Unless an IUP is diagnosed, the patient with threatened miscarriage should be given careful instructions on discharge to return if she has signs of hemodynamic instability, pain, or other symptoms that might indicate ectopic pregnancy. In conjunction with gynecologic colleagues, an ED protocol is useful to determine when follow-up sonographic evaluation and serial hCG measurements should be obtained since ultrasonography can be an inaccurate diagnostic tool if the hCG level is below 1500 mIU/mL, vaginal bleeding is significant, or sonographic findings do not include a fetal pole or yolk sac. The patient must be given explicit return precautions and close obstetrical follow-up is essential. Typically, serial hCG measurements are obtained between 48 to 72 hours after the initial ED visit and follow-up sonographic evaluation is obtained within 3 to 7 days of ED presentation.

Fifty percent or more of women with threatened miscarriage who are seen in the ED ultimately miscarry, and there is no proven treatment to prevent miscarriage. In most cases, spontaneous miscarriage is the body's natural method of expelling an abnormal or undeveloped (blighted) pregnancy. Thus, a major goal of early management should be patient education and support. Patients should be advised that moderate daily activities do not affect the pregnancy. Tampons, intercourse, and other activities that might induce uterine infection should be avoided as long as the patient is bleeding, and she should return immediately for fever, abdominal pain, or an increase in bleeding. Cramping from a known IUP can be safely treated with acetaminophen or oral synthetic narcotics, if needed. If the patient passes tissue, it should be brought to a provider to be examined for products of conception because differentiation of fetal parts or villi from decidual slough or casts is difficult.

Patient counseling is paramount with threatened miscarriage and education of the ED staff on this topic is critical. Determination of fetal viability can be helpful in reassuring the mother or preparing her for probable fetal loss. Miscarriages are associated with a grieving process, which is frequently more difficult because early pregnancy is unannounced, and early fetal death is not publicly recognized. Because many women consider that minor falls, injuries, or stress during the first trimester can precipitate miscarriage, patients should be reassured that they have done nothing to cause miscarriage. Patients should be made aware that miscarriage is common, grieving is normal, and counseling may be beneficial. A follow-up appointment should be scheduled after miscarriage to support the patient in resolving such issues.

Incomplete Miscarriage. Treatment of the patient with incomplete miscarriage includes expectant management, medical management, or surgical evacuation. When the miscarriage is incomplete, the uterus may be unable to contract adequately to limit bleeding from the implantation site. Bleeding may be brisk, and gentle removal of fetal tissue from the cervical os with ring forceps during the pelvic examination often slows bleeding considerably. Manual uterine aspiration performed in the ED may also be appropriate in cases of brisk uterine hemorrhage as a result of early pregnancy loss or retained products of conception up to 12 weeks gestational age.[4]

Completed Miscarriage. Management of patients with presumed completed miscarriage is more complicated. If the patient brings passed tissue with her, this should be sent to the pathology department for evaluation. Unless an intact gestational sac or fetus is visualized, it is rarely clear clinically whether miscarriage is complete. In women with a history consistent with miscarriage who have minimal remaining intrauterine tissue as determined by ultrasonography, expectant management is safe, but only if ectopic pregnancy can be excluded. If endometrial tissue is not seen with ultrasonography, bleeding is mild, and gestational age is less than 8 weeks, curettage is frequently unnecessary, and the patient can be safely observed by a gynecologist for serial hormonal assays. It is estimated that 65% of women with first-trimester miscarriage complete the miscarriage without intervention.[5] However, the need for later visits and procedures may be decreased by uterine curettage, particularly if the fetal pole or a gestational sac is visible on the sonogram at the time of evaluation. Medical management with misoprostol (800 µg intravaginal for one dose) instead of dilation and curettage is also an option and has a success rate of 80% to 91%.[5] The patient should be instructed to return if uncontrolled bleeding, severe pain or cramping, fever, or tissue passage occurs. Follow-up is recommended in 1 or 2 weeks to ensure that the miscarriage is complete.

After miscarriage, the patient should be advised that fetal loss can cause psychological stress. Follow-up in 1 or 2 weeks with a gynecologist should be provided. There is no conclusive evidence to support the use of antibioitics after D&C or miscarriage, and some evidence has suggested that the side effects of treatment may outweigh any potential benefit. For that reason, we do not recommend the routine use of antibiotics after a miscarriage. Ergonovine or methylergonovine (0.2 mg orally bid) can be used to stimulate uterine involution. The patient should be advised to return if signs of infection (e.g., fever, uterine tenderness) occur, bleeding resumes, or further tissue is passed.

Ectopic Pregnancy

KEY CONCEPTS

- An ectopic pregnancy can masquerade as a threatened miscarriage in the early stages of pregnancy and should always be considered in the differential diagnosis.
- Because the history and physical examination of the patient with ectopic pregnancy are insensitive and nonspecific, pelvic ultrasonography and determination of serum hCG levels are essential to locate the pregnancy in any patient who has abdominal pain or vaginal bleeding and a positive pregnancy test result.
- Ultrasonographic detection of an IUP is likely at hCG levels higher than 1500 to 2000 IU/L.

Foundations

Ectopic pregnancy is a pregnancy implanted outside the uterus, most commonly in the fallopian tube. It is increasing in frequency and the third leading cause of maternal death, responsible for 4% to 10% of cases.[6] Ectopic pregnancy is estimated to account for approximately 1% to 2% of all pregnancies, although national estimates of incidence are difficult to determine. Although the incidence of ectopic pregnancy is

highest in women aged 25 to 34 years, the rate is highest among older women and women belonging to minority groups. Simultaneous intrauterine and extrauterine gestations (heterotopic pregnancy) have historically been rare, occurring in approximately 1 in 4000 pregnancies; women who have undergone assisted reproduction techniques with embryo transfer are at high risk of one of the pregnancies being ectopic. The incidence of ectopic pregnancy among women presenting to the ED with vaginal bleeding or pain in the first trimester is approximately 10%, but may be as high as 16%.[7]

Pathophysiology

Implantation of the fertilized ovum occurs approximately 8 or 9 days after ovulation. Risk factors for an abnormal site of implantation include prior tubal infection (50% of cases), anatomic abnormalities of the fallopian tubes, assisted reproduction (especially multiple embryo transfers), and abnormal endometrium (host factors). This results in failure of the embryo to implant in the endometrium. The risk of ectopic pregnancy increases approximately threefold after a patient has had pelvic inflammatory disease (PID). If the patient is currently using an intrauterine device (IUD), increased risk can occur from complicating PID or from failure of the IUD to prevent pregnancy while preventing endometrial implantation. All forms of contraception, except the IUD and tubal sterilization, decrease the incidence of ectopic pregnancy. After an ectopic pregnancy, the risk of a subsequent ectopic pregnancy can be as high as 22%, depending on the characteristics and treatment of the ectopic pregnancy (e.g., location of implantation, surgical vs. medical management; Box 173.2).[8]

When abnormal implantation occurs in the fallopian tubes, on the ovaries, or in the cervix, the pregnancy usually grows at a less than normal rate, which can result in abnormally low or declining hCG production. Even if exceedingly low, a single hCG measurement cannot exclude the diagnosis of ectopic pregnancy. Blood leaks intermittently through the tubal wall or out the fimbrial ends, with spillage into the peritoneal cavity. Bleeding and other symptoms are usually intermittent. Three outcomes are possible: spontaneous involution of the pregnancy, tubal abortion into the peritoneal cavity or vagina, or rupture of the pregnancy with internal or vaginal bleeding. Implantation in the uterine horn (cornual pregnancy) is particularly dangerous because the growing embryo can use the myometrial blood supply to grow larger (10–14 weeks of gestation) before rupture occurs. Cornual pregnancy accounts for 2% to 4% of all ectopic pregnancies and can be difficult to identify by ultrasonography.[9]

Clinical Features

The classic clinical picture of ectopic pregnancy is a history of delayed menses, followed by abdominal pain and vaginal bleeding in a patient with known risk factors. Unfortunately, this history is neither sensitive nor specific. Risk factors for ectopic pregnancy are absent in almost half of patients. Of patients with symptomatic ectopic pregnancy, 15% to 20% have not missed a menstrual period, and occasionally the patient has no history of vaginal bleeding. Abdominal pain varies and can be described as crampy, intermittent, severe, or even absent.

The physical findings in ectopic pregnancy are likewise variable. Vaginal bleeding, uterine or adnexal tenderness, or both in the patient with a positive pregnancy test result should trigger consideration of ectopic pregnancy. Tachycardia is not always present, even with significant hemoperitoneum; the hemoglobin level is usually normal, and hypotension may be seen. The presence of peritoneal signs, cervical motion tenderness, or lateral or bilateral abdominal or pelvic tenderness indicates an increased likelihood of ectopic pregnancy. If peritoneal irritation is present, pain can preclude an accurate bimanual examination. Adnexal masses are palpated in only 10% to 20% of patients with ectopic pregnancy.

Vaginal bleeding is often mild. Heavy bleeding with clots or tissue usually suggests a threatened or incomplete miscarriage, although the patient with an ectopic pregnancy who has decreasing hormonal levels may experience endometrial sloughing, which can be mistaken for passage of fetal tissue. Passed tissue should be examined, as with cases of miscarriage, in tap water or saline (or under low-power microscopy). Unless fetal parts or chorionic villi are seen, ectopic pregnancy should not be excluded in the patient with bleeding or passage of tissue.

Differential Diagnoses

The spectrum of clinical presentations in ectopic pregnancy is wide, so the differential diagnosis includes essentially all first-trimester complications. Threatened miscarriage, the most common alternative diagnosis, can be recognized by sonographic evidence of an IUP, healthy or failed. Hypovolemia may be seen, particularly in incomplete miscarriage, but hypotension without significant vaginal hemorrhage is highly suggestive of ectopic pregnancy. Identification of fetal parts or chorionic villi in tissue expelled or obtained during D&C is useful to confirm a complication of IUP, although this is not sufficient to exclude ectopic pregnancy in a patient with an increased risk of heterotopic gestation, such as the patient undergoing assisted reproduction treatment.

A ruptured corpus luteum cyst should also be considered in the first trimester when bleeding is associated with peritoneal pain or irritation. The corpus luteum normally supports the pregnancy during the first 7 or 8 weeks. Rupture causes pelvic pain and peritoneal irritation. Ultrasonography is helpful if it reveals an IUP (except in patients with in vitro fertilization). During early gestation, when ultrasonography is nondiagnostic, free fluid is usually visible by ultrasonography, and serial observation may be required. If the patient is unstable, especially if an IUP cannot be identified by ultrasonography, laparoscopy or in rare cases laparotomy, may be required to differentiate between the two conditions.

Diagnostic Testing

Because the history and physical examination of the patient with ectopic pregnancy are insensitive and nonspecific, ancillary studies are essential to locate the pregnancy in any patient who has abdominal pain or vaginal bleeding and a positive pregnancy test result. Ultrasonography and hormonal assays are the most commonly used ancillary tests and advances in these technologies have allowed for more accurate detection and exclusion of ectopic pregnancy in patients with first trimester bleeding or pelvic pain. Laparoscopy may be the most efficient diagnostic tool in the hemodynamically unstable patient.

Ultrasonography. Ultrasonography is the primary method used to locate early gestation, establish gestational age, and assess fetal viability.

Transabdominal ultrasonography is most useful for identification of IUPs with fetal cardiac activity and exclusion of ectopic pregnancy, except in patients at high risk for heterotopic pregnancy because of infertility procedures. Transvaginal ultrasonography is more sensitive, recognizes IUP earlier than transabdominal ultrasonography, and is diagnostic in up to 80% of stable patients presenting in the first trimester. Transvaginal ultrasound requires operator training and can be limited by device availability and quality.

As home pregnancy tests and access to early ultrasound becomes more prominent, the risk of having a "pregnancy of unknown location" by ultrasound rises. Indeterminate sonograms, which demonstrate neither an IUP nor extrauterine findings suggestive of ectopic pregnancy, occur in approximately 20% of ED evaluations of women with first-trimester bleeding or pain. Ectopic pregnancy is more likely among this subgroup with indeterminate sonograms if the hCG level is less than 1000 mIU/mL and the uterus is empty. Endometrial debris and fluid in the uterus do not exclude ectopic pregnancy.

An indeterminate ultrasound study usually does not result in a diagnosis of normal pregnancy. In one series of more than 1000 pelvic ultrasound examinations, 53% of indeterminate ultrasound studies resulted in a diagnosis of embryonic demise, 15% were ectopic pregnancies, and only 29% had an IUP. However, correlation of sonographic results with quantitative hCG measurements can add to the predictive value. With no intrauterine pregnancy on transvaginal ultrasound and hCG greater than 1500 mIU/mL, ectopic pregnancy should be suspected keeping in mind that ectopic pregnancies can be discovered at any level of hCG. Normal pregnancy is unlikely if no gestational sac is seen by transvaginal ultrasonography with an hCG level higher than 1000 to 2000 mIU/mL, depending on the institution's discriminatory zone. Additional ultrasound findings that may predict early spontaneous abortion include crown rump length or fetal heart rate below the fifth percentile and fetal heart rate below 130 beats per minute.[10] The differential diagnosis includes miscarriage and ectopic pregnancy in these patients. Unfortunately, levels of approximately 1500 mIU/mL develop in only approximately 50% of patients with ectopic pregnancies (see Table 173.1). Sonographic findings in a patient with suspected ectopic pregnancy are listed in Box 173.3 and illustrated in Figures 173.1 to 173.5.

Hormonal Assays. Quantitative hCG levels serve two primary functions—serial levels can be used in the stable patient who can be observed as an outpatient, and a single level can be correlated with sonographic results for improved interpretation. Beginning 8 or 9 days after ovulation, serum hCG levels normally double every 1.8 to 3 days for the first 6 or 7 weeks of pregnancy. An initial quantitative level can be measured at the time of the ED visit, particularly if the sonogram is indeterminate or gestational age is estimated as less than 6 weeks. A repeated level should be measured 48 to 72 hours later. A doubling or rise of hCG by 66% generally indicates a viable intrauterine pregnancy, however approximately 15% of normal IUPs have a minimal rise in hCG, requiring a third serial test. A rapid decline in hCG tends to indicate miscarriage whereas a slow decline can indicate an ectopic pregnancy.

Single quantitative hCG levels can also be useful in conjunction with ultrasonography; normal IUPs should be visible transvaginally at 1000 to 2000 mIU/mL hCG or higher (see Table 173.1). A benign course for ectopic pregnancy cannot be assumed with low hCG levels. Ruptured ectopic pregnancies requiring surgery have been reported with very low or absent levels of hCG.

Serum progesterone levels have been studied as an additional or alternative marker to determine which patients need further evaluation and follow-up for possible ectopic pregnancy though it is not a standard tool in the ED. The progesterone level rises earlier than the hCG level in normal pregnancy and plateaus with levels higher than 20 ng/mL, so measurement of serial levels over time is not necessary. Levels below 5 ng/mL exclude a viable IUP with rare exceptions and can be used in combination with serum hCG ratios at presentation and 48 hours. Patients determined to have low risk of ectopic pregnancy by this algorithm can avoid additional testing and be managed conservatively.[11] A progesterone level should be sent when the hCG levels are low, ultrasonography is indeterminate, and the emergency clinician is considering consultation for D&C or laparoscopy.

Other Studies. Dilation and evacuation can be used in patients without a viable IUP or ectopic pregnancy on ultrasonography to differentiate intrauterine miscarriage from ectopic pregnancy. Identification of chorionic villi in endometrial samples is seen in approximately 70% of patients and excludes ectopic pregnancy,

except in patients undergoing assisted reproduction. Identification of chorionic villi can be made, even in 50% of women with an empty uterus on ultrasonography, and limits the need for laparoscopy to exclude ectopic pregnancy in this population.

Although it is invasive, laparoscopy is extremely accurate as a diagnostic (and therapeutic) procedure for possible ectopic pregnancy. It is the diagnostic treatment of choice in unstable first-trimester patients with peritoneal signs and is also indicated in patients with peritoneal fluid or an ectopic gestation in the pelvic cavity. Medical alternatives for the management of ectopic pregnancy have resulted in decreased indications for laparoscopy in stable patients.

Management and Disposition

Unstable Patients. Approximately 20% of women with ectopic pregnancies manifest signs and symptoms warranting immediate intervention. This includes patients with hypovolemia, large amounts of peritoneal fluid, or an open cervical os. For patients with signs of hypovolemia, rapid volume resuscitation should be instituted with intravenous (IV) fluids and blood products as necessary, and a baseline hemoglobin level and type and crossmatch should be obtained. If the patient remains unstable, immediate surgery is warranted. Laparoscopy may be indicated for patients who stabilize with treatment or those who are hemodynamically stable but exhibit peritoneal signs on abdominal examination. One study has reported that identification of free fluid in the Morison pouch on bedside ultrasonography predicts the need for operative intervention in most cases in patients with suspected ectopic pregnancies. A D&C or evacuation procedure with examination of the endometrial contents for products of conception can be performed urgently in the unstable patient with an open cervical os. All patients with ectopic pregnancy who are Rh-negative should be given Rh immune globulin, 50 μg intramuscularly.

Stable Patients. In stable patients with first-trimester bleeding, the goal is to exclude ectopic pregnancy in a timely manner. In the patient with pain by history or examination or risk factors for ectopic pregnancy, ultrasonography should be performed before discharge.

In low-risk patients with minor symptoms or bleeding, ectopic pregnancy is still a possibility. In most cases, ultrasonography is the initial screening tool because it provides the most accurate and rapid information (Fig. 173.6). If an IUP is not seen, quantitative hCG levels help risk stratify these patients. In all cases, if the patient is discharged, careful instructions are given for symptoms that would require her earlier return. An alternative strategy uses hCG levels first. However, waiting times for the serum assay can increase ED length of stay. In addition, ultrasonography is usually diagnostic of IUP or ectopic pregnancy, even if the hCG level is less than 1000 mIU/mL.

A minority of patients have indeterminate sonographic results and hCG levels below 1000 mIU/mL. When the hCG levels never rise to the discriminatory zone, the differential diagnosis includes intrauterine fetal demise and ectopic pregnancy. Early D&C with identification of the products of conception can be useful in the patient with nonrising hCG levels to detect chorionic villi and confirm a failed IUP or strongly suggest ectopic pregnancy. Alternatively, hCG levels can be followed until they reach zero, particularly if initial levels are low.

Although laparotomy may be required for patients who have an ectopic pregnancy, an increasing number of surgeries are being performed through the laparoscope. Salpingostomy is preferred to salpingectomy if the patient is stable and the procedure is technically feasible. Overall, the advent of transvaginal ultrasonography has resulted in earlier diagnosis and a trend toward nonoperative management.

Medical management is a safe and cost-effective treatment for the stable patient with minimal symptoms, especially when future fertility is desired. Methotrexate (50 mg/m2 IM or 1 mg/kg IM, alternating with folinic acid) is the drug most commonly used to treat early ectopic pregnancy. It interferes with fetal DNA synthesis and causes destruction of rapidly dividing fetal cells and involution of the pregnancy. Medical treatment is used most often for patients who are hemodynamically stable, with a

tubal mass smaller than 3.5 cm in diameter, no fetal cardiac activity, and no sonographic evidence of rupture. Although there is no agreed on hCG cutoff for single-dose methotrexate, studies have suggested that increasing hCG levels are significantly correlated with methotrexate failure. Medical therapies are associated with an 85% to 93% success rate, with no significant difference between single- and multiple-dose protocols. Pelvic pain is common in patients receiving methotrexate (60%), even when it is used successfully. Indications of methotrexate failure and need for rescue surgery include decreasing hemoglobin levels, significant pelvic fluid, and unstable vital signs. All patients receiving methotrexate require close follow-up until the hCG level reaches 0, which may take 2 or 3 months.

Molar Pregnancy

Foundations

Molar pregnancy, also known as a hydatidiform mole, comprises a spectrum of diseases characterized by disordered proliferation of chorionic villi. In the absence of fetal tissue, the pregnancy is termed a *complete hydatidiform mole*. Complete moles are caused by the fertilization of an ovum without maternal DNA and the subsequent duplication of the haploid genome. The term *incomplete mole* refers to a mole that is caused by the fertilization of a normal ovum by two sperm. The duplication of the triploid karyotype causes some fetal tissue to be present, along with focal trophoblastic hyperplasia. In approximately

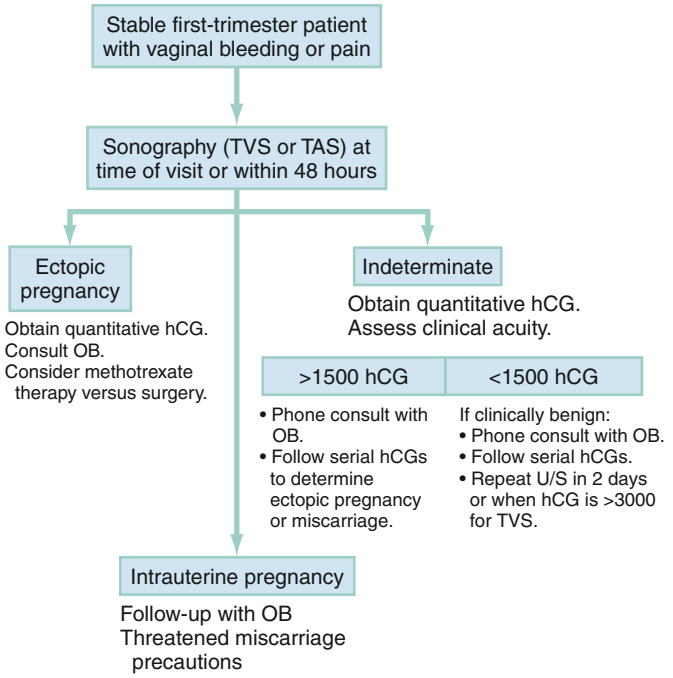

Fig. 173.6 Management of vaginal bleeding or pain in the stable first-trimester pregnant patient. *hCG,* Human chorionic gonadotropin; *OB,* obstetrics specialist; *TAS,* transabdominal sonography; *TVS,* transvaginal sonography; *U/S,* ultrasonography.

19% of molar pregnancies, neoplastic gestational disease develops, with persistence of molar tissue after the pregnancy has been evacuated.[12] Metastatic diseases can develop, requiring chemotherapy and intensive oncologic management.

