination, routine admission is not required[160,161] but is recommended for patients at high risk for delayed bleeding (e.g., supratherapeutic INR), those with comorbidities, those who live alone or do not have adequate supervision for neurologic checks, and those who cannot return to the hospital in a timely manner should symptoms of delayed bleeding appear.[63,64]

Antiplatelet medications are more likely to lead to immediate traumatic intracranial hemorrhage (12%) compared with patients receiving warfarin (5%), who are more likely to have delayed bleeding.[162] Compared to warfarin, DOACs have a lower incidence of immediate intracranial bleeding after MTBI.[163–166]

Patients with therapeutic anticoagulation and a negative initial head CT scan do not need to have their anticoagulation reversed.[63,64,167] In patients on warfarin with traumatic intracranial lesions, reversal should be considered. PCCs or fresh-frozen plasma, together with vitamin K can be initiated in the ED.[63,64]

There is inadequate evidence to support the routine use of platelet transfusion for intracranial hemorrhage for patients taking preinjury antiplatelet medications as it does not impact mortality.[69–71] Likewise, while desmopressin has been proposed as a means to improve platelet adhesion in patients taking antiplatelet medications, the available data is insufficient to recommend its routine use.

Dabigatran can be reversed using idarucizumab, a Fab fragment of a monoclonal antibody that binds and inactivates it.[65] If idarucizumab is not available, clotting factor products such as PCCs or fresh-frozen plasma can be used.[66] Dabigatran can also be reversed with hemodialysis. Patients requiring emergent reversal of Factor Xa inhibitors can be treated with Andexanet alfa or 4-factor PCCs.[67,68] Idarucizumab and Andexanet should not be combined with other clotting factor products.

The decision to reverse the patient's anticoagulation must take into account the severity of the injury and the risk of reversal.

Patients with inherent bleeding disorders. The most serious site of bleeding for children and adults with inherent bleeding disorders, such as hemophilia, is the CNS. Intracranial hemorrhage in patients with hemophilia can occur spontaneously or following mild head trauma. Over 50% of hemophiliacs with MTBI who have intracranial bleeding are initially asymptomatic, with a normal neurologic examination. Therefore, patients with inherent bleeding disorders should undergo head CT following a MTBI.[168] There should be a low threshold for factor replacement (e.g., factor VIII or IX, cryoprecipitate, fresh-frozen plasma) in patients with severe hemophilia or in those with MTBI symptoms, even prior to performing head CT.[169]

Head Trauma in Older Adults

Older patients have increased morbidity and mortality from TBI and have higher rates of intracranial injuries following head trauma.[1] They also experience MTBI more frequently than severe TBI. Furthermore, frequent falls put them at risk for repetitive brain injury. Within 7 months following a mild or moderate TBI, older patients can show a decline in language, memory, executive function, activities of daily living, and mood compared with their preinjury functioning and compared to controls.[170] Accordingly, older adults with preinjury warfarin or clopidogrel use are at an increased risk for unfavorable long-term neurologic outcomes compared with similar patients without preinjury use of these medications.[162,171]

With age, the brain atrophies and creates more space within the cranial vault for blood to accumulate before symptoms appear. Moreover, with atrophy comes stretching of bridging veins that may tear and lead to SDHs more easily. Therefore, older adults can have significant hemorrhage into their brain and not show signs of deterioration, especially if their baseline cognitive functioning is impaired. Occult intracranial hemorrhages occur in over 2% of older patients with head trauma. Alcohol abuse is one of the most prevalent comorbid conditions found in older patients admitted to the hospital with TBI, so screening for alcohol abuse in older patients with head trauma is recommended.[172] Elder abuse is an important consideration in this population as well and should be assessed during the ED evaluation.

The presence of comorbid medical conditions, use of anticoagulants, preexisting cognitive deficits, polypharmacy, alcohol consumption, and unique physiology of the aging brain make it challenging for the emergency clinician to detect brain injury.[173] Even low-mechanism falls should prompt health care providers to consider the possibility of brain injury in older patients. Many clinical decision rules recommend CT for patients older than 60 to 65 years following any suspected MTBI. Reducing the risk of falls in older adults can reduce the risk of TBI. Particular attention needs to be given to polypharmacy, drug interactions, safety issues in the living environment, risk of elder abuse, and covert alcohol consumption.