Clinical Findings

Early molar pregnancy is usually not clinically apparent. The most well-described risk factor for the development of a molar pregnancy is extreme maternal age. Many patients present with abdominal pain, nausea and vomiting, or vaginal bleeding, and it may be difficult to differentiate these patients from those with threatened miscarriage or ectopic pregnancy by historical features alone. Patients sometimes seek treatment for apparent persistent hyperemesis gravidarum from high circulating levels of hCG, bleeding or intermittent bloody discharge, or respiratory distress; failure to hear fetal heart tones during the second trimester is the usual initial clue to diagnosis. If molar pregnancy spontaneously aborts, it is usually in the second trimester (before 20 weeks), and the patient or physician may note the passage of grapelike hydatid vesicles. Uterine size is larger than expected by date (by >4 weeks) in approximately 30% to 40% of patients. Theca lutein cysts may be present on the ovaries as a result of excessive hormonal stimulation, and torsion of affected ovaries can be seen.

Diagnostic Tests

The characteristic sonographic appearance of hydropic vesicles within the uterus, described as a snowstorm appearance, is highly suggestive of a diagnosis of molar pregnancy (Fig. 173.7). Alternatively, cystic changes are seen in partial molar pregnancies. In some cases, a partial molar pregnancy is detected only on pathologic examination of abortion specimens. Complications of molar pregnancy include preeclampsia or eclampsia, which can develop before 24 weeks of gestation, respiratory failure or distress from pulmonary embolization of trophoblastic cells, hyperemesis gravidarum, and uterine bleeding. Ultrasonography usually provides the diagnosis of a complete molar

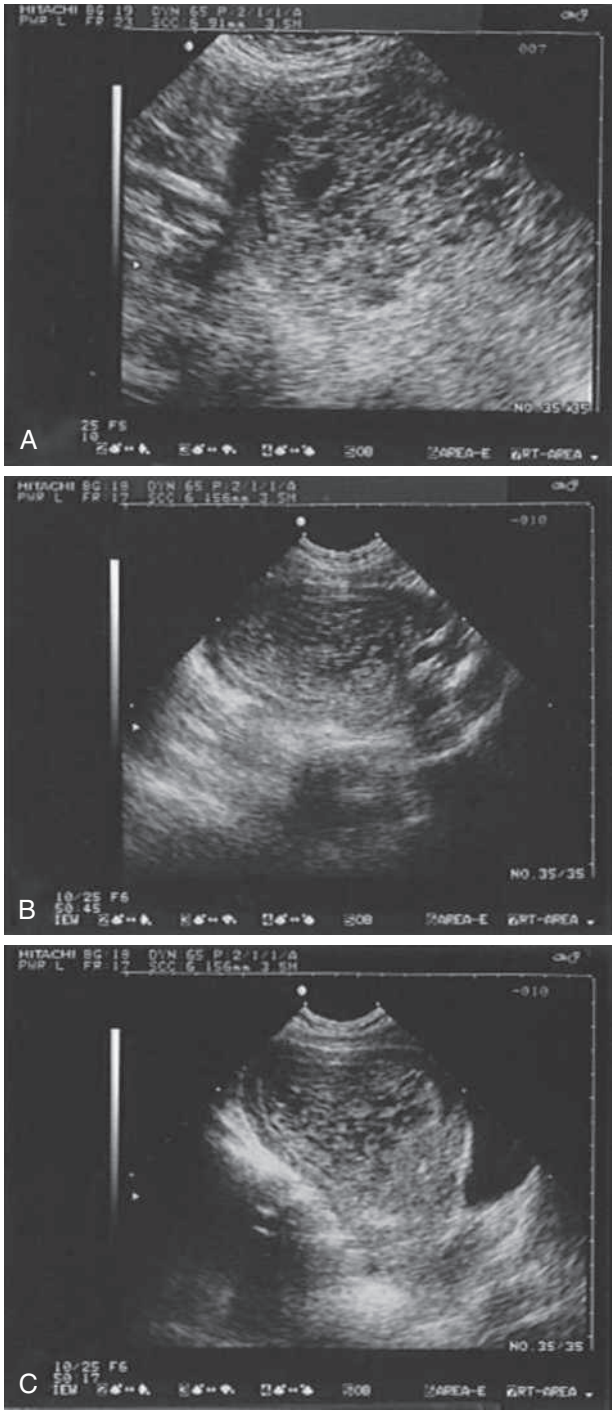

Fig. 173.7 Ultrasonogram showing molar pregnancy. (Courtesy Dr. Mary Ann Edens.)

pregnancy in the second-trimester patient who has "threatened miscarriage" or during sonographic assessment for fetal well-being and size. However, ultrasonography is only 58% sensitive, and diagnosis of a partial mole is made in only 17% of cases.[13] Up to two-thirds of molar pregnancies are diagnosed by pathologic specimens after miscarriage.

Management

Molar pregnancies are managed with uterine dilation and curettage (D&C). Following evacuation of a molar pregnancy, patients must be monitored in the outpatient setting for trophoblastic sequelae. Patients are at increased risk of an invasive mole, a benign tumor that invades the uterine wall and metastasizes to the lungs or vagina, or choriocarcinoma, a malignant tumor that invades the uterine wall and metastasizes to the lungs, brain, and liver via the patient's vasculature. Patients who present to the ED with complications of bleeding metastases are managed with a combination of chemotherapy, radiation, and surgery.

COMPLICATIONS OF LATE PREGNANCY

Vaginal Bleeding in Later Pregnancy

KEY CONCEPTS

- Bleeding during the second trimester (14 to 24 weeks) is not benign and is associated with a 33% risk of fetal loss. Management is supportive and expectant because fetal rescue is impossible at this level of fetal immaturity.
- The major conditions associated with vaginal bleeding in the second half of pregnancy include abruptio placentae and placenta previa. Patient history, physical examination, and results of ultrasonography can be used to distinguish them.
- All patients with painless, second-trimester vaginal bleeding should be assumed to have placenta previa until proven otherwise. Digital or instrumental probing of the cervix should be avoided until the diagnosis has been excluded via ultrasound.
- Abruptio placentae consists of a wide spectrum of severity of symptoms and risk. Up to 20% of women will have no pain or vaginal bleeding. Assessment is generally based on clinical features, coagulation parameters, and signs of fetal distress.

Foundations

Bleeding during the second half of pregnancy occurs in approximately 4% of pregnancies. Only 20% of miscarriages occur after the first trimester, and the most important differential diagnoses after 12 to 14 weeks of gestation are abruptio placentae and placenta previa. The cause is often not determined, although occult marginal placental separations, which can be recognized only by placental inspection at delivery, are believed to come from a common source of bleeding above the cervix. Other causes of late vaginal bleeding include early labor, various cervical and vaginal lesions, lower genital tract infections, and hemorrhoids.

Bleeding during the second trimester before the fetus is potentially viable (14 to 24 weeks) is not benign. One-third of fetuses are ultimately lost when maternal bleeding occurs. Management is supportive and expectant because fetal rescue is not possible at this level of fetal immaturity. In the third trimester, vaginal bleeding is still associated with significant morbidity in approximately one-third of women; treatment includes consideration of urgent delivery.

Abruptio Placentae

Pathophysiology. Abruptio placentae is a separation of the placenta from the uterine wall and complicates roughly 1% of pregnancies. Small subclinical or marginal separations may go undetected until the placenta is examined at delivery and probably account for many of the other self-limited episodes of bleeding for which no diagnosis is made. In cases of nontraumatic abruptio placentae, spontaneous hemorrhage into the decidua basalis occurs, causing separation and compression of the adjacent placenta. Small amounts of bleeding may be asymptomatic and remain undetected until delivery. In other cases, the hematoma expands and extends the dissection. Bleeding may be concealed or may be clinically apparent if dissection occurs along the uterine wall and through the cervix. Placental separation may be acute or may be an indolent problem throughout late pregnancy.

Abruptio placentae is most clearly associated with maternal hypertension and preeclampsia. It is also more common with maternal age younger than 20 or older than 35 years of age, parity of three or more, unexplained infertility, history of smoking, thrombophilia, prior miscarriage, prior abruptio placentae, and cocaine use. Placental separation can also be associated with blunt trauma to the abdomen. In such cases, the cause appears to be shearing of a nonelastic placenta from the easily distorted elastic uterine wall at the time of traumatic impact. Intimate partner violence affects 4% to 8% of pregnancy and torso injuries are reported in 21.5% of cases placing the patient at risk for premature labor, abruption, uterine rupture, or fetal death. A significant etiology of trauma in pregnancy is motor vehicle accidents in which placental abruption may complication up to 40% of patients severely injured in a motor vehicle accident.[7]

Clinical Features. Vaginal bleeding occurs in 70% of patients with abruptio placentae. Blood is characteristically dark and the amount is often insignificant, although the mother may have hemodynamic evidence of blood loss. Uterine tenderness or pain is seen in approximately two-thirds of women; uterine irritability or contractions are seen in one-third. With significant placental separation, fetal distress occurs and the maternal coagulation cascade may be triggered, causing disseminated intravascular coagulation (DIC).

There is a wide spectrum of severity of symptoms and risk in placental separation. About 10% of women will present only with occult bleeding. Assessment is generally based on clinical features, coagulation parameters, and signs of fetal distress. Mild abruption is characterized by slight vaginal bleeding, little or no uterine irritability, absence of signs of fetal distress, and normal coagulation. As the separation becomes more extensive, it is associated with increased vaginal bleeding (or hidden maternal blood loss), increased uterine irritability with or without tetanic contractions, declining fibrinogen levels, evidence of fetal distress, and maternal tachycardia. In severe abruptio placentae (15% of cases), the uterus is tetanically contracted and very painful, maternal hypotension results from visible or concealed uterine blood loss, fibrinogen levels are less than 150 mg/dL, and fetal death can occur. Ultrasonography is insensitive in the diagnosis of abruptio placentae, often because the echogenicity of fresh blood is similar to that of the placenta. Symptomatic or even fetus-threatening abruption can occur in the presence of a normal sonogram.

Fetal distress and death occur in approximately 15% of patients with abruptio placentae by interruption of placental blood and oxygen flow. Risk of fetal death increases in proportion to the percentage of the placental surface involved and rapidity of separation. Fetal distress may result from the loss of placental blood flow, associated maternal hemorrhage (into the uterine cavity or externally), increased uterine tone, or resultant DIC. Maternal death can result, usually from coagulopathy or exsanguination. Fetomaternal transfusion can occur. Placental separation also predisposes the mother to amniotic fluid embolism.

Differential Diagnoses. The main alternative diagnosis in the woman with late-pregnancy bleeding is placenta previa, which is usually associated with painless, bright red bleeding and is excluded with ultrasonography. Lower genital tract or rectal lesions and blood-tinged cervical mucous plug are also considerations.

In the patient with abdominal pain but no vaginal bleeding, abruptio placentae with concealed hemorrhage must be distinguished from other causes of abdominal pain in later pregnancy—complications of preeclampsia, pyelonephritis, various liver diseases, gallbladder disease, appendicitis, and ovarian torsion. Uterine irritability caused by abruptio placentae can also be confused with early labor. If the patient has acute catastrophic hypotension, amniotic fluid embolus, with or without abruptio placentae, and uterine rupture must be considered.

Placenta Previa

Pathophysiology. Placenta previa, or implantation of the placenta over the cervical os, is the other major cause of bleeding episodes during the second half of pregnancy. The risk of placenta previa is increased with maternal age, smoking, multiparity, cesarean section, prior miscarriage or induced abortions, and preterm labor. Bleeding occurs when marginal placental vessels implanted in the lower uterine segment are torn, either as the lower uterine wall elongates or with cervical dilation near the time of delivery. Early bleeding episodes tend to be self-limited unless separation of the placental margin is aggravated by iatrogenic cervical probing or the onset of labor.

Clinical Features. Painless, fresh vaginal bleeding is the most common symptom of placenta previa. In approximately 20% of cases, some degree of uterine irritability is present, but this is generally minor. Vaginal examination usually reveals bright red blood from the cervical os. All patients with painless, second-trimester vaginal bleeding should be assumed to have placenta previa until proven otherwise. Digital or instrumental probing of the cervix should be avoided until the diagnosis is excluded via ultrasound because this can precipitate severe hemorrhage in a patient with asymptomatic or minimally symptomatic placenta previa. Speculum examination of the vagina and cervix should be limited to an atraumatic partial speculum insertion to identify whether the bleeding is coming from the cervical os (and a presumed placenta previa), hemorrhoids, or a vaginal lesion that might not require urgent management.

Most cases of placenta previa identified during the mid-trimester resolve by the time of delivery as the lower uterine segment elongates and the placenta no longer overlaps the cervical os. Central or total previa, which occurs in approximately 20% of cases, can, however, cause severe hemorrhage, with the risk of exsanguination for the fetus and mother.

Diagnostic Testing. Ultrasonography is the diagnostic procedure of choice for localization of the placenta and diagnosis of placenta previa. Accuracy is excellent, but visualization of the placenta and of the internal cervical os is required. The bladder should be emptied before examination for suspected placenta previa to avoid overdiagnosis of placenta previa. Transvaginal ultrasonography is safe and even more accurate for visualization of the relationships between the placenta and internal os.

Management. Patients who experience vaginal bleeding during late pregnancy require immediate obstetric consultation and arrangements for safe transfer to an appropriate obstetric facility. Initial management consists of maternal stabilization, with establishment of two large-bore intravenous (IV) lines and fluid resuscitation, as well as continuous fetal monitoring, if available. A baseline hemoglobin level should be determined, and blood should be sent for type and crossmatch. Baseline coagulation studies, including platelet count, prothrombin time, and partial thromboplastin time, should be performed, and the fibrinogen level and presence of fibrin split products should be determined. The normal fibrinogen level in pregnancy is 400 to 450 mg/dL; values below 300 mg/dL indicate significant consumption of coagulation factors.

Blood loss requiring transfusion can occur in patients with placenta previa or abruptio placentae. Fresh-frozen plasma or fresh whole blood may be needed because of the potential for a coagulopathy. Fetomaternal hemorrhage can occur with abruption. If the Rh-negative patient has not yet received her routine Rh immune globulin prophylaxis at 28 weeks, 300 μg of Rh immune globulin should be administered within 72 hours. Transfer to the obstetric unit should be expedited if the patient is stable, or it should be done after initiation of resuscitation if she is unstable. If transfer to another hospital is required, a high-risk transfer team should be used if bleeding is significant or the fetus is in distress. Assessment is best accomplished by obstetricians who are

accustomed to the evaluation of late-pregnancy complications and who can perform an emergent cesarean section, if needed.

In the obstetrics unit, fetal monitoring is continued. Ultrasonography is used primarily to locate the placenta and diagnose placenta previa, but it may not be reliable in confirming the diagnosis of abruptio placentae. On occasion, subplacental hemorrhages of abruptio placentae can be seen, and changes in size of the collection can be monitored. If evidence of placenta previa is absent or equivocal, a vaginal examination is performed in the delivery suite, where an emergency cesarean section can be performed if uncontrolled bleeding is encountered.

Patients who have significant abruptio placentae may require early delivery—vaginal or surgical, depending on fetal status. If placenta previa is diagnosed or if abruptio placentae is considered mild, the patient is admitted for close monitoring. The goal is to support the patient, ideally until fetal maturity is demonstrated and a successful delivery can be accomplished.

Pregnancy-Induced Hypertension (Preeclampsia and Eclampsia)

KEY CONCEPTS

- Gestational hypertension occurs during pregnancy, resolves during the postpartum period, and is recognized by a new blood pressure reading of 140/90 mm Hg or higher.
- Preeclampsia is gestational hypertension after 20 weeks gestational age with proteinuria (>300 mg/24 hr) or signs of end-organ damage; eclampsia is the occurrence of seizures in a patient with signs of preeclampsia.
- The HELLP syndrome is a particularly severe form of preeclampsia characterized by ***h***emolysis, ***e***levated ***l***iver enzyme levels (ALT and AST > 70 U/L), and ***l***ow ***p***latelet count (<100,000/mL).
- Because progression of preeclampsia to eclampsia is unpredictable and can occur rapidly, blood pressure control in the pregnant patient is of utmost importance.
- Magnesium sulfate has little antihypertensive effect but is the most effective anticonvulsant in the setting of eclampsia, preventing recurrent seizures while maintaining uterine and fetal blood flow.

Foundations

Hypertension is observed in up to 8% of pregnancies and is generally divided into several categories[14]:

- Gestational hypertension occurs during pregnancy, resolves during the postpartum period, and is recognized by a new blood pressure reading of 140/90 mm Hg or higher.
- Preeclampsia is gestational hypertension with proteinuria (>300 mg/24 hr).
- Eclampsia is the occurrence of seizures in a patient with signs of preeclampsia. Progression of preeclampsia to eclampsia is unpredictable and can occur rapidly.
- Pregnancy-aggravated hypertension is chronic hypertension with superimposed preeclampsia or eclampsia.
- Chronic or coincidental hypertension is present before pregnancy or persists for more than 6 weeks postpartum.

Approximately 2% to 7% of pregnancies are complicated by pregnancy-induced hypertension. The incidence of actual eclampsia has progressively declined but is still one of the major causes of maternal mortality. The risk of pregnancy-induced hypertension is greatest in women younger than 20 years, primigravidas and those with twin or molar pregnancies, those with hypercholesterolemia, pregestational diabetes, or obesity, or those with a family history of pregnancy-induced hypertension.

Pathophysiology

Gestational hypertension or preeclampsia is a vasospastic disease of unknown cause unique to pregnant women. Vasospasm, ischemia, and thrombosis associated with preeclamptic changes cause injury to maternal organs, placental infarction and abruption, and fetal death from hypoxia and prematurity. The cause of eclampsia is unknown, but recent studies have centered on vascular responsiveness to endogenous vasopressors in the preeclamptic woman. Vascular responsiveness is normally depressed during pregnancy, which is a high-output, low-resistance state. Gestational hypertension is characterized by an even greater elevation in cardiac output, followed by an abnormally high peripheral resistance as clinical manifestations of the disease develop. In patients with preeclampsia, the cardiac output eventually drops as peripheral resistance rises. The cause of these changes is not known, but endothelial dysfunction is purported to release vasoactive mediators and result in vasoconstriction. Antiplatelet agents during pregnancy have been reported to reduce the risk of development of preeclampsia, supporting the premise of an imbalance between levels of thromboxane and prostacyclin in preeclampsia.[14]

The vasospastic effects of gestational hypertension and preeclampsia are protean. The intravascular volume is lower than in normal pregnancy, central venous pressures are normal, and capillary wedge pressures are variable. Liver effects are believed to be due to hepatocellular necrosis and edema resulting from vasospasm. Renal injury causes proteinuria and may result in decreased glomerular filtration. Microangiopathic hemolysis may result from vasospasm, causing thrombocytopenia. Central nervous system (CNS) effects include microvascular thrombosis and hemorrhage, as well as focal edema and hyperemia.

Clinical Features

Signs and Symptoms. The patient with gestational hypertension has mild systolic or diastolic blood pressure elevation, no proteinuria, and no evidence of organ damage. Mental status assessment, testing of reflexes, abdominal examination, liver function studies, and coagulation studies yield normal results. Preeclampsia is associated with kidney changes and, in severe cases, other end-organ symptoms. Edema is often difficult to assess because pregnancy is normally associated with excess extracellular fluid and dependent edema, and it is no longer used as a criterion for preeclampsia. Proteinuria (300 mg/24 hr) is variable at any given time and may not be detectable in a random urine specimen.

In cases of severe preeclampsia, the diastolic blood pressure can exceed 110 mm Hg, proteinuria is more severe, and there is evidence of vasospastic effects in various end organs. CNS effects commonly include headache or visual disturbances. In preeclampsia, the patient will become hyperreflexive before seizures develop. Thrombocytopenia may be present, liver function test findings may be elevated, and the liver is often tender. Renal dysfunction may be indicated by oliguria and elevated creatinine levels in addition to proteinuria.

Complications

The HELLP syndrome, a particularly severe form of preeclampsia that develops in 5% to 10% of women who have preeclamptic symptoms, is characterized by ***h***emolysis, ***e***levated ***l***iver enzyme levels (alanine transaminase [ALT] and aspartate transaminase [AST] > 70 U/L), and ***l***ow ***p***latelet count (<100,000/mL). Prothrombin time, partial thromboplastin time, and fibrinogen are normal, and blood studies reveal microangiopathic hemolytic anemia. Other complications of preeclampsia include spontaneous hepatic and splenic hemorrhage and abruptio placentae.

The most dangerous complication is eclampsia, which is the occurrence of seizures or coma in the setting of signs and symptoms of

preeclampsia. Warning signs for the development of eclampsia include headache, nausea and vomiting, and visual disturbances. Elevated total leukocyte count, creatinine, and AST levels are also predictive of increased morbidity for the patient with severe preeclampsia. Particularly in early eclampsia before 32 weeks of gestation, seizures may develop abruptly, and hypertension may not be associated with edema or proteinuria. In postpartum women who have eclampsia, more than half (55%) have not been previously diagnosed with preeclampsia, and patients may present with headache, vision changes, elevated blood pressure, and seizures, often within 48 hours of delivery, but in up to 6 weeks after delivery and in rare cases up to 12 weeks postpartum.[15] After 48 hours postpartum and without predelivery signs of preeclampsia, other diagnoses, such as intracranial hemorrhage, should be considered. Maternal complications of eclampsia include permanent CNS damage from recurrent seizures or intracranial bleeding, renal insufficiency, and death.

The maternal mortality rate from eclampsia has been reduced to less than 1% with modern management. Perinatal mortality has also decreased, although it remains at 4% to 8%.[14] Causes of neonatal death include placental infarcts, intrauterine growth retardation, and abruptio placentae. In addition, fetal hypoxia from maternal seizures and the complications of premature delivery contribute significantly to fetal morbidity and mortality.

Differential Diagnoses

Peripheral edema is common in normal pregnancy, and it may be difficult to differentiate normal edema from that of early preeclampsia. Differentiation of gestational hypertension from preexistent hypertension is often impossible if no record of normal blood pressure is available. Seizures during pregnancy may be due to epilepsy as well as other intracranial catastrophes, such as thrombosis or hemorrhage.

Diagnostic Testing

The patient who has severe preeclampsia should have an IV line and fetal monitoring initiated. Blood testing includes a complete blood cell count, renal function studies, liver function tests, platelet count, coagulation profile, and a baseline magnesium level. The serum glucose concentration is determined in patients with seizures.

If a history of preeclampsia is not obtained or the symptoms are refractory to magnesium sulfate therapy, a computed tomography (CT) scan of the head is performed to exclude cerebral venous thrombosis or an intracranial hemorrhage, either of which can occur in pregnancy—with or without pregnancy-induced hypertension—and may require specific treatment. CT scan abnormalities can be seen in 50% of patients with eclampsia. Patchy hemorrhage and microinfarcts of the cortex are characteristic and may be due to loss of cerebral autoregulation in patients with severe pregnancy-related hypertension. Diffuse cerebral edema can also be seen.

Management

Mild Preeclampsia. The management of patients with mild preeclampsia includes documentation of blood pressure, reflexes, weight, and blood testing to ensure normal end-organ function. Accurate determination of gestational age by ultrasonography is needed to allow optimal management if symptoms progress. Limitation of physical activities, including bed rest, is the only demonstrated means of reducing blood pressure and allowing the pregnancy to be sustained longer. Definitive treatment is delivery of the fetus, although expectant management is standard in women at less than 34 weeks of gestation. Arrangement for close follow-up is important for patients who are not hospitalized.

Severe Preeclampsia. Hospitalization is recommended for patients with sustained hypertension above 140/90 mm Hg and signs of severe preeclampsia. Baseline laboratory studies are recommended to identify end-organ effects in the liver, kidney, and hematologic systems. Both diuresis and antihypertensive therapy have been remarkably unsuccessful in improving fetal outcome or prolonging pregnancy. However, admission does allow the obstetrician to assess fetal age and well-being accurately, maternal organ function, and effect of bed rest on blood pressure before the optimal timing of delivery is decided.

Fulminant or severe preeclampsia, with marked blood pressure elevation (≥160/110 mm Hg) associated with epigastric or liver tenderness, visual disturbance, or severe headache, is managed in the same way as eclampsia (Box 173.4). The goal is prevention of seizures and permanent damage to maternal organs. Magnesium sulfate is given for seizure prophylaxis.

Seizures and coma are the hallmarks of eclampsia, the ultimate consequence of preeclampsia. As in all seizure patients, hypoglycemia, drug overdose, and other causes of seizures should be excluded with appropriate tests. Eclamptic seizures are controlled in almost all patients by administering magnesium sulfate, although the mechanism of action remains elusive. Magnesium has little antihypertensive effect but is the most effective anticonvulsant, preventing recurrent seizures while maintaining uterine and fetal blood flow. The goals of magnesium sulfate therapy are to terminate ongoing seizures and prevent recurrence. An IV loading dose of 4 to 6 g magnesium given over 15 to 20 minutes, followed by 2 g/hr IV, is recommended. Magnesium administration should be accompanied by clinical observation for loss of reflexes (which occurs at ≈10 mg/dL) or respiratory depression (which occurs at levels of 12 mg/dL, although actual serum magnesium levels are rarely monitored). The infusion should be stopped if signs of hypermagnesemia (loss of reflexes or respiratory depression as manifest by a decrease in the respiratory rate or an increase in end tidal CO_2 are seen. IV calcium gluconate, 1 g given slowly, will reverse the adverse effects of hypermagnesemia.

Despite ongoing controversy, the familiarity with magnesium sulfate and its physiologic advantages to the fetus, wide margin of safety, and high success rate in controlling seizures make it the first-line drug in patients with eclampsia. If seizures persist after the recommended doses of magnesium sulfate have been administered, the following agents may be used in the treatment of eclampsia in conjunction with

BOX 173.4 Management of Eclampsia and Severe Preeclampsia

- Control seizures with magnesium sulfate, 4–6 g given over 15–20 minutes, followed by 2 g/hr IV.
- Control hypertension after seizure control if diastolic blood pressure >105 mm Hg; hydralazine (5–10 mg IV push, repeat q 2-4h) or labetalol (20 mg IV bolus, repeat q10 min PRN up to 300 mg/total dose)
- Obtain initial laboratory studies to assess organ injury:
  - Complete blood count and platelet count
  - Liver function tests
  - Blood urea nitrogen, creatinine
- Monitor urine output; maintain at >25 mL/hr.
- Limit intravenous fluid administration unless significant losses occur.
- Avoid diuretics and hyperosmotic agents.
- Perform a computed tomography scan of the head if consciousness is decreased or seizures persist, lateralizing signs are present, or there are other concerns.
- Initiate steps to delivery.

Adapted from: Pritchard JA, Cunningham FG, Pritchard SA. The Parkland Memorial Hospital protocol for treatment of eclampsia: evaluation of 245 cases. *Am J Obstet Gynecol.* 1984;148:951-963.

obstetric consultation: lorazepam (2–4 mg IV for one dose, may repeat ×1 after 10–15 min), phenytoin or fosphenytoin (15–20 mg/kg IV ×1, may repeat at 10 mg/kg after 20 min), or levetiracetam (20–60 mg/kg IV, may repeat in 12 hours). In addition, a careful search for other causes of seizures (e.g., hypoglycemia and intracranial hemorrhage) should be instituted based on history and examination of the patient.[16]

Although magnesium sulfate is not a direct antihypertensive, the hypertension associated with eclampsia is often controlled adequately by stoppage of the seizures. Rapid lowering of blood pressure can result in uterine hypoperfusion, so specific antihypertensive treatment is initiated only if the diastolic blood pressure remains above 105 mm Hg or the systolic blood pressure remains above 160 mm Hg after control of seizures.[17] The goal is to lower maternal blood pressure by 15% to 20% with a systolic goal of 140 to 150 mm Hg and a diastolic goal of 90 to 100 mm Hg. Many patients do not require specific antihypertensive treatment after treatment with magnesium sulfate. The antihypertensives used most often by obstetricians are hydralazine (5–10 mg IV push, repeat q 2-4h) or labetalol (20 mg IV bolus, may repeat q10 min PRN up to 300 mg/total dose). Rapid-release nifedipine (10 mg PO) can be used if IV access is not immediately available. Other antihypertensive agents have not been well studied in this population because there are specific risks to uncontrolled lowering of blood pressure and loss of uteroplacental blood flow.

Although total body water in the eclamptic patient is excessive, intravascular volume is contracted, and the eclamptic patient is sensitive to further volume changes. Hypovolemia results in decreased uterine perfusion. Thus, diuretics and hyperosmotic agents should be avoided in these patients. Invasive monitoring has demonstrated that vasospasm is not reversed with IV fluid administration. Rather, excessive IV fluids increase extravascular fluid stores that are difficult to mobilize postpartum, resulting in a higher incidence of pulmonary edema in patients treated aggressively with fluid therapy. Invasive pulmonary artery pressure monitoring may be required for accurate fluid management in the eclamptic patient.

Amniotic Fluid Embolus

KEY CONCEPTS

- Amniotic fluid embolus should be suspected during the second or third trimester of pregnancy, particularly in the setting of uterine manipulation or contraction, when a patient experiences sudden onset of hypotension, hypoxia, and coagulopathy.
- Treatment of amniotic fluid embolus consists of supplemental oxygenation and ventilation, aggressive fluid resuscitation, inotropic cardiovascular support, and anticipation and management of consumptive coagulopathy.

Foundations

Amniotic fluid embolus is the release of amniotic fluid into the maternal circulation. This occurs during intense uterine contractions or uterine manipulation at areas of placental separation from the uterine decidua basalis (abruptio placentae) and triggers a rapidly fatal, anaphylactoid-type maternal response. Although amniotic fluid embolus usually occurs during labor, with the maternal mortality rate at 25% or higher, it can also occur after induced abortions, miscarriages, and spontaneously during the second and third trimesters. Amniotic fluid embolus can also occur after amniocentesis or in association with abruptio placentae after abdominal trauma. Although it is a rare syndrome, amniotic fluid embolus is the leading cause of cardiovascular collapse during labor.

Clinical Features

Amniotic fluid embolus should be suspected during the second or third trimester of pregnancy, particularly in the setting of uterine manipulation or contraction, when a patient experiences sudden hypotension, hypoxia, and coagulopathy. The embolization of amniotic fluid and the particulate matter suspended in it triggers a profound immunologic response when it enters the maternal circulation. The list of proposed mediators is extensive and includes histamine, endothelin, and leukotrienes. In survivors, DIC, acute respiratory distress syndrome, and left ventricular dysfunction develop. An initial seizure is seen in approximately 20% of patients. Bleeding diathesis may be the initial sign in some women, and DIC occurs in approximately 50% of cases.

Differential Diagnoses

Catastrophic pulmonary embolus, drug-induced anaphylaxis, and septic shock must be considered in the differential diagnosis. Seizures occur in patients with eclampsia, but hypertension rather than cardiovascular collapse is usually observed in that condition. Coagulopathy may be seen in patients with preeclampsia (HELLP syndrome), abruptio placentae, or other chronic coagulopathies seen in the nonpregnant patient.

Diagnostic Testing

When amniotic fluid embolus is suspected, a complete blood cell count, coagulation studies, arterial blood gas analysis, and chest radiograph are obtained. Urine output is monitored after urinary catheter placement. The diagnosis is usually made with certainty only at autopsy, with the finding of fetal hairs, squamous cells, and debris in the maternal circulation. Because squamous epithelial cells can be seen normally in the maternal pulmonary circulation, the typical clinical syndrome is also required for diagnosis.

Management

Amniotic fluid embolus is uncommon, so treatment recommendations are anecdotal and based on animal studies. The most helpful modalities appear to be high-flow oxygen, support of ventilation and oxygenation with intubation, aggressive fluid resuscitation, inotropic cardiovascular support, and anticipation and management of consumptive coagulopathy. Treatment usually requires invasive hemodynamic monitoring in an intensive care unit.

Rh (Anti-D) Immunization in Pregnancy

KEY CONCEPTS

- Rh immunization occurs when an Rh-negative woman is exposed to Rh-positive fetal blood. To prevent this, a dose of 50 μg of Rh immune globulin can be used if the patient less than 12 weeks of gestation. After 12 weeks, a 300-μg dose is recommended.

Rh immunization occurs when an Rh-negative woman is exposed to Rh-positive fetal blood. Sensitization occurs in up to 15% of Rh-negative women carrying Rh-positive fetuses. Small numbers of fetal cells enter the maternal circulation spontaneously throughout pregnancy, and the maternal immune system is triggered by as little as 0.1 mL of fetal-maternal hemorrhage. Fetal-maternal hemorrhage occurs in 3% to 11% of women with threatened abortions in the first trimester and approximately 45% during birth in the third trimester. To prevent this, anti-D immune globulin (RhoGAM) is routinely administered to Rh-negative mothers—if the father is Rh positive or his status is unknown—at approximately the 28th week of gestation to protect

the mother from spontaneous sensitization, which occurs during the third trimester, and at the time of delivery. Transplacental hemorrhage can also occur during uterine manipulation, threatened miscarriage (even without fetal loss), spontaneous miscarriage, surgery for ectopic pregnancy, and amniocentesis, although the risk is not clear. Anti-D immune globulin should be administered when these events occur. A dose of 50 μg can be used if the patient is at less than 12 weeks of gestation, although many pharmacies carry only the 300-μg dose, which can also be given. After 12 weeks, a 300-μg dose should be given. The half-life of immune globulin is 24 days, and it needs to be administered within 72 hours of a sensitization event to prevent antibody development.

The Kleihauer-Betke test of maternal blood has been used to detect fetal cells in the maternal circulation. Unfortunately, the test is difficult to perform, not immediately available in most emergency laboratories, and only sensitive enough to detect 5 mL of fetal cells in the maternal circulation. Because only 0.1 mL of fetal cells is required to sensitize the mother, routine immune globulin administration has been recommended in situations likely to result in sensitization. Patients with third-trimester bleeding are not at increased risk of sensitization compared with patients with normal pregnancy. Thus, RhoGAM should be administered only if the patient did not receive her prophylactic dose at 28 weeks. In cases of blunt trauma to the uterus, the Kleihauer-Betke test should be ordered to detect the rare, large fetal transfusions that may require specific fetal blood therapy or administration of additional immune globulin to the mother. The standard dose (300 μg) is sufficient to prevent maternal immunization for fetal transfusions of up to 15 mL of red blood cells or 30 mL of whole blood.

MEDICAL AND SURGICAL PROBLEMS IN THE PREGNANT PATIENT

Clinicians should be aware of a variety of illnesses, related and unrelated to pregnancy, that may have altered symptoms, risk, and treatment in the pregnant patient (Tables 173.2 and 173.3). See also Chapter 174.

Abdominal Pain

KEY CONCEPTS

- Appendicitis is the most common surgical emergency in pregnancy. Clinical presentations may be atypical, leading to a misdiagnosis rate of 30% to 35% in pregnant patients. Right lower quadrant pain is the most common finding, especially early in pregnancy. Ultrasound, CT, and MRI are useful for the diagnosis.
- Cholelithiasis presents with similar symptoms to those in nonpregnant women and is similarly diagnosed through ultrasound. Surgery, if required, is optimally performed during the second trimester.
- During pregnancy, albumin levels decrease while alkaline phosphatase levels may increase up to double; amylase levels may also be slightly elevated.
- Hepatitis is the most common cause of liver disease in pregnancy; hepatitis E has increased maternal mortality and rate of fetal loss.
- Acute fatty liver of pregnancy is a rare disorder of the third trimester that can result in hepatic failure, complicated labor, and fetal mortality. Coagulopathy, jaundice, seizures, DIC, and hepatic encephalopathy may also result.
- Intrahepatic cholestasis of pregnancy typically presents with generalized pruritus and mild jaundice. Resolution occurs with delivery. Women are at increased risk for preterm delivery, meconium passage, and intrauterine fetal demise.

TABLE 173.2 Differential Diagnosis of Abdominal Pain in Pregnancy

Diagnosis	Gestational Age	Signs/Symptoms/ Diagnostic Testing
Gynecologic		
Miscarriage	<20 wk; 80% <12 wk	Vaginal bleeding, pelvic pain, ultrasonography to confirm location, no fetal activity at 8 weeks, decreasing hCG level
Septic abortion	<20 wk	Fever, uterine tenderness
Ectopic pregnancy	<14 wk	Pelvic pain, hypotension
Corpus luteum cyst	<12 wk	Sudden focal peritoneal pain; no fever
Ovarian torsion	Especially <24 wk	Ischemic pain, episodic
Pelvic inflammatory disease	<12 wk	Very rare, pelvic pain, vaginal discharge
Chorioamnionitis	>16 wk	Tender uterus, fever, amniocentesis reveals white blood cells
Abruptio placentae	>16 wk	Focal uterine tenderness, fetal distress, variable bleeding
Preeclampsia	>20 wk	Hypertension, proteinuria, edema, right upper quadrant pain
Nongynecologic		
Appendicitis	Throughout	Guarding may be less prominent; location changes
Cholecystitis	Throughout	Confirm with ultrasonography
Hepatitis	Throughout	Confirm with liver function tests
Pyelonephritis	Throughout	Flank pain, fever, positive catheterized urinalysis

Appendicitis

Foundations. Appendicitis is the most common surgical emergency in pregnant patients. The incidence of appendicitis in pregnant patients is the same as that in nonpregnant patients, but delays in diagnosis contribute to an increased rate of perforation, which may result in fetal mortality and maternal morbidity. There is also an increased rate of other complications of appendicitis in pregnancy. A large, population-based study found an almost twofold increase in sepsis and septic shock, transfusion, pneumonia, bowel obstruction, postoperative infection, and length of stay longer than 3 days.[18] During the first half of pregnancy, diagnostic findings are usually similar to those in the nonpregnant woman, but the clinical picture becomes more atypical during the second half of pregnancy.

Traditionally, the appendix was thought to be displaced counterclockwise out of the right lower quadrant after the third month of gestation, with its ultimate location deep in the right upper quadrant, superior to the iliac crest (Fig. 173.8). However, even in the third trimester, the location changes from the right lower quadrant in less than 25% of pregnant patients. Displacement of the abdominal wall away from the abdominal viscera can result in difficulty in palpation of organs and loss of signs of parietal peritoneal irritation. The physiologic increase in white blood cell count and erythrocyte sedimentation rate in pregnancy should also be considered in the evaluation of the patient with possible appendicitis because these may confuse the overall clinical picture.

TABLE 173.3 Differential Diagnosis of Common Symptoms in Pregnancy

Diagnosis	Gestational Age	Signs, Symptoms, Diagnostic Testing
Vaginal Bleeding		
Miscarriage	<20 wk	Vaginal bleeding, pelvic pain, ultrasonography to confirm location, no fetal activity at 8 weeks, decreasing hCG level
Ectopic pregnancy	<14 wk	Pelvic pain, hypotension, evaluate with ultrasonography
Molar pregnancy	12-24 wk	No fetal heart tones, characteristic sonogram showing snow storm appearance
Cervical lesions	Throughout	Perineal and vaginal inspection
Vaginitis, cervicitis	Throughout	White blood cells on wet mount, with culture
Placenta previa	>16 wk	Ultrasonography to localize placenta
Abruptio placentae	>16 wk	Focal uterine tenderness, fetal distress, variable bleeding
Seizure		
Eclampsia	>24 wk	Blood pressure > 140/90 mm Hg; usually history of PIH, edema, proteinuria
Amniotic fluid embolus	>12 wk	Hypotension, respiratory distress, DIC
Epilepsy	Throughout	History; lack of PIH findings
Dyspnea		
Pulmonary embolus	Especially 6 wk prepartum and postpartum	Usual diagnostic studies including use of CT, Ventilation/perfusion studies, and extremity doppler ultrasound
Dyspnea of pregnancy	>24 wk	Exclude other causes
Pulmonary infection	Throughout	Examination; radiography
Amniotic fluid embolus	>12 wk	Uterine manipulation, bleeding diathesis, hypotension
Jaundice		
Cholestasis of pregnancy	>24 wk	Well patient; itching and jaundice
Hepatitis	Throughout	Abnormal liver function test results
Acute fatty liver	>24 wk	Rapid liver failure; coma, seizures, hypoglycemia
Bleeding Diathesis		
Eclampsia	>24 wk	Blood pressure > 140/90 mm Hg; proteinuria, edema, HELLP syndrome
Amniotic fluid embolus	>12 wk	Respiratory distress, cardiovascular collapse
Abruptio placentae	>20 wk	Uterine tenderness; vaginal bleeding; fetal distress

DIC, Disseminated intravascular coagulation; *hCG,* human chorionic gonadotropin; *HELLP,* hemolysis, elevated liver enzyme levels, low platelets; *PIH,* pregnancy-induced hypertension.

Clinical Features. The gastrointestinal symptoms of appendicitis, such as anorexia, nausea, and vomiting, mimic those of pregnancy, particularly during the first trimester, making such symptoms relatively nonspecific. Right-sided abdominal pain is the most constant finding, although this is less reliable later in pregnancy. Peritoneal signs are also most common during the first trimester. The absence of fever, leukocytosis, or tachycardia has been reported. The lack of these clinical findings in pregnant patients with appendicitis may be the result of a blunted inflammatory response caused by elevated maternal levels of pregnancy-related steroids. Pyuria without bacteriuria may be seen

These confounding factors contribute to the misdiagnosis rate for appendicitis of 30% to 35% overall in pregnancy, with a 40% to 50% rate of removal of normal appendix during the third trimester. In contrast to the relative safety of performing an exploratory laparotomy or laparoscopy during pregnancy, the risk of fetal loss and maternal morbidity from failure to diagnose appendicitis and perforation is considerable, so clinical vigilance is required, even in the absence of classic signs. In one study, in the setting of acute appendicitis, the relative risk of pregnancy loss at less than 20 weeks was 5.3, and was 6.0 at less than 24 weeks.[19] In later pregnancy, when peritoneal signs are often absent and the uterus obscures normal physical findings, diagnosis is frequently delayed, and the perforation rate may approach 25%.

Differential Diagnoses. Pyelonephritis, cholecystitis, nephrolithiasis, and pregnancy-related diseases such as ectopic pregnancy, round ligament pain, broad ligament pain, corpus luteum cyst leakage, and ovarian torsion should be considered in the patient who has right-sided abdominal pain. Pyelonephritis is the most common condition that is confused with appendicitis. During its migration, the appendix is located very near the kidney, resulting in a high incidence of sterile pyuria and flank pain (see Fig. 173.8). In cases of appendicitis, unless there is coincident urinary tract infection, the urine is free of bacteria, a feature distinguishing it from pyelonephritis. Salpingitis, another common misdiagnosis, is very rare in pregnancy, although it can occur before 12 weeks of gestation.

Diagnostic Testing. Leukocytosis is common in pregnant patients with appendicitis, although it is rarely high enough to distinguish it from the physiologic leukocytosis of pregnancy. A leukocytosis greater than 18,000 makes the diagnosis of appendicitis 10 times more likely.[19] Pyuria in a catheterized urine specimen suggests pyelonephritis, but may be seen in 20% of patients with appendicitis,[20] whereas bacteriuria is uncommon in appendicitis.

Ultrasonography with a graded compression technique may reveal a non-compressible tubular structure in the right lower quadrant consistent with appendicitis. Studies of the diagnostic value of

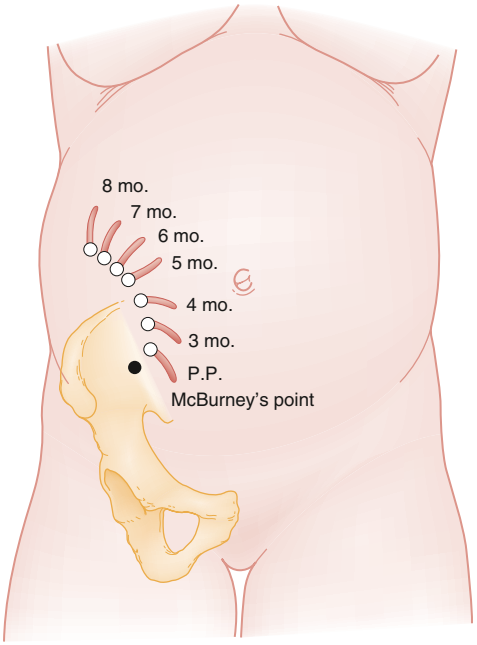

Fig. 173.8 Locations of the appendix during succeeding months of pregnancy. In planning an operation, it is better to make the abdominal incision over the point of maximal tenderness unless there is great disparity between that point and the theoretic location of the appendix. *P.P.,* postpartum. (From: Gabbe SG, Niebyl JR, Simpson JL, Galan HL. *Obstetrics: Normal and Problem Pregnancies.* New York: Churchill Livingstone; 2007.)

ultrasonography in the diagnosis of appendicitis are limited but have suggested that it has a high positive predictive value but a low negative predictive value.[21] Abdominal ultrasonography is recommended as the first imaging modality, followed by CT when ultrasound findings are inconclusive. Surgical, obstetric, and radiologic society guidelines agree that magnetic resonance imaging (MRI) is also useful in the evaluation of pregnant patients with suspected appendicitis (see Chapter 79).[21] Otherwise, laparoscopy or laparotomy is the diagnostic procedure of choice in the pregnant patient thought to have appendicitis. Early exploration is highly encouraged in pregnant patients because of the variability of clinical signs and increased fetal risk if diagnosis is delayed.

Management. The pregnant patient with suspected appendicitis should be hospitalized after consultation with a surgeon and obstetrician. Ultrasonography, MRI, or CT scan are diagnostic options. The patient should be kept on nothing by mouth (NPO) status, with IV fluid hydration to maintain intravascular volume. Although prompt surgery is required if the diagnosis is clear, in unclear cases the patient should undergo observation to allow for clarification of signs and symptoms. Patients undergoing observation are treated empirically with IV antibiotics, commonly piperacillin/tazobactam (3.375–4.5 g IV q6–8h) or ceftriaxone (2 g IV q24h) plus metronidazole (500 mg q8h).

Gallbladder Disease

Foundations

Cholelithiasis is present in approximately 5% of pregnant women and is the second most common non-obstetric surgical condition in pregnant patients. The natural history of asymptomatic cholelithiasis is believed to be similar to that in nonpregnant women, with less than 50% of patients with gallstones developing symptoms.

Changes in gallbladder kinetics are believed to be due to high pregnancy-related steroid levels. Progesterone decreases smooth muscle tone and induces gallbladder hypomotility and cholestasis, causing an increased risk of stone formation. In addition, pregnancy induces changes in bile composition and increased cholesterol secretion, thus increasing the incidence of cholesterol stone formation.

Clinical Features

The signs and symptoms of acute cholecystitis during pregnancy are the same as those in nonpregnant women. Epigastric or right upper quadrant pain and tenderness and nausea predominate. Leukocytosis must be interpreted carefully because of the normally increased white blood cell count seen in pregnancy. Likewise, a slightly elevated amylase level can be normal during pregnancy, and alkaline phosphatase, which is produced by the placenta, may be twice the nonpregnant level. A history of previous self-limited pain episodes associated with food intake suggests the diagnosis.

Differential Diagnoses

Pyelonephritis should be considered in the patient with right upper quadrant pain, with or without fever. During the third trimester, appendicitis can also be associated with right upper quadrant pain. Hepatitis and fatty liver infiltration occur in pregnancy; liver distention and inflammation associated with pregnancy-induced hypertension can also cause right upper quadrant pain. In addition, spontaneous intrahepatic bleeding can occur during late pregnancy, mimicking cholecystitis. Because of the potential for other serious diseases, diagnostic studies should be performed to verify a clinical diagnosis of symptomatic cholelithiasis and cholecystitis in pregnancy.

Diagnostic Testing

Ultrasonography is a reliable means of recognizing stones in the gallbladder, although it may not differentiate symptomatic from asymptomatic stones. In the patient with right upper quadrant pain, simultaneous sonographic evaluation of the liver is useful but technically difficult, particularly during the third trimester, when subcapsular liver hematomas and other intrinsic hepatocellular disease can occur but the liver may be obscured under the ribs.

Management and Disposition

The patient who has fever, leukocytosis, prolonged pain, or evidence of cholecystitis should be made NPO and given IV fluid hydration, adequate pain control, and broad-spectrum antibiotics. Some patients with uncomplicated cholecystitis can be managed medically. Patients with obstructive jaundice, gallstone pancreatitis, sepsis or failure to respond to conservative management are candidates for surgery (optimally, during the second trimester, if possible).[22] Approximately 40% of patients presenting with symptomatic cholelithiasis intrapartum require cholecystectomy during pregnancy, and recent evidence suggests that operative management compared to nonoperative management from uncomplicated disease has a reduced overall morbidity including reduced maternal and fetal complications.[22]

Discharge should be considered only for patients with uncomplicated and sonographically proven cholelithiasis who are not otherwise candidates for admission after consultation with an obstetrician. Pregnant patients with symptomatic cholelithiasis have a high rate of symptomatic relapse and increased severity of disease with each relapse. Early follow-up should be arranged, and the patient should be given careful instructions to return if she experiences fever, vomiting, or persistent pain.

Liver Disorders

Foundations

Pregnancy is associated with several unique liver abnormalities in addition to more usual hepatic diseases. Liver metabolism increases during

TABLE 173.4 Lab Abnormalities in Select Complications of Pregnancy

	WBC	Plt	BUN/Cr	AST/ALT	Alk Phos	PT/PTT	Fibrinogen	Bili	Other
Normal pregnancy	Mild ↑	nl	nl	nl	↑ (up to double)	nl	Nl	nl	nl LDH ↓albumin ↑amylase
Hepatitis				↑↑↑	Mild ↑	↑ (severe)		↑	Obtain: Acute hep panel APAP level

pregnancy, but hepatic blood flow is unchanged, and little change occurs in liver function. Bilirubin, transaminase, and lactate dehydrogenase levels and prothrombin times are unchanged from those in the nonpregnant state. Albumin levels decrease secondary to an increase in maternal circulating plasma volume. Alkaline phosphatase levels may be up to double the nonpregnant values, and amylase levels may also be slightly elevated.

Hepatitis

Hepatitis is the most common cause of liver disease in pregnancy, accounting for 40% of cases of jaundice during pregnancy. Management and treatment are supportive and unchanged from those for nonpregnant patients. Hepatitis E is reported to have a more aggressive course in pregnancy, with an increased maternal mortality rate and rate of fetal loss. Maintenance of adequate nutrition is a priority. Vertical transmission of hepatitis B can occur if the disease is not recognized. Pregnant women should be vaccinated for hepatitis B. Prophylaxis should be administered to the newborn born to chronically infected mothers with both the hepatitis B vaccine (10 or 20 micrograms) as well as hepatitis B immune globulin (HBIG) given in 0.5 mL dose at birth. If no hepatitis vaccine is given, additional doses of HBIG are required at 3 months and 6 months.

Acute Fatty Liver

Pathophysiology. Acute fatty liver of pregnancy is a disorder of the third trimester that can result in hepatic failure, complicated labor, and fetal mortality. The disease is rare, occurring most often in primiparous patients and patients with twin gestations.

The cause of acute fatty liver of pregnancy is unknown, although studies have suggested that a deficiency in the fetus's fatty acid metabolism leads to an accumulation of hepatotoxic metabolites in the maternal circulation. On microscopic examination, fatty infiltration of the hepatocytes with edema and vacuolization can be seen, but there is no necrosis or inflammation. Liver function returns to normal after delivery if the patient can be supported through the acute phase. Although up to 50% of patients have signs of preeclampsia, the two are not clearly related. The diagnosis must be differentiated from viral hepatitis and HELLP syndrome, which have similar disease presentations and laboratory findings but, again, are not clearly related.

Clinical Features. Nausea and vomiting associated with malaise or jaundice during the third trimester should trigger consideration of a diagnosis of acute fatty liver. The right upper quadrant or epigastrium is usually tender. The disease may progress to coagulopathy, jaundice, seizures, DIC, and hepatic encephalopathy. Hemorrhage from coagulopathy is the most common complication at delivery. The diagnosis is often delayed secondary to the multiple differential considerations.

Differential Diagnoses. Liver tenderness and coagulopathy usually suggest preeclampsia during the third trimester. Jaundice and increases in the ALT level are distinguishing features because they are unusual in cases of liver disease associated with pregnancy-induced hypertension. Similarly, rapid progression of hepatic failure, hypoglycemia, and coagulopathy are unlikely in cases of preeclampsia. Elevations in the creatinine level are more common in acute fatty liver of pregnancy. The patient with viral hepatitis is likely to have more marked elevations in transaminase levels. Drug-induced hepatic failure should be excluded by history and toxicologic screening for acetaminophen and other toxins, if appropriate. Cholecystitis may be distinguished by ultrasound examination but may also be characterized by right upper quadrant pain; it is not associated with coagulopathy or progressive liver failure (Table 173.4).

Diagnostic Testing. Typically, leukocytosis is present, the platelet count and fibrinogen level are low, prothrombin and partial thromboplastin times are elevated, and fibrin split products are present. Elevated bilirubin levels (a late finding), AST and ALT levels, and uric acid levels may be seen. Hypoglycemia and dehydration are frequently present. Additionally, elevated BUN and serum creatinine levels with associated oliguria may be seen. In contrast to Reye syndrome, the serum ammonia level is only mildly elevated. CT scan and liver ultrasonography may be normal, so liver biopsy is used to make the definitive diagnosis.

Management. The patient with acute fatty liver of pregnancy may require acute stabilization for seizures or coma. Hypoglycemia may occur, which is rapidly corrected with dextrose. Coagulation parameters should be assessed. Fluid resuscitation and replacement of clotting factors may be required, and the patient should be admitted to an obstetric service capable of managing this serious disease. The diagnosis is usually made with liver biopsy if the disease has not progressed to severe coagulopathy. Rapid delivery is usually advisable when the diagnosis has been established. Fresh-frozen plasma, platelet transfusions, and glucose may be needed to sustain the patient until delivery can be accomplished.

Intrahepatic Cholestasis

Pathophysiology. Intrahepatic cholestasis of pregnancy, also termed *idiopathic jaundice of pregnancy*, *icterus gravidarum*, or *pruritus*

gravidarum, is a rare syndrome that occurs during the third trimester of pregnancy. It is the second most common cause of jaundice in pregnancy, after hepatitis. On histologic examination, the disease is characterized by cholestasis and dilated canaliculi in the biliary tree. The liver is normal. It is more common with increasing maternal age, multiple gestations, and in the winter months.

Clinical Features. Generalized pruritus and mild jaundice are the hallmarks of intrahepatic cholestasis of pregnancy. However, only 20% of patients present with this combination, and 80% present with pruritus alone. The pruritus usually begins in the palms and soles and ascends to the trunk. Although insomnia and fatigue occasionally accompany the pruritus, the patient appears nontoxic, without fever, vomiting, diarrhea, or significant malaise. The bilirubin level is rarely above 5 mg/dL, the alkaline phosphatase level can be elevated sevenfold to tenfold, and transaminase levels are in the normal range. Resolution occurs after delivery. Although maternal outcome is favorable, women with intrahepatic cholestasis of pregnancy are at increased risk for preterm delivery, meconium passage, and intrauterine fetal demise.

Differential Diagnoses and Management. Exclusion of more serious entities, such as viral hepatitis, acute fatty liver, drug-induced cholestasis, and complicated cholecystitis, is required. Outpatient management is appropriate, provided the diagnosis is clear and the patient has close obstetric follow-up. Some have advocated aggressive fetal surveillance and delivery after fetal lung maturity to improve the fetal outcome. Symptomatic treatment with antihistamines (chlorpheniramine 4 mg PO q4–6h) and ursodeoxycholic acid (300 mg PO BID) are considered first line; additional treatments including bile salts, guar gum, and benzodiazepines have been tried, with variable success.[23]

Nausea and Vomiting in Pregnancy

KEY CONCEPTS

- Nausea and vomiting in pregnancy are common and may be treated conservatively with diet modification and avoidance of environmental triggers. If conservative measures fail, Diclegis, a delayed-release combination of doxylamine, 10 mg, and pyridoxine (vitamin B_6), 10 mg, is the first-line pharmacologic agent for the treatment of nausea and vomiting in pregnancy.
- Hyperemesis gravidarum is defined as nausea and vomiting that cause starvation metabolism, weight loss, dehydration, and prolonged ketonemia and ketonuria. Initial management involves rehydration with IV fluids, antiemetics, and demonstration of ability to take oral hydration.

Normal Pregnancy

Nausea and vomiting are common in pregnancy, particularly from 6 to 20 weeks of gestation. Prevalence rates of nausea and vomiting are as high as 50% to 80%. Symptoms are usually self-limited and often resolve with lifestyle changes, such as diet modification and avoidance of environmental triggers. Although evidence supporting nonpharmacologic agents is mixed, in several randomized trials, ginger has been found to be effective. Treatment is recommended at a dose of 250 mg QID, in capsule or syrup form.

In women who fail conservative management, pharmacologic therapy may be initiated. The American College of Obstetricians and Gynecologists recommends doxylamine-pyridoxine (1–2 tab QD–BID), a delayed-release combination of doxylamine, 10 mg, and pyridoxine (vitamin B_6), 10 mg, as the first-line pharmacologic agent for the treatment of nausea and vomiting in pregnancy.[24] Multiple studies and the Centers for Disease Control and Prevention (CDC) Birth Defect Monitoring Program data have demonstrated its safety and it is US Food and Drug Administration (FDA) approved for use in pregnancy.

If there are circumstances preventing the prescription of Diclegis, or in case of treatment failure, other antiemetics may be considered. Although the FDA has not explicitly approved metoclopramide (5–10 mg PO/IV/IM q 6h) or promethazine (12.5–25 mg PO/IV/IM/rectal q 4–6h, max 100 mg/day) for the treatment of nausea and vomiting in pregnancy, both drugs have been widely used and are generally considered safe. Ondansetron (4 mg PO/IV q8h) has also been widely used, though recent studies have suggested that ondansetron may be associated with an increased risk of fetal anomalies. However, the evidence is mixed and the prevalence of fetal anomalies associated with ondansetron use may not be significantly higher than the background 3% to 5% risk of fetal anomalies in the first trimester.[25] We recommend that ondansetron be used only when alternative antiemetics have failed and preferably after 10 weeks' gestation.[25]

Hyperemesis Gravidarum

Pathophysiology. Hyperemesis gravidarum occurs in approximately 1% of pregnant patients and is defined by nausea and vomiting that cause starvation metabolism, weight loss greater than 5% of total body weight, dehydration, and prolonged ketonemia and ketonuria. Without treatment, there is an increased risk of micronutrient deficiency and their respective sequelae to the patient (e.g., vitamin B_1 deficiency, Wernicke encephalopathy) and fetus (e.g., vitamin K deficiency, bleeding diatheses).[24]

The cause of hyperemesis gravidarum is not clear; associations have been made with increasing estradiol and hCG levels, as well as with maternal cytokines. Several studies have suggested an increased infection rate with *Helicobacter pylori* in patients with hyperemesis gravidarum; a nonteratogenic regimen for *H. pylori* treatment has been shown to decrease vomiting in hyperemesis patients.[26] Studies have also suggested that early treatment of nausea and vomiting of pregnancy may prevent progression to hyperemesis gravidarum.

Diagnostic Testing. Laboratory studies should assess volume status and reversible electrolyte abnormalities. A urinalysis screens for the presence of ketosis, elevated specific gravity, and infection. Serum chemistry assess the presence of hypokalemia, contraction alkalosis, elevated anion gap, or other metabolic abnormalities. Bilirubin and alkaline phosphatase levels can be mildly elevated but should return to normal after delivery. Hyperemesis may be complicated by liver disease and abnormal liver function test results, which are expected to resolve with supportive treatment.

Management. Initial management of hyperemesis involves rehydration with IV fluids (2 L of Ringer lactate [LR] at a rate of 500 ml/h), antiemetics (Diclegis is first line), and demonstration of ability to take oral hydration. Following the 2 liters of LR, expert consensus favors dextrose-containing IV fluids (D5/.45NS). Thiamine is administered before dextrose to prevent progression to Wernicke encephalopathy.[24] Dextrose-containing IV fluids are continued until ketones have cleared from the urine or the patient is able to tolerate oral intake. Patients who cannot tolerate oral intake should be admitted. Potassium and magnesium are repleted as needed. Antiemetics are used as previously described for nausea and vomiting in pregnancy. A short course of methylprednisolone (16 mg PO or IV q8h for 3 days) has been reported to be therapeutic for intractable hyperemesis; however, it is considered a last-line agent and its risk profile should be weighed carefully before administration.[24]

In women who cannot maintain their weight despite medical therapy, enteral nutrition via a nasogastric (NG) tube should be considered.

Thromboembolic Disease

KEY CONCEPTS

- Thromboembolic disease is a cause of maternal mortality in developed countries.
- CT angiography and lung scintigraphy (V/Q scan) are used for the diagnosis of pulmonary embolism (PE).
- Low-molecular-weight heparin is preferred for anticoagulation.

Foundations

Thromboembolic disease is associated with increased mortality in pregnancy and is among the most common causes of maternal death in developed countries. Pregnancy is a hypercoagulable state, with increased coagulation factors and stasis as pregnancy progresses and significant vascular trauma at the time of delivery. The risk of venous thrombosis increases during pregnancy to five or six times that of nonpregnant women. Although the risk is increased throughout pregnancy, it is highest during the first six weeks after delivery. Risk factors include smoking, obesity, age older than 35 years, hypercoagulable state, varicose veins, and prior superficial venous thrombosis. Women who deliver prematurely or have postpartum hemorrhage are also at increased risk.

Clinical Features

As in nonpregnant patients, clinical signs of pain, tenderness, and swelling are poor predictors of deep venous thrombosis (DVT) in pregnancy. The clinical diagnosis of pulmonary embolism (PE) is also difficult. Although tachypnea, tachycardia, dyspnea, and pleuritic pain are commonly associated with PE, the symptoms are nonspecific and may be associated with diverse diseases such as hepatic inflammation, pyelonephritis, and diaphragmatic impingement from a normal gravid uterus.

Diagnostic Testing

Deep Venous Thrombosis. Because of its widespread availability and avoidance of radiation, Doppler ultrasonography is the first-line test for the diagnosis of DVT. An abnormal study result is usually sufficient reason to treat the pregnant patient. However, normal leg study results can be seen with isolated iliac vein disease, which is common in pregnancy, and requires imaging with magnetic resonance venogram (MRV) or CT venogram (CTV) of the lower extremities for diagnosis. The risk of anticoagulation usually outweighs the risk of definitive studies when the diagnosis is equivocal.

Pulmonary Embolism. Currently, studies do not support the use of D-dimer tests in pregnancy to exclude the diagnosis of PE because this test may lack sufficient sensitivity in pregnant patients.[27] Chest radiography (shielding the pelvis and uterus) should be performed to exclude other disease processes that may mimic a PE. The diaphragm is normally symmetrically elevated during late pregnancy.

Magnetic resonance angiography (MRA) is considered a diagnostic modality of choice in pregnant patients because there is no risk of radiation exposure to the fetus.[27] MRA for PE is not often readily available for diagnosis of PE in the ED, therefore imaging with lung scintigraphy (V/Q scan) or CT angiography is recommended. The American Thoracic Society and The Society of Thoracic Radiology clinical practice guidelines for the evaluation of suspected PE in pregnancy suggest that chest x-ray be used as an initial evaluation and if chest x-ray is normal proceed to V/Q scan and if chest x-ray is abnormal, proceed to CTA.[27] Both have comparable performances for PE diagnosis during pregnancy. CTA delivers a lower fetal radiation dose but a higher maternal radiation dose when compared to V/Q scan.[27] However, the selection of the most appropriate test relies on local availability and expertise. In most EDs, the rapid availability of CTA makes it the diagnostic modality of choice for the evaluation of PE in pregnancy patients. Pulmonary angiography may be required if the diagnosis of PE is unclear after less invasive studies have been performed.

Management and Disposition

Warfarin (Coumadin) is contraindicated during pregnancy because of its teratogenic effects, high risk of abortions, and fetal hemorrhage. Heparinoids are used to treat thromboembolic disease during pregnancy. Unfractionated heparin carries a poorly understood risk of fetal osteoporosis, thrombocytopenia, prematurity, or miscarriage. In general, acute anticoagulation with IV heparin (80 units/kg bolus followed by 18 units/kg/hr) is followed by subcutaneous heparin (minimum 10,000 units subcutaneous q 12h), usually continued for 3 to 6 months postpartum in patients who have DVT or PE during pregnancy.

Patients receiving this treatment require laboratory testing every 1 or 2 weeks, and the efficacy of anticoagulation may be variable during pregnancy. We recommend low-molecular-weight heparin (enoxaparin 1 mg/kg subcutaneous q 12h) because it is considered safe in pregnancy and offers several advantages over unfractionated heparin. This includes decreased bleeding risk, reliable pharmacokinetics, decreased risk of heparin-induced thrombocytopenia, fixed dosages, less frequent dosing, and decreased risk of osteoporosis and thrombocytopenia. In patients with a history of DVT or PE, prophylaxis for subsequent gestations is usually recommended. Oral direct thrombin inhibitors (dabigatran) and anti-Xa inhibitors (rivaroxaban) should be avoided in pregnancy and lactation because there is insufficient data to evaluate the safety of these drugs to mother, fetus, and the breast-feeding neonate.[27]

Genitourinary Infections

KEY CONCEPTS

- Asymptomatic bacteriuria in pregnancy predisposes the patient to the development of symptomatic lower and upper tract genitourinary infections. Because up to 30% of women who have asymptomatic bacteriuria will have pyelonephritis if they are untreated, treatment of bacteriuria is cost-effective and important.
- Treatment of bacterial vaginosis is directed toward symptomatic relief for the patient and does not necessarily improve fetal outcomes. Management includes a 7-day course of either metronidazole or clindamycin.
- For the treatment of vulvovaginal candidiasis, oral azoles are contraindicated in pregnancy because of an association with adverse fetal outcomes. Treatment with vaginal azoles for 7 days during pregnancy is considered safe, with an estimated 80% cure rate.
- Of patients who have trichomoniasis, 50% are asymptomatic. Diagnosis is made by direct visualization of protozoans on a wet mount. The recommended treatment is metronidazole, a one-time dose of 2 g, for symptomatic patients only.
- Regarding the treatment of sexually transmitted diseases, in general, tetracyclines and quinolones are contraindicated in pregnant patients. Treatment of genital tract infections may be important for preventing preterm labor and decreasing transmission to the infant.
- *Chlamydia trachomatis* infection is the most common sexually transmitted disease in the United States and worldwide. Treatment during pregnancy or breast-feeding is azithromycin (single 1-g dose); a 7-day course of amoxicillin is an acceptable alternative.
- Women who have genital herpes during the third trimester have a 30% to 50% increased risk of fetal transmission compared to women with herpes simplex virus (HSV) infection in the first trimester (1%).
- Suppressive therapy can reduce the need for cesarean section in women whose first clinical episode of genital HSV occurred during pregnancy.

- Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy; treatment includes cephalosporins or azithromycin.
- PID is rarely encountered in pregnancy and does not occur after the first trimester. Given the risk of endometrial infection in pregnancy and the need to consider other diagnoses, pregnant patients who have suspected PID require hospitalization and IV antibiotics.
- Chorioamnionitis is diagnosed by the findings of fever, maternal and fetal tachycardia, and uterine tenderness in a patient past 16 weeks of pregnancy. Patients are usually treated with IV ampicillin and gentamicin.

Urinary Tract Infection

Foundations. Asymptomatic bacteriuria in pregnancy predisposes the patient to the development of symptomatic lower and upper tract genitourinary infections. This has led to the US Preventive Services Task Force recommendation to screen for asymptomatic bacteriuria with urine culture for pregnant women at 12 to 16 weeks' gestation or at the first prenatal visit, if later (grade A recommendation). Uterine pressure exerted on the bladder and ureters, poor emptying of the bladder with voiding, and progesterone-induced smooth muscle relaxation that inhibits ureteral peristalsis appear to contribute to an increased risk of infection during pregnancy.

Prenatal screening of patients with asymptomatic bacteriuria in early pregnancy identifies approximately 95% of those at risk for subsequent bacteriuria during the pregnancy. Because up to 30% of women who have asymptomatic bacteriuria will have pyelonephritis if they are untreated, the treatment of bacteriuria is cost-effective and important. Antibiotic treatment may also reduce the risk of preterm delivery and low birth weight.

Clinical Features and Diagnostic Testing. The pregnant patient who presents with lower urinary tract symptoms (e.g., dysuria, frequency, urgency) or upper tract symptoms (e.g., fever, malaise, back pain) should have a pelvic examination and evaluation of an uncontaminated urine specimen. There is a predominance of right-sided symptoms during pregnancy, probably the result of increased mechanical forces on the right ureter, but left-sided flank pain or bilateral symptoms may be caused by pyelonephritis. Rarely, urinalysis may yield normal results or cultures may produce negative findings because of failure to report lower colony counts or because of complete obstruction of the involved ureter.

The major risk of asymptomatic and lower urinary tract infection is spread to the renal parenchyma. Acute pyelonephritis carries considerable morbidity in pregnancy, including maternal sepsis, permanent renal injury, and premature labor. The risk of prematurity can be minimized by effective treatment and continued monitoring for recurrence. The development of premature labor in the pregnant patient who has pyelonephritis is ominous; it can be prevented only by aggressive recognition and treatment earlier in pregnancy.

Differential Diagnosis. Vaginitis, herpes genitalis, chlamydial infection of the urethra, and ovarian torsion can masquerade as urinary tract symptoms. A history of external dysuria (burning at the perineum with urination) suggests herpes or vaginitis. A pelvic examination should be performed to obtain cervical culture specimens and identify perineal or vaginal causes of dysuria. Appendicitis, cholecystitis, pancreatitis, and liver diseases in pregnancy must be considered in the differential diagnosis of an upper urinary tract infection. Back pain may also be a sign of premature labor. Careful evaluation of an uncontaminated catheterized urine specimen is essential to the correct diagnosis.

Management. Patients with asymptomatic bacteriuria or lower urinary tract signs and symptoms should be treated with 7 to 10 days of an antibiotic that is active against common urinary pathogens and safe in pregnancy. The most common choices are a cephalosporin, such as cephalexin, 500 mg orally BID for 3 to 7 days; nitrofurantoin, 100 mg orally bid for 3 to 7 days; amoxicillin 500 mg TID for 7 days; or a sulfonamide, such as trimethoprim-sulfamethoxazole, 800/160 mg BID for 3 days (except during the third trimester). Clinicians should choose their antibiotic based on local antibiograms and consider factors such as cost, local availability, and side effects when selecting the best treatment option.

Patients with fever, back pain, and evidence of acute pyelonephritis in pregnancy are usually admitted for IV antibiotic administration. In such cases, IV hydration, obstetric consultation, and testing of urine cultures should be initiated. At least one parenteral dose of antibiotics should be given, with antibiotic coverage guided by known organism susceptibilities in a given hospital. Because the resistance of *Escherichia coli* to ampicillin is considerable in most regions, a cephalosporin, such as ceftriaxone, 1 g IV daily, is usually administered. Culture testing must be performed to ensure that the original choice of antibiotic was correct, and the patient must have a repeated culture and be observed closely after treatment.

Vaginitis

Bacterial Vaginosis. Bacterial vaginosis (formerly known as *Gardnerella* vaginitis or *Haemophilus vaginalis* vaginitis) is an overgrowth of multiple endogenous vaginal bacteria, in some cases producing excessive discharge and vaginal malodor. Prevalence rates for bacterial vaginosis in pregnancy are estimated at 15% to 20%. Bacterial vaginosis is associated with an increased risk of chorioamnionitis, subclinical PID, premature rupture of membranes, fetal prematurity, and postpartum endometritis after vaginal delivery. However, treatment of bacterial vaginosis is directed toward symptomatic relief for the patient and does not necessarily improve fetal outcomes. Management includes a 7-day oral course of metronidazole (500 mg BID) or 7-day oral course of clindamycin (300 mg BID). Intravaginal treatment is not recommended in pregnant patients.

Candida Albicans *Vaginitis.* The incidence of vulvovaginal candidiasis is increased during pregnancy by high levels of estrogen and other steroids. There is no association of *Candida* colonization with adverse pregnancy outcomes, so treatment is for relief of symptoms only. Oral azoles are contraindicated in pregnancy because of an association with adverse fetal outcomes. Treatment with vaginal azoles (intravaginal topical clotrimazole or miconazole) for 7 days during pregnancy is considered safe, with an estimated 80% cure rate.[28] Recurrent disease may require a vaginal culture to confirm the diagnosis and identify unusual *Candida* species (e.g., *Candida glabrata*) that may be resistant to conventional treatment. Longer treatment or treatment of a potential *Candida* reservoir in the patient's sexual partner(s) may also be required.

Trichomonas *Vaginitis.* Trichomoniasis is a sexually transmitted vaginitis caused by a protozoan parasite, *Trichomonas vaginalis*. Of patients who have trichomoniasis, 50% are asymptomatic. Symptoms include vaginal itching, malodorous discharge, and vaginal irritation. Diagnosis is made by direct visualization of protozoans on wet mount. Symptomatic pregnant women, regardless of pregnancy stage, should be tested and considered for treatment. The recommended treatment is metronidazole, 500 mg BID for 7 days.[28] Intravaginal treatment is not recommended in pregnant patients.

Sexually Transmitted Disease

Sexually transmitted diseases are treated in pregnant patients according to CDC guidelines.[29] In general, tetracyclines and quinolones are contraindicated in pregnant patients. Treatment of genital tract infections may be important in preventing preterm labor and decreasing transmission to the infant.

Chlamydia Trachomatis. *Chlamydia trachomatis* infection is the most common sexually transmitted disease in the United States and worldwide. Its prevalence is currently three to five times that of *Neisseria gonorrhoeae* infection. Clinical diagnosis is difficult during pregnancy because cervical mucus is usually cloudy and contains white blood cells, but urine sampling can be done and is equivalent to endocervical sampling in pregnancy infections. Routine chlamydia screening during pregnancy is important to prevent complications of preterm labor and postpartum endometritis, both of which are more common in patients who have chlamydial cervical infections. Additionally, repeat chlamydia screening should be considered in adolescent and young adult women and those who tested positive earlier in pregnancy.[29] Chlamydial infections of infants born to infected mothers include conjunctivitis and pneumonitis. Treatment during pregnancy or breastfeeding is azithromycin (single 1-g dose), which improves compliance and decreases gastrointestinal side effects; a 7-day course of amoxicillin (500 mg PO TID) is an acceptable alternative.

Neisseria Gonorrhoeae. Gonococcal infection of the cervix occurs in 1% of pregnant women.[30] Symptoms are similar to those in nonpregnant women. Salpingitis is rare but may develop during the first trimester from upper genital extension of cervical infection. Some practitioners believe that the incidence of the disseminated infection is increased in pregnant patients because of elevated progesterone levels and increased vascularity in the area of the cervix.

Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy; treatment includes cephalosporins (ceftriaxone 250 mg IM) or azithromycin (single 2-g dose PO). Treatment of possible coexistent chlamydial infection is recommended for pregnant and nonpregnant women. The major complications of third-trimester gonococcal infection are neonatal gonococcal ophthalmia and sepsis.

Herpes Simplex. Herpes simplex virus (HSV) infections pose a risk in pregnancy to the mother and newborn. Women who have genital herpes during the third trimester have a 30% to 50% increased risk of transmission compared to those in the first trimester (1%). The virus can be transmitted prenatally through transplacental infection or ascending vaginal infection and by vaginal delivery, particularly when herpetic lesions are present. Infections in the neonate often are disseminated or involve the CNS, causing significant morbidity and mortality. In the ED, culture of new suspected herpetic lesions of the cervix, vagina, or perineum identifies patients at risk for perinatal complications. Although the risk of oral acyclovir (400 mg TID for 7–10 days) and valacyclovir (1 g BID for 7–10 days) use in pregnancy is not well known, it is recommended for first-episode genital herpes. Suppressive therapy can reduce the need for cesarean section in women whose first clinical episode of genital herpes simplex occurred during pregnancy but may not eliminate the need for cesarean section in women with recurrent herpes simplex. Treatment should be undertaken with obstetric consultation and careful patient monitoring.

Upper Genital Tract Infection

Pelvic Inflammatory Disease. PID is very rare in pregnancy and does not occur after the first trimester. The differential diagnosis includes ectopic pregnancy, septic abortion, and appendicitis, all of which are more common. In the patient with suspected infection, smears or cultures for *Chlamydia* and *N. gonorrhea* should be performed. Given the risk of endometrial infection in pregnancy and the need to consider other diagnoses, pregnant patients who have suspected PID require hospitalization and IV antibiotics.

Chorioamnionitis. Chorioamnionitis is the infection or inflammation of the placenta and fetal membranes. After 16 weeks of pregnancy, the chorioamniotic membranes adhere to the cervical os and may become infected. The risk is increased in women with preterm labor. Chorioamnionitis is diagnosed by the findings of fever, maternal and fetal tachycardia, and uterine tenderness in a patient past 16 weeks of pregnancy. Leukocytosis can be suggestive of chorioamnionitis but is not diagnostic. Patients should have blood specimens drawn for culture. Vaginal and cervical culture specimens for group B streptococci, *E. coli,* chlamydia, and gonorrhea should also be obtained. Urgent obstetric consultation should be obtained, and hospitalization for IV administration of antibiotics is required. Patients are usually treated with IV ampicillin (2 g q6 hr) and gentamicin (5 mg/kg q day).[31]

Endocrine Disorders

Thyroid Disorders

KEY CONCEPTS

- During pregnancy, the thyroid gland increases in size, requires more iodine, and produces more thyroid hormone than in the nonpregnant state.
- Hyperthyroidism, characterized by a suppressed TSH level and elevated T_4 and/or T_3 levels occurs in 0.1% to 0.4% of all pregnancies. Graves disease and hCG-mediated hyperthyroidism are the most common causes.
- When US women are diagnosed with hypothyroidism, the most common cause is Hashimoto (autoimmune) thyroiditis.
- Postpartum thyroiditis is characterized by transient hyperthyroidism or hypothyroidism, or both, in the postpartum period. Approximately 25% of these women develop permanent hypothyroidism in the subsequent 10 years.
- Hyperthyroidism may be associated with hydatidiform mole and usually resolves with evacuation of the mole.
- The diagnosis of hyperthyroidism is confirmed by a low (<0.1 mU/L) or undetectable (<0.01 mU/L) serum TSH level and levels of free T_3 and T_4 that exceed the normal range for pregnancy.
- Confirmation of hypothyroidism is based on an elevated serum TSH level, relying on trimester-specific TSH reference ranges.
- Propylthiouracil (PTU) is the preferred treatment of hyperthyroidism in the United States. For thyroid storm, dexamethasone and beta blockers are added, with the patient admitted to the intensive care unit.
- Hypothyroidism in pregnancy is managed with levothyroxine supplementation (1.6 µg/kg/day).

Foundations. Thyroid disorders are common in women of childbearing age. During pregnancy, however, this is associated with a range of adverse maternal and fetal outcomes, including spontaneous miscarriage, preeclampsia, heart failure, preterm delivery, intrauterine growth restriction, and stillbirth.[32] The evaluation and management of pregnant women with thyroid dysfunction parallel those of nonpregnant women but require attention to the physiologic changes to the thyroid gland that occur during pregnancy.

Normal pregnancy exerts stress on the thyroid gland. During pregnancy, the thyroid gland increases in size, requires more iodine, and produces more thyroid hormone than in the nonpregnant state. Moreover, maternal and fetal thyroid function are strongly linked, with maternal thyroxine accounting for a substantial portion of fetal thyroid function at birth.[32] Thyroid dysfunction in pregnancy can occur during pregnancy or the postpartum state.

Hyperthyroidism, characterized by suppressed thyroid stimulating hormone (TSH) levels, elevated triiodothyronine (T3) and/or thyroxine (T4), occurs in only 0.1% to 0.4% of all pregnancies.[33] Hyperthyroidism in pregnancy can be a result of any cause, but

Graves disease and hCG-mediated hyperthyroidism are the most common causes. Graves disease is an autoimmune process associated with thyroid-stimulating antibodies and usually becomes less severe during the later stages of pregnancy. hCG, which is homologous to TSH, has some thyroid-stimulating activity and may transiently cause hyperthyroidism in the first half of gestation. hCG-mediated hyperthyroidism is typically less severe than Graves disease–associated hyperthyroidism.

Hypothyroidism complicates 2% to 3% of pregnancies.[33] Although nutritional iodine deficiency is a common cause of hypothyroidism globally, it is rare in the United States. When women in the United States are diagnosed with hypothyroidism, the most common cause is Hashimoto (autoimmune) thyroiditis, in which autoantibodies cause destruction of the thyroid gland. Hypothyroidism is associated with adverse pregnancy effects, including preeclampsia, placental abruption, low birth weight, and an increased risk of stillbirth.

Postpartum thyroiditis is characterized by transient hyperthyroidism or hypothyroidism, or both, in the postpartum period. It is estimated that 5% to 10% of women have postpartum thyroiditis. Most women return to a euthyroid state within 1 year postpartum, but approximately 20% to 40% of these women develop permanent hypothyroidism in the subsequent 10 years.[33] The diagnostic triad consists of a lack of previous history of thyroid disorders, an abnormal TSH concentration during the first postpartum year, and the absence of TSH receptor antibodies (Graves disease) or a toxic nodule.

Clinical Features. The diagnosis of thyroid dysfunction during pregnancy is difficult because pregnancy itself can mimic the findings in mild to moderate hypothyroidism and hyperthyroidism.

Hyperthyroidism in pregnancy should be suspected when the patient exhibits disproportionate tachycardia, thyromegaly, exophthalmos, weight loss, or inadequate weight gain during pregnancy. Hyperthyroidism may be associated with hydatidiform mole and usually resolves with evacuation of the mole. Patients may present with signs of thyroid storm, including altered mental status, severe tachycardia, and signs of high-output heart failure (e.g., edema, dyspnea, orthopnea).

Like hyperthyroidism, *hypothyroidism* in pregnancy is difficult to diagnose. Signs such as edema, fatigue, and weight gain may be attributed to the pregnancy rather than thyroid dysfunction. Enlargement of the thyroid gland may be absent depending on the cause of the hypothyroidism. The diagnosis of hypothyroidism during pregnancy should be suspected when the patient exhibits edema, dry skin, hair loss, and a prolonged relaxation phase of deep tendon reflexes.

Patients with *postpartum thyroiditis* classically present with thyrotoxicosis 6 weeks to 6 months postpartum, followed by a hypothyroid state lasting up to 6 months. A euthyroid state returns by the end of the first postpartum year. However, most patients present with hyperthyroidism alone or lone hypothyroidism. The recurrence rate in subsequent pregnancy is estimated at 69%, and 25% of women eventually develop permanent hypothyroidism.

Differential Diagnoses. Thyroid dysfunction should be considered in the patient with nonspecific symptoms, including fatigue, anxiety, depression, and unexplained weight loss or weight gain. When a diagnosis of hypothyroidism or hyperthyroidism is recognized, their respective causes and differential diagnoses should be considered (see Chapter 117 for more detailed information).

Diagnostic Testing. Normal values of thyroid hormones vary based on stage of pregnancy. The diagnosis of hyperthyroidism is confirmed by a low (<0.1 mU/L) or undetectable (<0.01 mU/L) serum TSH level and levels of free T_3 and T_4 that exceed the normal range for pregnancy. Confirmation of hypothyroidism is based on an elevated serum TSH level, relying on trimester-specific TSH reference ranges.[33] Overt hypothyroidism is defined as an elevated trimester-specific TSH, along with a decreased, trimester-specific free T_4 concentration. Subclinical hypothyroidism is defined as an elevated trimester-specific serum TSH concentration and a normal free T_4 concentration.

Management. Generally, no treatment is required for hCG-mediated hyperthyroidism. Treatment of pregnant women with overt hyperthyroidism due to Graves disease is of utmost importance because good fetal and maternal outcomes depend on controlling the mother's hyperthyroidism. Although thyroid ablation with radioactive iodine is contraindicated in pregnancy, medical treatments are available. Propylthiouracil (PTU) is the preferred treatment of hyperthyroidism in the United States. Methimazole is equally effective at treating hyperthyroidism in pregnancy but may be associated with fetal anomalies such as aplasia cutis, esophageal atresia, and choanal atresia. It is therefore not recommended as first-line treatment for hyperthyroidism in pregnancy.

Patients with symptoms of thyroid storm should be managed in an intensive care setting. Treatment with PTU (100 mg q8hr) should be initiated early.[33] Beta blockers such as propranolol (20–40 mg q6h) should be considered to control tachycardia; labetalol, esmolol, and propranolol have been used intrapartum.[33] A subtotal thyroidectomy may be considered once the symptoms of thyrotoxicosis are managed medically.

Hypothyroidism in pregnancy is managed with levothyroxine supplementation (1.6 μg/kg/day). Patients in the hypothyroid phase of postpartum thyroiditis require levothyroxine when they have a TSH level higher than 10 mU/L or between 4 and 10 mU/L with symptoms or active attempt at becoming pregnant. The hyperthyroid phase of postpartum thyroiditis is usually managed with a limited course of beta blockers.

Disorders of the Hypothalamic-Pituitary Axis

Foundations. The pituitary gland is normally enlarged in pregnancy due to estrogen stimulation. Disorders of the hypothalamic-pituitary axis may increase the incidence of maternal and fetal morbidity and mortality.

Pregnancy profoundly affects the hypothalamic-pituitary axis, resulting in increased circulating levels of cortisol and adrenocorticotropic hormone due to increased estrogen production. In contrast, levels of growth hormone decrease in pregnancy. Disorders of the hypothalamic-pituitary axis in pregnancy can result in adrenal insufficiency, Cushing syndrome, acromegaly, diabetes insipidus, and prolactinomas. Although these disorders are rare, they are associated with maternal morbidity (e.g., hypertension, hyperglycemia, eclampsia) and up to 20% fetal mortality.

Clinical Features. Disorders of the hypothalamic-pituitary axis usually present as an insidious set of chronic symptoms, many of which can mimic normal pregnancy, making diagnosis difficult. Symptoms vary depending on the specific disease but include fatigue, malaise, vomiting, weight gain or loss, amenorrhea, galactorrhea, and hyperprolactinemia. Normal pregnancy can be associated with slight decreases in the serum sodium level; more severe decreases in the serum sodium level may be signs of diabetes insipidus or adrenal insufficiency.

Diabetes insipidus may also be caused by pituitary infarction in the setting of severe obstetric hemorrhage (Sheehan syndrome). Advancements in the management and resuscitation of obstetric hemorrhage have made Sheehan syndrome increasingly rare, but it remains an important clinical consideration. The symptoms of Sheehan syndrome are dependent on the degree of the patient's hypopituitarism. Patients present with signs and symptoms that vary according to the deficient

hormones. The failure of postpartum lactation and resumption of normal menstruation are strongly suggestive of Sheehan syndrome. Following postpartum hemorrhage, patients may have persistent tachycardia, hypotension, and latency between hemorrhage, and the onset of symptoms can vary, from months to years after pregnancy.

Diagnostic Testing. Diagnostic considerations vary according to the patient's presentation. Growth hormone levels are elevated in patients with acromegaly. Patients with adrenal insufficiency may present with hyponatremia and hyperkalemia, although these may be absent in many patients. MRI is helpful in the detection of prolactinoma or Sheehan syndrome.

Management. Stabilization consists of treatment of serious manifestations, such as hyperkalemia, tachycardia, and hypotension. Outpatient management is appropriate in the stable patient, provided there is urgent endocrinology follow-up.

Acknowledgment

We thank Dr. Sidhant Nagrani and Dr. Bisan Salhi for their contributions to previous editions of this chapter.

CHAPTER 173: QUESTIONS AND ANSWERS

1. An 18-year-old G1P0 at 8 weeks of gestation presents with abdominal pain and vaginal bleeding for 1 day. Her serum human chorionic gonadotropin (hCG) level is 3700 IU/L. Transvaginal ultrasonography does not reveal an intrauterine pregnancy (IUP) or mass. The pelvic examination is remarkable for a closed cervical os and a small amount of blood. Which of the following should be the next step?

a. Coagulation panel
b. Gynecologic consultation
c. RhoGAM, 300 μg intramuscularly
d. Repeat hCG in 2 days
e. Serum progesterone level

Answer: B. Ultrasonographic detection of an IUP is likely at hCG levels higher than 1500 to 2000 IU/L. A negative ultrasound, with an hCG level of 3700 IU/L, is concerning for an ectopic pregnancy or miscarriage. β-hCG levels should peak at the 7- to 10-week range, with mean values of 50,000 IU/L. A persistently low hCG level is even more suspicious for ectopic pregnancy, and gynecologic consultation is warranted.

2. A 36-year-old G3P2 presents with painless vaginal bleeding during the past hour. She is at 33 weeks of gestation, and her pregnancy has been uncomplicated. Her bleeding lasted approximately 20 minutes. Which of the following should not be included in the management of this patient?

a. Baseline hemoglobin level and platelet count
b. Immediate complete pelvic examination
c. Immediate obstetric consultation
d. Intravenous fluid resuscitation
e. Transvaginal ultrasound

CHAPTER 173: QUESTIONS AND ANSWERS—cont'd

Answer: B. Painless late pregnancy bleeding is placenta previa until proven otherwise. Digital or instrumental probing of the cervix should be avoided until the diagnosis is excluded via ultrasound. An injudicious vaginal examination can precipitate severe hemorrhage in the patient with an asymptomatic or minimally symptomatic placenta previa.

3. Which of the following sexually transmitted diseases does not require treatment during pregnancy?
   a. *Chlamydia trachomatis*
   b. Herpes simplex virus
   c. *Neisseria gonorrhoeae*
   d. Pelvic inflammatory disease (PID)
   e. *Trichomonas vaginalis*

Answer: E. Although trichomoniasis has been associated with increased prematurity, treatment with metronidazole has not been shown to improve fetal outcomes, so emergency clinicians should counsel patients and consider deferring treatment in asymptomatic pregnant women until after 37 weeks' gestation.

4. A 28-year-old G3P0 at 34 weeks of gestation presents with new-onset seizures. The patient has multiple seizures in the ED and is noted to be hypertensive at a blood pressure of 164/87 mm Hg. Which of the following should be administered next?
   a. Benzodiazepines
   b. Calcium gluconate
   c. Labetalol
   d. Magnesium sulfate
   e. Pralidoxime

Answer: D. Magnesium sulfate has little antihypertensive effect but is the most effective anticonvulsant, preventing recurrent seizures while maintaining uterine and fetal blood flow. A loading dose of 4 g intravenous (IV) magnesium, followed by 2 g IV/hr, is recommended.

5. A 36-year-old G5P4 at 8 weeks of gestation presents to the ED with painless vaginal bleeding. Ultrasonography shows products of conception in the uterus. The pelvic examination shows a dilated cervix and a moderate amount of blood in the vaginal vault. Which of the following is appropriate management?
   a. Surgical evacuation
   b. Expectant management
   c. Medical management with misoprostol
   d. None of these
   e. All of these

Answer: E. All of these are appropriate management options for an incomplete miscarriage.

6. Which of these is the most common surgical emergency in pregnancy?
   a. Abruptio placentae
   b. Appendicitis
   c. Cholecystitis
   d. Ovarian torsion
   e. Ruptured peptic ulcer

Answer: B. Appendicitis is the most common surgical emergency in pregnancy. Clinical presentations may be atypical, particularly during the second half of pregnancy.

7. For the treatment of nausea and vomiting in pregnancy, which of the following has been found to have some associated risk of fetal abnormalities?
   a. Diclegis (delayed-release combination of doxylamine and pyridoxine)
   b. Ginger
   c. Metoclopramide
   d. Ondansetron
   e. Promethazine

Answer: D. Ondansetron has been shown in studies to be linked with fetal cardiac abnormalities, as well as cleft lip and palate. Diclegis is first-line pharmacologic treatment of nausea and vomiting in pregnancy; metoclopramide and promethazine are alternatives if it fails. Ginger, a nonpharmacologic treatment, has been shown to be safe and effective at a dose of 250 mg QID.

Medical Emergencies During Pregnancy

Diane L. Gorgas and Robert Cooper

KEY CONCEPTS

Asthma

- The treatment goal for a pregnant woman with an acute asthma exacerbation is to prevent fetal hypoxia by keeping maternal oxygen saturation above 95%. Inhaled beta-agonists and corticosteroids are first-line emergency department treatment and are considered safe for use in pregnancy.

Cardiac Disease

- Hypertensive emergency in pregnancy is defined as acute-onset persistent hypertension with systolic blood pressure greater than 160 mm Hg or diastolic blood pressure greater than 110 mm Hg that is persistent for greater than 15 minutes. In these cases, antihypertensive therapy should be administered as soon as reasonably possible, and no later than 30 to 60 minutes after diagnosis with a target blood pressure of 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic. The drugs of choice are oral nifedipine, IV hydralazine, and IV labetalol.
- The risk for acute coronary syndrome and acute myocardial infarction is increased in pregnant women compared to age-matched controls. The most common cause of AMI in the pregnant women is spontaneous coronary artery dissection. Treatment is similar to the nonpregnant agent, although P2Y12 receptor inhibitors should be avoided and fibrinolytic agent use should be carefully considered in women close to term.

Anemia

- Anemia in pregnancy is defined as a hemoglobin less than 11. Serum ferritin is the most accurate lab value for diagnosing iron deficiency anemia in pregnancy. Women with mild iron deficiency anemia can be started on daily iron supplementation while those with severe iron deficiency in the second and third trimester can be referred for IV iron infusion.
- Sickle cell disease causes maternal complications including more frequent pain crises, and increased risk of venous thromboembolism and preeclampsia. Treatment of pain crises is the same as in nonpregnant patients with the exception that hydroxyurea is contraindicated due to known teratogenicity.

Epilepsy

- Gravid patients with epilepsy have a tenfold risk of death compared to pregnant women without epilepsy. Many antiepileptic drugs (AEDs) have known teratogenicity and levetiracetam and lamotrigine are considered the safest agents during pregnancy. Treatment of status epilepticus is with benzodiazepines followed by a phenytoin as first-line AED and levetiracetam as second-line AED.

Endocrine

- Pregnant patients with type 1 diabetes mellitus (T1DM) are recommended to transition to insulin during gestation to achieve HgbA1C values <6%.
- Hypoglycemia is most common in the first trimester, and up to 40% of pregnancies are marked with at least 1 episode of severe hypoglycemia.
- Comorbid obesity increases the risk of cesarean section and venous thromboembolism.
- Graves disease commonly rebounds in the immediate postpartum period with thyrotoxicosis.
- Radioiodine is strongly contraindicated for the treatment of hyperthyroidism in pregnancy.
- All gravid patients with new-onset nephrolithiasis should be screened for hypercalcemia. Treatment of hypercalcemia with bisphosphonates is contraindicated in pregnancy.

Psychiatric Disorders

- Prenatal discontinuation of methamphetamines and other stimulants, although desirable, can cause depression and psychosis.
- Maternal and neonatal outcomes in women on opioid agnostic therapy show decreased rates of neonatal abstinence syndrome (neonatal opioid withdrawal syndrome).

Inflammatory Disorders

- Antiphospholipid syndrome (APS) in lupus patients is characterized by deep vessel clotting, pregnancy-related morbidity, and positive anticoagulant serum markers. Catastrophic APS has rapid-onset small vessel thrombosis, multiorgan dysfunction, and a high maternal mortality rate.

Renal Disease

- Management of chronic kidney disease (CKD) in pregnancy can be treated with intensified hemodialysis (increased length of treatment time or increased frequency) to improve fetal outcome.
- Patients post renal transplantation have fertility rates that return to normal within 6 months.

Infectious Disorders

- Moderate to severe anemia in pregnancy in an HIV-infected mother should prompt a workup for tuberculosis.
- During pregnancy, penicillin is the only known effective treatment for congenital syphilis, and pregnant patients with penicillin allergy should be desensitized and treated with penicillin.
- Lamivudine given in late pregnancy to women with high viral loads of HBV DNA reduces viral transmission when given in conjunction with HBV vaccine and immune globulin.
- Obstetric hemorrhagic complications, including DIC and shock and subsequent need for transfusion, are more common with HCV infection.

FOUNDATIONS

The physiologic changes that occur in pregnancy may exceed the patient's underlying compensatory mechanisms, resulting in initial symptom onset or rapid decompensation of medical illness during pregnancy. Certain chronic medical conditions also pose a serious threat to the mother's health or result in a poor fetal outcome. Finally, some medical illnesses result in a difficult delivery or the need for special resuscitation measures in the neonate.

The incidence of pregnancy in chronically ill patients has been increasing because of improved survival of patients with diseases such as diabetes, epilepsy, renal failure, obesity, and various cancers. Also, the demographics of pregnancy are changing in that maternal age at the time of first pregnancy is increasing. Advances in assisted reproduction, including in vitro fertilization and oocyte donation, have made it possible for older women—including those who are postmenopausal—to become pregnant. Older pregnant women experience an increased rate of antepartum and intrapartum complications and are more likely to have comorbid conditions such as cardiovascular disease.

The recognition of an unexpected or even expected pregnancy may occur in the setting of the emergency department (ED), and many interventions are time-sensitive, requiring treatment in the ED. All emergency clinicians should have an understanding of critical diagnostic and treatment possibilities when encountering a pregnant patient with a preexisting illness.

ASTHMA

Asthma exacerbations occur in up to 45% of pregnant asthmatics with almost half of those exacerbations requiring rescue oral corticosteroids or hospitalization.[1] Poorly controlled asthma is associated with an increased risk of preeclampsia or eclampsia, premature contractions, cesarean section, low birth weight, and small-for-gestational-age status. The risk of such complications varies with the severity of the disease and degree of control during pregnancy. Adverse perinatal outcomes increase with the severity of asthma during pregnancy. Controlling asthma during pregnancy leads to less intrauterine growth retardation and fewer adverse perinatal outcomes. It has been well documented that asthma may worsen, improve, or remain the same during pregnancy, but no studies have examined whether this is caused by changes in asthma triggers, treatment, or severity.

Maternal respiratory function changes can make it more difficult to recognize the decompensating pregnant asthmatic patient. Tidal volume and minute ventilation increase by 45% over the course of pregnancy resulting in an average P_{CO_2} of 32 mm Hg. The kidneys compensate and maintain an average bicarbonate level of 19 mEq/mL, which results in a compensated respiratory alkalosis with a serum pH between 7.40 and 7.45.

Many adverse perinatal outcomes associated with maternal asthma are thought to be due to fetal hypoxia. Thus, the overall goal of treatment is maintaining maternal oxygen saturations above 95%. Both the American College of Obstetrics and Gynecology (ACOG) and National Asthma Education and Prevention Program have clearly stated that it is safer to use asthma medications to treat pregnant women than to allow severe asthma symptoms and exacerbations to occur during pregnancy. Despite the support for aggressive asthma treatment from consensus guidelines, studies show variation in the amount of dispensed asthma medications before and during pregnancy.

The standard treatment for a pregnant asthmatic patient is the same as that for a nonpregnant patient with an asthma exacerbation. After history and the performance of a physical examination, the peak expiratory flow (PEF) or forced expiratory volume in 1 second (FEV_1) should be measured. There is no significant change in the FEV_1/ FVC ratio throughout pregnancy and a decline in these values is of concern. Patients with an FEV_1 or PEF less than 50% of their predicted maximum are classified as having a severe exacerbation. An initial fetal assessment should be performed, including fetal heart tones and continuous electronic fetal monitoring with a biophysical profile if the pregnancy has reached viability. Supplemental oxygen should be given to all mothers with oxygen saturation below 95%.

Inhaled short acting β_2-agonists are the first-line treatment for an asthma exacerbation and can be given continuously, if needed, for a severe exacerbation. Adjunctive anticholinergic medications are considered and albuterol and can used as in nonpregnant patients. Long-acting selective β_2-agonists and inhaled corticosteroids can be added as controller medications on discharge from the ED.[2] Multiple studies have shown no increased risk of adverse perinatal outcomes from inhaled corticosteroids. Budesonide is the preferred agent in pregnancy.[3] Nonselective β-agonists such as epinephrine are generally avoided because of concern for uterine vasoconstriction. β-agonists are tocolytics and will often halt labor.

Oral corticosteroids are indicated for use in moderate to severe asthma exacerbations and should be prescribed for the same indications as in nonpregnant asthmatics. Despite these recommendations, in one study only 63% of pregnant women treated in the ED received systemic corticosteroids at discharge despite 100% of these women receiving inhaled β-agonists during their visit.[4] There is weak evidence that oral corticosteroid use increases the risk of preterm delivery and low-birth-weight infants; there is also conflicting evidence of an increased risk of orofacial clefts. The benefits of oral corticosteroid use for avoiding fetal hypoxia greatly outweighs the risk of adverse perinatal outcomes and all expert guidelines recommend oral corticosteroid use.

Second-line agents for asthma control (e.g., cromolyn sodium) are considered safe in pregnancy. In limited studies, magnesium has been shown to improve respiratory function in pregnant females with severe asthma exacerbations without adverse fetal outcomes.

CARDIOVASCULAR DISORDERS

Foundations

Heart disease in pregnant women is the leading cause of nonobstetric maternal deaths.[5,6] The proportion of maternal deaths due to cardiovascular disease has increased as pulmonary hypertension, cardiomyopathies, aortic dissection, and myocardial infarction have become more prevalent in pregnant women. The increase in blood volume due to pregnancy, along with the increases in preload, cardiac output, and oxygen consumption, can worsen or reveal cardiac disease in pregnant women. Because the signs and symptoms of acute coronary syndromes and heart failure (e.g., shortness of breath, mild chest pain, edema) can be seen in normal pregnancies, these entities are especially difficult to diagnose.

Hypertension

Chronic Hypertension

The definitions of hypertension and hypertensive crisis differ for pregnant and nonpregnant patients, as do the blood pressure values at which to start treatment. As opposed to the American College of Cardiology (ACC)/American Heart Association definition, chronic hypertension in pregnancy is defined as hypertension (>140 mm Hg systolic or > 90 mm Hg diastolic) diagnosed prior to pregnancy or before 20 weeks' gestation (Table 174.1).[7] Chronic hypertension in pregnancy increases the risk of superimposed preeclampsia, preterm delivery, intrauterine growth restriction, and cesarean section.

TABLE 174.1 Hypertensive Disorders of Pregnancy

	Chronic Hypertension	Gestational Hypertension	Preeclampsia	Chronic Hypertension With Superimposed Preeclampsia
Definition	Hypertension that antedates pregnancy[a]	Hypertension diagnosed after 20 wk of gestation in the absence of proteinuria or other evidence of preeclampsia	Hypertension that begins after 20 wk of gestation in association with new-onset proteinuria (>300 mg/24 hr) or symptoms below in the absence of proteinuria	Hypertension that antedates pregnancy in association with new-onset proteinuria
	Hypertension diagnosed before 20 wk of gestation		Decreased platelets, elevated liver transaminase levels, renal insufficiency, pulmonary edema	Sudden increase in proteinuria in woman with chronic hypertension[a] and proteinuria before 20 wk of gestation
				Hypertension that antedates pregnancy in association with sudden increase in blood pressure
	Comment—rarely, preeclampsia presents before 20 wk of gestation	Comment—may progress to preeclampsia; may also represent previously undiagnosed hypertension		Hypertension that antedates pregnancy in association with decreased platelets, elevated liver transaminase levels, renal insufficiency, pulmonary edema, or cerebral or visual symptoms

[a]Defined as blood pressure > 140 mm Hg systolic or > 90 mm Hg diastolic.
Adapted from: Nishimura RA, Otto CM, Bonow RO, et al, ACC/AHA Task Force Members. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2010;129:e521e643.

Chronic hypertension of pregnancy is categorized as mild hypertension (systolic blood pressure of 140–159 mm Hg or diastolic blood pressure of 90–109 mm Hg) or severe hypertension (systolic blood pressure greater than 160 mm Hg or diastolic blood pressure greater than 110 mm Hg). Previously there was agreement that mild hypertension of pregnancy did not require treatment. However, tight control of blood pressure (goal diastolic blood pressure less than 85 mm Hg) has been shown to lower the frequency of severe maternal hypertension. There is no difference in the risk of pregnancy loss, high-level neonatal care, or overall maternal complication between "tight" and "less-tight" blood pressure control groups.[8] ACOG recommends that antihypertensive treatment be started when blood pressures are consistently higher than 160 mm Hg systolic and/or higher than 110 mm Hg diastolic. The European Society of Cardiology endorses treating chronic hypertension of pregnancy at 150/95 mm HG, though it sites a lack of evidence. Finally, the International Society for the study of Hypertension in Pregnancy endorses treating hypertension if blood pressures are consistently above 140/90 mm Hg.

The major risk posed by severe chronic hypertension is a progression to preeclampsia, which occurs in 25% of these pregnancies. Severe hypertension is associated with low birth weight, preterm delivery, elevated liver enzymes, and prolonged hospital stays as compared to women with chronic hypertension without severe hypertension.[9] Antihypertensive drugs are effective in preventing this progression. The first-line oral agents for the treatment of chronic hypertension are labetalol 200 to 1200 mg/day in 2 to 3 divided doses, nifedipine XL 30 to 120 mg/day, and methyldopa 500 to 3000 mg/day in 2 divided doses.

Hypertensive Emergencies

All major society guidelines define a hypertensive emergency as acute-onset persistent hypertension with systolic blood pressure greater than 160 mm Hg or diastolic blood pressure greater than 110 mm Hg that is persistent for greater than 15 minutes. In these cases, antihypertensive therapy should be administered as soon as reasonably possible, and no later than 30 to 60 minutes after diagnosis. Goal blood pressure is within the range of 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic in order to prevent loss of cerebral autoregulation. IV labetalol, IV hydralazine, and oral nifedipine are all considered first-line treatment, with oral nifedipine indicated when IV access has not yet been established (Fig. 174.1).[10]

In 2013, ACOG changed its diagnostic criteria for preeclampsia to no longer require proteinuria. In the absence of proteinuria, preeclampsia is diagnosed as hypertension in the presence of thrombocytopenia, impaired liver function, pulmonary edema, visual disturbances, or the development of renal insufficiency.

Cardiac Disorders

Acute Coronary Syndromes

In a United Kingdom Registry, cardiac disease was the largest indirect cause of maternal death with ischemic heart disease accounting for more than one-fifth of cardiac mortality.[11] The mortality rate in pregnant women who have had an acute myocardial infarction (AMI) is from 5% to 7%. Pregnant women are two to four times more likely to have an AMI as compared to age-matched nonpregnant individuals. The number of older women becoming pregnant is increasing; pregnant women aged 40 years or older have a 30-fold greater risk for acute coronary syndrome (ACS) than pregnant women 20 years of age or younger. The incidence of AMI is highest during the last trimester and peripartum period with 21% of pregnancy related MIs occurring in the antepartum period.[12]

Multiple factors are hypothesized to increase the risk of AMI in pregnancy, including a prothrombotic state, increased myocardial oxygen demand secondary to increased cardiac output and heart rate, and decreased oxygen-carrying capacity secondary to physiologic anemia, which may precipitate angina. Hypertension, thrombophilia, anemia, diabetes, advanced maternal age, multiparous state, and smoking increase the risk of pregnancy-associated AMI.

Most cases of ACS in pregnancy are related to causes other than atherosclerosis. The most common cause of ACS is spontaneous coronary artery dissection (SCAD) accounting for anywhere from 23% to 43%

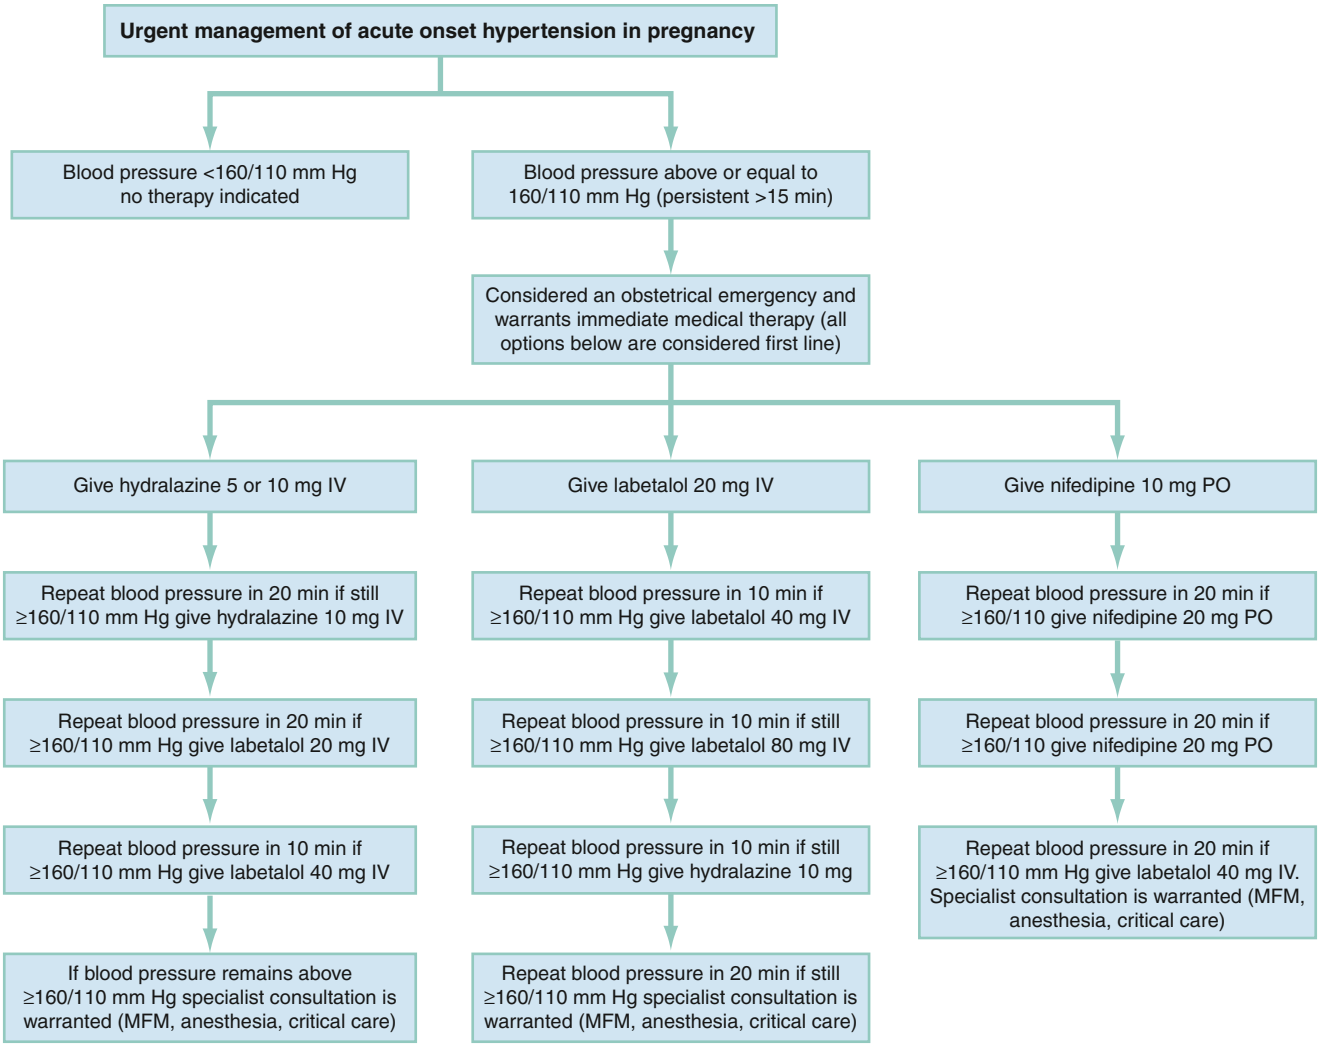

Fig. 174.1 Urgent management of acute-onset hypertension in pregnancy. (From: ElFarra J, C. Bean C, Martin, JN. Management of hypertensive crisis for the obstetrician/gynecologist. *Obstet Gynecol Clin North Am.* 2016;43, 623-637.)

of pregnancy-related MIs. In one study, 90% of patients presenting with a SCAD related AMI were postpartum while in another study 72% of SCAD related AMIs were postpartum.[13,14] Pulmonary embolus, reflux esophagitis, biliary colic, and aortic dissection are all more common than myocardial ischemia during pregnancy and should be considered in the differential diagnosis of the pregnant patient who presents with chest pain. Initial signs and symptoms of AMI, such as chest pain and shortness of breath, are often attributed to the normal physiologic changes of pregnancy.

The diagnosis of ACS is similar to that in nonpregnant patients, with certain exceptions. Electrocardiographic changes sometimes occur in normal pregnancies and delivery. These include T wave flattening, T wave inversion (mainly in lead III), and nonspecific ST changes during pregnancy, as well as ST depression during labor induction for cesarean section. As a result, an additional evaluation may be necessary. Echocardiography is useful in the correlation of suspicious electrocardiographic findings with wall motion abnormalities. The enzymatic diagnosis of myocardial infarction is unchanged, and a serial troponin rise suggests myocardial ischemia, even in preeclampsia.

Treatment of AMI during pregnancy is similar in most respects to treatment of the nonpregnant patient, with survival of the mother as the goal. Standard treatments including antiplatelet agents, nitroglycerin, and beta blockers: antithrombotic agents are considered safe during pregnancy but the decision to use them should be made jointly by emergent consultation with a cardiologist and the patient's obstetrician. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, aldosterone antagonists, and statins are not advised until the postpartum period. Aspirin is the first-line antiplatelet agent. Clopidogrel has been studied in case reports with no adverse fetal outcomes and ACOG recommends that it can be used with caution, primarily after stenting. Ticagrelor, prasugrel, and bivalirudin are not recommended due to teratogenicity in animal studies. Heparin has long been the antithrombotic of choice for pregnant patients, although low-molecular-weight agents such as enoxaparin also do not cross the placenta and are considered efficacious and safe in pregnancy.

Cardiac catheterization with stenting is the treatment of choice for AMI in the pregnant patient and, with shielding, exposes the fetus to less than 1 radiation-absorbed dose (rad). However, both ACOG and the European Society of Cardiology recommend a conservative approach when considering cardiac catheterization in patients who may potentially have a coronary artery dissection. When a catheterization laboratory is unavailable, lifesaving thrombolytic therapy should not be withheld. Although thrombolytics do not cross the placenta, there is an increased risk of maternal hemorrhage and, in the setting of

AMI caused by coronary dissection, thrombolytic use can worsen the dissection. Because thrombolytic therapy precludes major surgery and epidural anesthesia in the hours to days immediately after administration, one must carefully consider whether to use these agents in pregnant women who are close to term, especially if the need for cesarean delivery is anticipated.

In the setting of peripartum AMI, labor should be conducted with continuous monitoring of the mother's hemodynamic status and fetal well-being. Assisted vaginal delivery is preferred unless there is an indication for cesarean section. Cesarean section avoids prolonged exertion by the mother but can subject the patient to general anesthesia if the use of antithrombotic agents precludes epidural catheter placement.

Valvular Heart Disease and Pulmonary Hypertension

Foundations. Valvular heart disease, including both native and mechanical valves, can lead to acute heart failure during pregnancy and is associated with both higher maternal and fetal mortality. The ability of patients to tolerate pregnancy without significant adverse effects depends on the type and severity of the lesion. Mild to moderate lesions (New York Heart Association [NYHA] classes I and II) are often associated with good outcomes for the mother and fetus. On the other hand, mitral stenosis (beyond class I), advanced aortic stenosis, and aortic and mitral lesions associated with moderate to severe ventricular dysfunction or pulmonary hypertension, as well as mechanical prosthetic valves requiring anticoagulation, can result in maternal mortality and require directed therapy and expert cardiology consultation.

Heart failure is the most common maternal complication in pregnancy with valvular heart disease, and women with cardiomyopathy, an NYHA functional class III or higher, pre-pregnancy heart failure, and pulmonary hypertension are at the highest risk. Diagnosing heart failure is challenging because women in the last months of pregnancy experience symptoms such as dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, and pedal edema that are identical to those of heart failure. Normal B-type natriuretic peptide (BNP) levels can be used to rule out heart failure in pregnant females but, because BNP levels increase twofold in pregnant females, a mildly elevated BNP level can be difficult to interpret.

Pulmonary Hypertension. Pregnancy is poorly tolerated by patients with pulmonary hypertension because the pulmonary circulation cannot cope with the increased stroke volume and cardiac output of pregnancy, causing pulmonary pressures to rise. This causes dyspnea, heart failure, and syncope. Mortality in pregnant women with pulmonary hypertension can approach 30%. Pregnancy is contraindicated, and patients early in pregnancy should be counseled about elective pregnancy termination.

The treatment of the pregnant patient with pulmonary hypertension focuses on diuresis and pulmonary vasodilation. Diuretics are indicated for the management of volume overload, and common diuretics—with the exception of spironolactone—are considered safe, although limited data exist regarding their effect on the fetus. Specific agents for treating pulmonary hypertension include endothelin receptor agonists (ERAs), phosphodiesterase inhibitors, and prostanoids. Phosphodiesterase inhibitors such as sildenafil and tadalafil, as well as the prostacyclin derivatives epoprostenol and treprostinil, are fetotoxic in animals; however, the benefits outweighs the risks, so they are regularly used in pregnancy. ERAs such as bosentan and ambrisentan are teratogenic.

Mitral Stenosis. Mitral stenosis is the most commonly encountered valvular lesion in pregnancy but is typically well tolerated except in moderate to severe disease. The increased resting heart rate and stroke volume in normal pregnancy increase the pressure gradient across the mitral valve and can cause symptoms of left heart failure, as well as atrial arrhythmias such as atrial fibrillation. The likelihood of maternal symptoms and worsening of cardiovascular status is directly related to the severity of disease.

Beta blockers are the mainstay of treatment for patients with symptomatic mitral stenosis in order to prevent tachycardia and maintain preload to overcome obstruction. Diuretics may also be used for patients with symptoms of heart failure. Surgical intervention is indicated for patients with refractory symptoms despite optimal medical management and in patients with pulmonary hypertension.

Aortic and Mitral Regurgitation. Mitral valve prolapse is the most common cause of mitral regurgitation in developed countries, whereas rheumatic heart disease is the most common cause worldwide. In most cases, chronic regurgitation lesions are well tolerated during pregnancy and may even improve because the reduced systemic vascular resistance of pregnancy allows more forward and less regurgitant flow. However, heart failure occurs in 20% to 25% of women with moderate or severe mitral regurgitation. When necessary, medical therapy consists of diuresis, digoxin, and vasodilators.

Aortic Stenosis. Symptomatic aortic stenosis during pregnancy usually occurs in the setting of a congenital bicuspid valve and patients with severe aortic stenosis may first become symptomatic during pregnancy. Patients with mild to moderate aortic stenosis tend to have uncomplicated pregnancies; conservative management is often possible, especially if the aortic valve area is greater than 1.0 cm^2. Patients with symptomatic aortic stenosis may respond to bed rest or preload reduction with diuretics. Severely symptomatic patients may need percutaneous valvotomy and surgical replacement.

Prosthetic Heart Valves. Pregnant women with mechanical heart valves are classified as high risk with a World Health Organization (WHO) risk classification III. The Registry of Pregnancy and Cardiac Disease (ROPAC) found that 82% of pregnancies in women with a mechanical heart valve ended with a live mother and child compared to 98% in pregnant women without a mechanical heart valve.[15] Thrombotic events occurred in 5% of women in the ROPAC registry with a mortality of 20%. Warfarin is the most effective anticoagulant in preventing maternal thromboembolic events. However, warfarin is considered teratogenic in the first trimester and is associated with a higher risk of fetal loss and fetal hemorrhage. Neither unfractionated heparin (UFH) nor low-molecular-weight heparin (LMWH) crosses the placenta and are not teratogenic. However, their use throughout pregnancy is not recommended due to the increased risk of thromboembolic events as compared to using UFH or LMWH in the first trimester, followed by warfarin for the remainder of pregnancy.[16]

Current anticoagulation recommendations in pregnant patients with prosthetic heart valves are to continue using warfarin until pregnancy has been achieved. If an international normalized ratio of 2.5 to 3.5 can be achieved with a warfarin dose less than or equal to 5 mg, the AHA/ACC and European Society of Cardiology Guidelines slightly prefer the use of warfarin throughout pregnancy after a full discussion with the patient about the benefits and risks of the therapy. If a dose more than 5 mg is required, UFH or LWMH is recommended in the first trimester, with warfarin being resumed for the second and third trimesters. Warfarin should again be replaced by UFH or LWMH several weeks before delivery.

HEMATOLOGIC DISORDERS

Anemia

Anemia is the most common medical complication of pregnancy and is associated with maternal mortality, perinatal mortality, preterm birth,

low birth weight, and small-for-gestational-age infants. The classic clinical presentations of anemia include pallor, fatigue, and shortness of breath. Most anemia, however, is asymptomatic. The WHO defines anemia of pregnancy as a hemoglobin of less than 11 g/dL. The hemoglobin threshold for severe anemia requiring blood transfusions is typically considered to be less than 7 g/dL for gravid patients and less than 8 g/dL for postpartum patients. There are several types of anemia, but four types predominate: dilutional anemia, iron deficiency, folate deficiency, and sickle cell hemoglobinopathy.

Dilutional Anemia

Dilutional anemia is normally seen with pregnancy. In preparation for blood loss at delivery, blood volume increases by nearly 50% between weeks 6 and 34. This rapid blood volume increase, accompanied by a lag in red blood cell (RBC) production, results in a dilution of hemoglobin. The result is that the threshold for diagnosing anemia in gravid patients is slightly lower (11 g/dL) than in nongravid patients (12 g/dL). Hemoglobin concentrations typically reach their nadir between weeks 26 to 28 of pregnancy. Clinicians should consider that gravid patients with hemoglobin values of 13 to 15 g/dL have inadequate expansion of their plasma volume, which can result in outcomes like low birthweight and premature birth.

Iron Deficiency Anemia

Iron deficiency occurs in 18% of pregnancies in the United States (US) with iron deficiency anemia occurring in approximately 5%.[17] The risks of adverse pregnancy outcomes are correlated to the severity of the anemia. Studies show a higher risk of preterm birth and low birth weight in women with mild to moderate anemia. Severe anemia (<6 to 7 g/dL or 60–70 g/L) is associated with increased fetal mortality, abnormal fetal oxygenation, premature rupture of membranes, gestational hypertension, and reduced volume of amniotic fluid. The diagnosis of iron deficiency is difficult to make because many of the serum biomarkers typically used are affected by the changes in maternal physiology. Ferritin is the most sensitive test for iron deficiency in pregnancy, with a cutoff of 30 ng/mL showing a 92% sensitivity and a 98% specificity, but it is affected by the increased plasma volume in later pregnancy. Mean corpuscular volume, total iron-binding capacity, and transferrin are less sensitive and specific than ferritin for iron deficiency

The ACOG has developed guidelines for the management of iron deficiency anemia. Patients with an uncomplicated physiologic anemia who are not iron deficient can be expected to have good obstetric outcomes without therapy and do not require treatment. Patients presenting with mild iron deficiency anemia (i.e., a hemoglobin of 9–10.5 g/dL) should be treated with non–enteric-coated supplemental iron. A single daily dose of iron appears to be as effective as multiple-dosing regimens and decreases the risk for GERD, which is already heightened in pregnancy. Intravenous iron is not used in the first trimester, but is the treatment of choice for all iron deficiency anemia in the third trimester and severe iron deficiency anemia (hemoglobin < 9 g/dL) in the second trimester.

The evidence for the use of prophylactic supplementation in women with normal hemoglobin levels (>11 g/dL [110 g/L]) and normal iron stores (ferritin > 30 mg/dL [20 μg/L]) to prevent anemia in late pregnancy is mixed. However, recent studies demonstrate that prenatal iron supplementation reduces the risk of iron deficiency anemia at term. ACOG, the WHO, and other major health authorities recommend at least 30 mg of ferrous iron daily during pregnancy. Intermittent dosing at two to three times a week provides the same maternal and offspring benefits while reducing the risk of side effects like heartburn, constipation, and nausea.[18]

Folate Deficiency

Folate is critical to several intracellular processes associated with cell growth. However, due to the 5- to 10-fold increase in folate requirements during pregnancy, gravid patients are at risk for folate deficiency. Folate deficiency is one of a number of causes of megaloblastic anemia, which is the second most common anemia. The incidence of folate deficiency in pregnancy is low in high income countries but remains higher in other populations. The risk for development of folate deficiency is increased in patients with multiple gestations, short interpregnancy intervals, preexisting malnutrition, hyperemesis gravidarum, malabsorption syndromes, alcoholism, use of certain antiepileptic drugs, and diets lacking green leafy vegetables and animal protein. Low maternal folate stores have, most importantly, been linked to increased risk of neural tube defects, as well as increased risk of placental abruption, preterm birth and low birth weight, preeclampsia, and spontaneous abortion. As is the case for iron deficiency, effects on the fetus depend on the degree of anemia.

Iron deficiency and folate deficiency anemias often coexist, making the peripheral blood smear difficult to interpret. In cases of suspected folate deficiency, the measurement of serum and RBC folate levels is indicated. However, the serum folate level is noted to exhibit a rapid response to folate intake, and low levels may normalize within days after a folate-rich meal. Oral folate supplementation with 0.4 mg daily is routinely recommended for all women before conception, and 0.4 to 0.8 mg is recommended during pregnancy as the requirement for this micronutrient increases during gestation. ACOG recommends 1.0 mg for those women who have a known pregnancy-related folate deficiency. Women at higher risk for neural tube defects (e.g., neural tube defects in prior pregnancy) are advised to take much higher doses of folate, 4 mg daily for 1 month pre-conception and at least until 12 weeks gestational age under close supervision of their obstetrician. ACOG advises continuing oral folate supplementation throughout the second and third trimesters.

Sickle Cell Anemia

Sickle cell disease (SCD) is one of the major sources of maternal and fetal complications in the United States. Patients with SCD are subject to many chronic medical problems due to a variety of pathophysiologic mechanisms, including sickling of RBCs, anemia, immunosuppression caused by auto-splenectomy, and repeated transfusion. Median life expectancy is in the fifth decade for both genders affected by SCD, and female fertility is generally unaffected, so it is likely that the emergency clinician will encounter pregnant patients with the disease. Maternal complications are common in patients with SCD; these include preterm labor, premature rupture of membranes, maternal infections, more frequent pain crises, thrombosis, preeclampsia, and increased need for cesarean delivery. Due to these complications, pregnant women with SCD have a sixfold increased risk of maternal death compared with controls.

SCD also results in adverse effects on the fetus. Placental infarction and insufficiency are common, and the incidence of premature labor, small-for-gestational-age infants, and low-birth-weight infants is significantly increased in SCD pregnancies compared with normal controls. Perinatal mortality rates vary but are low in the setting of appropriate maternal and neonatal care.

Vasoocclusive crises and anemia occur more often in pregnancy and are the most common complications of SCD in pregnancy. Studies have also demonstrated that venous thromboembolisms occur 1.7 to 10 times more frequently in pregnant women with SCD. Recommended treatment is similar to that for the nonpregnant patient with a few exceptions. Hydroxyurea is not recommended for use in pregnancy because of potential teratogenicity, and nonsteroidal antiinflammatory drugs (NSAIDs) are avoided after 30 weeks of gestation.

General anesthesia can result in an increase in postpartum sickling complications, so regional anesthesia is preferred in the case of cesarean delivery. The use of supplemental iron and transfusion is controversial because of the potential for iron overload, alloimmunization, volume overload, and hyperviscosity syndrome.

Therapeutic transfusions should be given to patients with severe disease manifestations such as symptomatic anemia, cardiopulmonary instability, acute chest syndrome, intrapartum hemorrhage, and preeclampsia. In general, the goal with transfusion or exchange transfusion is to lower the percentage of hemoglobin S to 40% and achieve hemoglobin values of approximately 10 g/dL (110 g/L). Prophylactic red blood cell transfusions are often used in pregnant women with SCD without the indications for a therapeutic transfusion in order to decrease the frequency and severity of vaso-occlusive pain episodes during pregnancy.[19] Only low quality studies are available, but they show a reduction in maternal mortality, vasoocclusive pain episodes, pulmonary complications, and neonatal death. There is no consensus at this time whether the benefits of prophylactic transfusions outweigh the risks.

NEUROLOGIC DISORDERS

Epilepsy

Epilepsy is the most common neurologic complication of pregnancy but remains relatively rare, affecting less than 1% of all gestations. The treatment of epilepsy during pregnancy entails balancing the risk of increased frequency and duration of seizures to the mother and fetus against the teratogenic risks of antiepileptic drugs (AEDs).

Gravid patients with epilepsy have more than a tenfold increased risk of death compared to pregnant women without epilepsy. Pregnant women with epilepsy are also at increased risk for cesarean section, postpartum hemorrhage, hypertensive disorders and other adverse outcomes. Approximately 15% of patients experience an increase in seizure frequency during pregnancy. Delivery and the first 24 hours postpartum are the most likely times for a seizure to occur, with a ninefold greater incidence of seizure than during pregnancy in general.

A decrease in plasma drug concentrations is expected due to pharmacokinetic alterations including decreased absorption, increased volume of distribution, elevated renal excretion, and induction of hepatic metabolism; many experts recommend that maternal plasma drug levels be monitored and compared to prepregnancy levels.[20] Antiepileptic medications also increase the clearance of medications, including oral contraceptives, making unintentional pregnancy a possibility. Patients who have nonconvulsive seizure disorders or who are seizure-free for a sufficient period of time before conception are candidates for nonpharmacologic observation because the risk of treatment with AEDs can outweigh the benefit. This decision should be deferred to the patient's primary physician or neurologist. However, there are obstetric complications related to prolonged seizure activity, and long-term treatment with an AED for most patients with seizures is warranted.

The primary complication of AED use in pregnancy is congenital malformations. Of primary concern is the risk for neural tube defects, facial clefts, cardiac anomalies, and cognitive defects with the older generation agents (e.g., valproate, carbamazepine, phenytoin) and several of the newer generation agents (e.g., gabapentin, topiramate). There is a two- to three-fold increase in the incidence of serious congenital malformations in offspring of epileptic mothers taking these agents. The risk is greatest with valproate and is also increased with AED polypharmacy and increased dose of individual agents. Recent studies have found that monotherapy with lamotrigine and levetiracetam does not have a higher risk of major congenital malformations than control.[21]

When compared to the older AEDs, levetiracetam performed as well at controlling seizures when used in monotherapy, while lamotrigine and topiramate, when used in monotherapy, showed worse seizure control. In the case of lamotrigine, this was due to increased renal clearance leading to variable levels. Because phenytoin, carbamazepine, valproate, and possibly other AEDs interfere with folate metabolism, oral supplementation with at least 0.4 to 1.0 mg/day is recommended for all women of childbearing age taking these drugs to help prevent congenital malformations such as neural tube defects. Enzyme-inducing AEDs such as carbamazepine, phenytoin, and phenobarbital have been reported to cause neonatal vitamin K deficiency and neonatal hemorrhage, but the American Academy of Neurology and American Epilepsy Society have noted that there is inadequate evidence to determine a definitive relationship.

Status epilepticus in pregnancy is relatively rare and can occur at any time during gestation, with a higher likelihood in the postpartum period. Any potential cause of seizure may result in status epilepticus, and recent studies have shown that eclampsia, posterior reversible encephalopathy syndrome, and cerebral venous thrombosis are all common causes. It may also occur in patients who have been seizure-free throughout pregnancy, and no specific risk factors for its occurrence have been identified. The risk of untreated status epilepticus to the mother and fetus clearly outweighs the potential for adverse teratogenic effects, and standard resuscitative measures, as well as drug therapy, are indicated. Benzodiazepines followed by levetiracetam are recommended.[22] Continuous fetal monitoring should be instituted as soon as possible to observe for signs of fetal hypoxia, and the mother should be positioned in the left lateral decubitus position to avoid the supine hypotensive syndrome.

Multiple Sclerosis

Multiple sclerosis (MS) affects approximately 400,000 Americans and is twice as common in women as in men. The peak age at onset is 20 to 35 years, which overlaps peak childbearing years. The disease is characterized by intermittent episodes of central nervous system (CNS) demyelination, with consequent neurologic impairment that follows a relapsing-remitting course. Progressive neurologic deficits and permanent disability develop in certain patients.

The frequency and severity of exacerbations of MS often improve during pregnancy, particularly during the third trimester. During the 3 months after delivery, the rate of relapse increases and then returns to the patients' pre-pregnancy baseline. Relapses are more likely in MS patients with higher disability at the time of pregnancy onset, as well as women treated with natalizumab and fingolimod.[23] However, it does not seem that postpartum relapses are related to the duration of disease or total number of relapses before conception.

MS patients with disease exacerbation are often treated with immunomodulators such as intravenous immune globulin (IVIG), corticosteroids, glatiramer acetate, and interferon beta. Small studies in gravid patients have shown that the use of IVIG during pregnancy and in the postpartum period is safe and may decrease the relapse rate. Likewise, the use of intermittent steroids in the postpartum period may decrease the likelihood of disease relapse. Glatiramer acetate may also be used in pregnancy as needed as studies have not shown any fetal toxicity.[24]

Spinal Cord Injury

Because spinal cord injury (SCI) occurs mainly in young people and usually does not impair fertility, there is a relatively large population of paraplegic and quadriplegic patients who become pregnant. The most common complication in pregnant women with SCI is urinary tract

infection (UTI). One study showed that pregnant women with SCI were 26 times more likely to get a UTI than controls, while another found that 30% of gravid women with SCI developed pyelonephritis.[25] A high suspicion must be kept for UTIs in this population, as untreated infections carry an increased risk of fetal loss, prematurity, and maternal sepsis.

The hypercoagulable state of pregnancy, combined with chronic immobilization, results in an increased incidence of thromboembolic disease, with a nine times greater risk of venous thromboembolism versus control.

Autonomic dysreflexia is the most serious complication of SCI and occurs in up to 56% of women with high lesions (above T5-T6); it occurs with increased frequency during pregnancy. Autonomic dysreflexia is manifested as severe paroxysmal hypertension, headache, tachycardia, diaphoresis, piloerection, mydriasis, and nasal congestion. It is often precipitated by afferent stimuli from the hollow viscus such as the bladder, bowel, or uterus. Symptoms of autonomic dysreflexia often occur with uterine contractions during labor. However, labor may be difficult to detect because patients with spinal cord lesions below T10 to T12 have an intact uterine nerve supply and experience labor pains; however, with lesions above T10, labor may be imperceptible or experienced as only mild abdominal discomfort. Pregnant patients with SCI with symptoms of autonomic dysreflexia should be assessed for cervical dilation and have uterine contractions monitored. ED treatment is directed at the restoration of normal blood pressure with standard agents. Definitive therapy is with regional anesthesia. Spinal anesthesia and epidural anesthesia obliterate and prevent this response and should be used as soon as possible during labor for all women with SCI. Finally, it can be difficult to differentiate between the symptoms of autonomic dysreflexia and preeclampsia. In autonomic dysreflexia, symptoms such as hypertension will resolve once the stimuli to the skin or hollow viscus have been relieved; in preeclampsia, the symptoms and laboratory abnormalities are more likely to persist.

Myasthenia Gravis

Myasthenia gravis is a rare disorder in which autoimmune destruction of the postsynaptic cholinergic receptor results in profound muscle fatigability. The effect of pregnancy and the postpartum state on myasthenia gravis is unpredictable in the individual patient, but overall, approximately 25% to 50% of patients experience exacerbation of disease, with the remainder having improvement or no change in disease severity.[26] Disease exacerbations can occur anytime during pregnancy and the postpartum period and are not more likely in one trimester than in another. Additionally up to 15% of women will experience their first myasthenia symptoms in the pregnancy or postpartum period. Because of weight gain, anemia, and other physiologic adjustments of pregnancy that may result in fatigue, the distinction between normal pregnancy symptoms and myasthenia may be difficult.

Most deliveries are accomplished vaginally without complication in adequately treated patients; assisted and surgical delivery in these women is indicated mainly for obstetric reasons rather than for specific myasthenia-related care.[27] Between 10% and 20% of neonates born to mothers with myasthenia gravis have a transient neonatal myasthenia syndrome through the placental transport of acetylcholine receptor antibodies. There is no correlation between the severity of maternal disease and occurrence of neonatal myasthenia. The onset of neonatal myasthenia is typically within the first hours of life but may be delayed by a period of days. Manifestations include poor feeding and suck, diminished reflexes, hypotonia, and bulbar and respiratory muscle weakness. As in adults, the symptoms respond to cholinesterase inhibitors, but treatment should be carried out in an intensive care unit setting.

Myasthenia crises during pregnancy present with typical symptoms of painless fluctuating weakness of skeletal muscles. Diplopia and ptosis are the most common early symptoms. When exacerbations do occur, treatment is no different from the treatment of nonpregnant patients. Acetylcholine esterase inhibitors, corticosteroids, IVIG, and plasmapheresis are all considered safe for the mother and fetus. Azathioprine and cyclosporine are considered second-line options for patients who are not controlled or who cannot tolerate corticosteroids. Assessment of pulse oximetry, forced vital capacity, and arterial blood gas parameters will guide respiratory therapy.

Magnesium sulfate is contraindicated for treatment of eclampsia in myasthenia gravis because of its neuromuscular blocking effects; barbiturates or phenytoin should be used instead.[27] Epidural anesthesia is also recommended to reduce pain and fatigue.

RENAL DISORDERS

Chronic kidney disease (CKD) can be silent well into its disease course and is more difficult to diagnose in pregnancy because of expected decreased blood urea nitrogen (BUN) and creatinine levels during pregnancy. For women with known renal disease, including end-stage renal disease (ERSD), on hemodialysis, conception rates have shown some improvement, but seem plateaued at roughly 10%.

CKD in and of itself is an independent risk factor for maternal and fetal complications. The degree of underlying renal dysfunction is a strong determinant of morbidity associated with pregnancy. Patients with moderate to severe renal dysfunction have a much higher risk of further decline in renal function, as well as adverse obstetric outcomes, including preeclampsia, placental abruption, fetal loss, preterm delivery, low birth weight, polyhydramnios, and increased need for cesarean section and neonatal intensive care. Worsening of underlying renal function is more likely in patients with a decreased glomerular filtration rate who also have associated proteinuria or hypertension. Because worsening renal function is manifested by hypertension and proteinuria, differentiation from preeclampsia can be difficult. In this setting, it is best to treat the patient for presumed preeclampsia, with the caveat that magnesium administration should be performed judiciously and carefully guided by serum magnesium levels.

Pregnant women with chronic renal failure require aggressive and timely management to optimize their chances for a successful gestation without causing further deterioration in renal function. One of the most successful tenets of CKD management in pregnancy is close control of blood pressure and monitoring for proteinuria. Thresholds for initiation of hemodialysis (HD) in pregnant patients are considered lower than those in nongravid patients. Intensified HD, through longer and/or more frequent dialysis sessions, offers improved maternal and neonatal outcomes.

Adverse pregnancy outcomes in HD patients include miscarriage, placental detachment, anemia, infections, premature rupture of membranes, polyhydramnios, preterm birth, uncontrolled arterial hypertension, preeclampsia/eclampsia, hemorrhage, need for a caesarean section and maternal death

For patients who are post–renal transplantation, fertility rates return to prerenal failure levels within 1 to 6 months post-transplantation, so pregnancy is not an uncommon finding in post-transplantation women of childbearing age. Obstetric outcomes for this patient population show live birth rates exceeding 70%, and adverse outcomes mostly associated with preterm births and with infants small for gestational age (SGA).

METABOLIC AND ENDOCRINE DISORDERS

Diabetes

General Management

Three types of diabetes affect pregnant patients—type 1, or insulin-dependent diabetes mellitus (T1DM); type 2, or non–insulin-dependent diabetes mellitus (T2DM); and gestational diabetes mellitus (GDM). The considerations for glycemic control in GDM are the same as those for T1DM and T2DM.

Both T1DM and T2DM are growing in prevalence, representing a challenge to the management of these high-risk obstetric patients. Technical advances in glycemic control have improved the potential for successful pregnancy outcomes, but euglycemic control is not the norm for these patient populations, especially given the tight control advised by ACOG.

Although T2DM is sometimes considered a more benign form of disease, the risk of pregnancy complications and fetal malformations is still significant and rates of elective cesarean section are increased compared to nondiabetic norms due to the development of neonatal macrosomia. Ideally, hemoglobin A_{1c} (HbA_{1c}) values should not be higher than 6%. T2DM patients are generally recommended to transition to insulin therapy to achieve tighter glycemic regulation during pregnancy.

T1DM does connote a much higher rate of preeclampsia, maternal mortality, premature delivery, neonatal hypoglycemia, congenital abnormalities and stillbirths. Preconception planning in this patient population is paramount, and tight glycemic control for at least 4 months prior to conception is recommended. Maternal and fetal complications are largely related to inadequate glycemic control and to the presence of vascular complications or severe renal insufficiency more than to the type of diabetes.

The effects of pregnancy on underlying diabetes vary by organ system. The data are limited, but pregnancy is not advised for diabetic patients with coronary artery disease because of the cardiovascular demands of pregnancy and high mortality rates of AMI during pregnancy. Given the likelihood of silent ischemic events in the diabetic population, atypical or vague presentations of angina or MI, including new-onset congestive heart failure should be carefully evaluated in those with preexisting known coronary artery disease, but also in any diabetic mother.

Patients with diabetic nephropathy are at increased risk for preeclampsia and the subsequent requirement for preterm delivery. Following progression of nephropathy closely in conjunction with aggressive blood pressure control and optimizing protein intake are strongly recommended.

Angioproliferation is a natural physiologic response in pregnancy, and because of this, diabetic retinopathy worsens acutely in 30% of DM1 and 12% of DM2 patients during pregnancy. Those at greatest risk for this are patients with high HbA_{1c} levels, hypertension, nephropathy, and active nonproliferative or proliferative retinopathy. New onset diabetic retinopathy during pregnancy occurs 10% of the time with DM1. Laser therapy of preexisting retinopathy is recommended before conception, as well as for pregnant patients with severe disease. Patients with known proliferative retinopathy should be counseled to avoid excessive, aggressive Valsalva maneuvers during labor to minimize the risk of retinal hemorrhages.

Autonomic neuropathy does not accelerate during pregnancy, with the exception of a possible increase in symptomatic severity of gastroparesis.

Hyperglycemic

Physiologically, insulin sensitivity increases in the first trimester, allowing for decreased insulin usage. This reverses in the second and third trimesters, ultimately increasing to 70% to 100% of baseline nonpregnant insulin requirements. The increased risk of diabetic ketoacidosis (DKA) results from intercurrent illness including hyperemesis, inadequate insulin administration, or iatrogenically from use of betamimetic medications for tocolysis, and use of corticosteroids to hasten fetal lung maturity, or from withholding insulin therapy for planned procedures. During pregnancy there is a continuous need for a basal rate of insulin, whether by insulin pump or long-acting (Lantus) insulin. Relying on a basic metabolic profile as screening for DKA in pregnancy (e.g., insulin glargine) can be dangerous. The serum pH may be deceptively normal in a pregnant patient with DKA because the initial pH tends to be higher in pregnancy as a result of physiologic hyperventilation. In addition, the serum glucose concentration may be normal or only moderately elevated. Screening with serum acetone or betahydroxybutarate is recommended for any pregnant DM patient with vague symptoms of headache, nausea, vomiting, or fatigue.

The treatment of DKA does not differ in pregnancy versus nonpregnant patients, except that fluid resuscitation and insulin therapy should be maintained in the presence of normoglycemia until bicarbonate levels return to normal, indicating that any lagging acidemia has cleared. Fetal viability and well-being should be assessed in all cases of maternal DKA. Fetal mortality associated with DKA can be as high as 35%.

Hypoglycemia

The risk for hypoglycemia is bimodal, mostly in the first trimester but also in the peripartum period. In the first trimester, insulin needs decrease and physiologic hormonal counter-regulation to hypoglycemia including glucagon, cortisol, and epinephrine surge is blunted. A contributing factor for some patients is the comorbid condition of gastroparesis, which can worsen hyperemesis gravidarum (HG); 18% to 40% of patients have at least 1 severe episode of hypoglycemia in the first trimester, almost always at night. Even subclinical hypoglycemia (sustained levels <85 mg/dl) can lead to low-birth-weight neonates, so ideal ranges for glycemic control are extremely tight between 90 to 120 mg/dl.

Fetal Effects

Diabetes has many deleterious effects on the fetus. The risk of congenital anomalies in infants of diabetic mothers (IDMs) is as high as 10%. The rate of congenital malformations in patients with prepregnancy diabetes is increased threefold or fourfold compared with the nondiabetic population, with anomalies being more likely in pregnant women with poor glycemic control. Macrosomia is the most likely factor leading to the need for cesarean section and has been associated with shoulder dystocia. Conversely, preeclampsia and placental infarction secondary to vascular disease may result in impaired fetal development and stillbirth. Diabetic patients are also at increased risk of spontaneous preterm delivery and labor-induced preterm deliveries. Neonatal complications seen at increased rates in infants of diabetic mothers (IDMs) include transient tachypnea of the newborn, neonatal hypoglycemia, hypocalcemia in the peripartum period, hyperbilirubinemia, polycythemia, cardiomyopathy, and respiratory distress as a result of fetal hyperinsulinemia. Elective delivery is indicated in the setting of poor metabolic control, significant diabetic complications, and fetal macrosomia with suspected birth weight more than 4500 g.

OBESITY

The incidence of obesity is increasing, and it has become the most common medical condition in women of childbearing age. It is an independent risk factor of poor outcomes, even without the comorbid conditions of diabetes, vascular disease, or hypertension. In early

gestation, obesity is associated with spontaneous pregnancy loss and congenital anomalies. Increased insulin resistance in obese gravid patients can manifest clinically in late gestation as glucose intolerance and fetal overgrowth. At term, the risk of cesarean section is increased, threefold of that seen in the nonobese population because of inadequate contraction patterns in labor, leading to failure to progress, caused by an independent influence of obesity on myometrial activity, compounded by macrosomia.

Peripartum and postpartum, obese women have a more marked increased risk of venous thromboembolism and depression compared to nonobese counterparts. Meta-analysis has shown obesity to be an independent risk factor for infant death and neonatal asthma; this risk is proportional to increased body mass index (BMI). The BMI does not appear to be correlated with postpartum hemorrhage requiring intervention, severe maternal morbidity or maternal mortality, or spontaneous preterm delivery before 32 weeks of gestation.

THYROID DISORDERS

Hyperthyroidism

Hyperthyroidism affects less than 0.5% of all pregnancies, of which 85% are Graves disease. Because the symptoms of worsening hyperthyroidism resemble the physiologic changes expected during pregnancy in many respects, the diagnosis may not be immediately evident. In the first trimester, most gravid patients with Graves disease will experience a transient exacerbation, but improvement in later pregnancy. A postpartum rebound exacerbation is common.

Thyroid storm is the most serious manifestation of the disease and may be precipitated by stressors such as infection and delivery; it is manifested by fever, dysrhythmias, myocardial dysfunction, and circulatory collapse. Many of these symptoms appear similar to those of eclampsia, so obtaining TSH and free T4 levels on eclamptic patients is recommended. The symptom most helpful in differentiating thyrotoxicosis from thyroid storm is markedly altered mental status seen with thyroid storm. Untreated, mortality approaches 100%, but prompt recognition and aggressive therapy have lowered mortality to 20% to 30%. In addition to more general complications stemming from thyroid hormone excess, early (spontaneous abortion) and late (stillbirth) fetal loss, commonly as a result of placental abruption, are more common in hyperthyroid patients than in the general population.

The mainstay of treating hyperthyroidism consists of thyreostatic drugs. Propylthiouracil is recommended in the first trimester; there is an increased potential for adverse congenital drug effects from methimazole. Post organogenesis, in the second and third trimesters, methimazole is used to limit maternal hepatotoxicity. Most patients respond to pharmacologic manipulation, although thyroidectomy may be considered in severe cases in which patients cannot tolerate antithyroid medication or in the setting of medication failure. Radioiodine is strongly contraindicated during all stages of pregnancy because it will also destroy the fetal thyroid gland.

Additional therapy with beta blockade to mitigate the hemodynamic effects of sympathetic stimulation may be required in certain cases pending disease control with antithyroid medications. Iodide is considered class D in pregnancy because of fetal thyroid sensitivity to the medication; its use should be reserved for severe cases, with duration of therapy limited to days.

Graves disease places the fetus at risk for autoimmune-mediated thyroid dysfunction through placental transfer of maternal thyroid-stimulating immunoglobulins. Up to 20% of neonates of mothers with Graves disease and positive thyroid-stimulating immunoglobulin values have transient hyperthyroidism lasting 3 to 12 weeks. The condition gradually clears as maternal antibodies are metabolized. Manifestations are potentially severe and include irritability, tachycardia, goiter, cardiomegaly, congestive heart failure, premature craniosynostosis, low birth weight, and failure to thrive.

Hypothyroidism

Overt hypothyroidism is often associated with infertility, so most cases seen during pregnancy are less severe. Subclinical disease forms can also be seen or may occur in patients already undergoing levothyroxine therapy for known disease. Undiagnosed subclinical hypothyroidism may become clinically apparent as the metabolic demands of pregnancy unmask deficient thyroid hormone levels. When signs and symptoms do occur, they are generally the same as those in the nonpregnant state. Myxedema coma is extremely rare but should be considered along with other causes of coma in a pregnant patient.

Patients who are already undergoing treatment for hypothyroidism should have therapy optimized pre-conception, but will also require an increased dosage of levothyroxine during pregnancy, especially during the first trimester, in which increases from 20% to 30% are usually required. Compared with euthyroid status, subclinical hypothyroidism in pregnancy is associated with higher rates of gestational hypertension, premature rupture of membranes, intrauterine growth restriction, and low-birth-weight infants; long-term, there is a decreased IQ of the child at age 6 years.

Adrenal Insufficiency

The most common reason for adrenal insufficiency in pregnancy is Addison disease. Early in pregnancy, Addisonian crisis can be mistaken for hyperemesis gravidarum because the clinical features and some electrolyte abnormalities are similar. Overall complications of Addison are greatest in the third trimester, when there is the biggest need for increased cortisol replacement. Careful monitoring of replacement steroids is important to avoid neonatal adrenal insufficiency. Addisonian crisis is precipitated in the gravid patient population by infection, trauma, surgery, delivery or any other significant metabolic stress.

Electrolyte Abnormalities

Gravid patients with primary hyperparathyroidism may develop hypercalcemia, which most commonly presents as nephrolithiasis. Indeed, all pregnant patients with new onset nephrolithiasis should be screened for hypercalcemia. The presence of untreated maternal primary hyperparathyroidism can lead to neonatal hypocalcemia which presents with intrauterine growth restriction, low birth weight, and or neonatal tetany secondary to suppressed development of parathyroid glands. Treatment of the condition is like that in the nongravid state, except that bisphosphonates are contraindicated in pregnancy.

SYSTEMIC INFECTIONS

Human Immunodeficiency Virus Infection

Seroprevalence of HIV infection in pregnant women is decreasing, with more than 8500 annually in 2006 to an estimated less than 5000 in 2018. Treatment of the seropositive HIV pregnant patient with opportunistic infections generally follows similar regimens to nonpregnant patients. There are limited data on specific therapy for opportunistic infections during pregnancy, but clinicians should consider that medication clearance may be affected by various pregnancy-related changes, including increased renal clearance, dilutional anemia, and fetal metabolism of medications. Maternal mortality is increased in HIV-positive mothers, including perinatal sepsis and sepsis related to abortion. Nonpregnancy-related infections, particularly tuberculosis, malaria, and pneumonia, are important causes of maternal death in HIV-infected pregnant or postpartum women.

In patients who are already taking antiretroviral therapy (ART) with good disease control (viral load <1000 copies/mL) at the time of pregnancy diagnosis, the current medication regimen should be continued. For those with a recent diagnosis of HIV, timing of initiation of ART is being reexamined, with a recent meta-analysis suggesting increased risk of preterm or very preterm infants, and low-birthweight neonates, compared to initiating treatment after conception.[28] In the absence of ART treatment, progression of maternal disease does not appear to accelerate during pregnancy, but disease progression is more rapid postpartum. Elective cesarean section is recommended in mothers with a viral load greater than 1000 copies/mL.

HIV does not appear to be an independent risk factor for pregnancy loss and pregnancies generally have good outcomes in patients who receive appropriate HIV treatment during pregnancy. Maternal HIV infection in women who have not received antiretroviral therapy is associated with preterm birth, low birthweight, small for gestational age, and stillbirth.

Vertical transmission of HIV infection (maternal to neonate) remains a monumental challenge in low resource countries with high HIV prevalence (notably sub-Saharan Africa), but is less prevalent in the US due to wide-ranging maternal HIV screening practices. In 2017, only 73 children under the age of 13 received a diagnosis of perinatally acquired HIV in the U.S. Patients presenting to the ED without prenatal care should be screened for HIV as a first point of contact, even if this is shortly after a precipitous delivery. Screening should consist of a rapid combination or fourth generation (antibody/antigen) test, followed by Nucleic Acid Tests (NATs) in high-risk individuals.

Tuberculosis

Comorbid infection or activation of latent tuberculosis (TB) during pregnancy can be challenging to diagnose because pregnancy may mimic and thus mask the symptoms of early tuberculosis (e.g., tachypnea and fatigue). Presenting symptoms in pregnancy are similar to those in the nonpregnant population, including cough, weight loss, fever, malaise, and fatigue. Moderate to severe anemia in an HIV-infected mother during pregnancy should prompt a workup for TB.

Tuberculosis does not appear to accelerate during pregnancy, nor does the pregnant state affect the site of infections. TB activation much more common in the postpartum period than in the prenatal period.

Infants born to TB-infected mothers have a twofold to threefold increased risk of prematurity and low birth weight and increased perinatal death. There is a well-defined constellation of neonatal clinical manifestations marked by cutaneous and mucosal lesions within the first week of life and a primary hepatic complex including caseating hepatic granulomas. These increased risks are highly associated with late diagnosis, inadequate treatment, and advanced disease. Pregnant women with active tuberculosis should begin therapy as soon as the diagnosis is established. The risk of transmission of the organism to the infant outweighs the risks of the drugs to the mother's own health.

The preferred initial treatment for pregnant women is the combination of INH, rifampin, and ethambutol, which has not been shown to be teratogenic. Rifampin and INH freely cross the placenta. Second-line drugs have higher risks of teratogenicity and require more judicious use.

Syphilis

The incidence of primary and secondary syphilis among US reproductive age women has steadily increased since the late 1990s and the incidence of congenital syphilis has shown a similar increase.

Syphilis causes numerous gestational complications, but its most significant sequela is congenital syphilis. This syndrome is characterized by hepatosplenomegaly, osteochondritis, jaundice, rash, lymphadenopathy, rhinitis, Hutchinson teeth, and anemia. Infant mortality related to congenital syphilis is high. Fetal ultrasonography before the 20th week of gestation is indicated to assess for abnormalities consistent with congenital syphilis. Sonographic signs of fetal syphilis confer a higher risk of congenital syphilis at delivery, and few of these completely regress after sufficient treatment.

Treatment is identical to that given to nonpregnant patients, with the use of benzathine penicillin G appropriate for the disease stage. During pregnancy, penicillin is the only known effective treatment for congenital syphilis, and pregnant patients with penicillin allergy should be desensitized and treated with penicillin. Treatment failures leading to congenital syphilis are more likely in mothers with secondary syphilis, high Venereal Disease Research Laboratory or rapid plasma reagin test levels, and an interval from treatment to delivery of less than 30 days.

Viral Hepatitis

Hepatitis B

There are 14,000 new cases of hepatitis B reported annually in the United States, but this is likely an underestimation of disease burden, given the absence of symptoms in early infection. From 800,000 to 1.4 million people in the United States have chronic hepatitis B. Perinatal transmission is approximately 10% to 20% in women seropositive for HBV surface antigen (HBsAg) alone but approaches 90% in mothers who are seropositive for HBsAg and HBV envelope antigen (HBeAg); it is also more likely if the mother has acute infection during the third trimester. Of infants who have HBV infection, up to 90% become chronic carriers as adults and are at risk for complications such as cirrhosis and hepatocellular carcinoma.

Studies have suggested that lamivudine given in late pregnancy to women with high viral loads of HBV DNA reduces viral transmission when used in conjunction with HBV vaccine and immune globulin. Infants of HBsAg-positive mothers should receive hepatitis B immune globulin and the first dose of vaccine within 12 hours of birth. Two additional doses of vaccine are administered at a later date.

Hepatitis C

Between 2009 and 2019, there were 94,824 reported cases of maternal HCV infection among 31 million (0.30%) live births in the United States. The rate of maternal HCV infection increased from 1.8 to 4.7 cases per 1000 live births.[29]

Vertical transmission is rare in mothers with anti-HCV antibodies and no circulating HCV RNA. However, perinatal transmission is increased by the presence of HCV viremia, occurring in approximately 5% of cases. The transmission rate is even higher in the setting of co-infection with HIV; the rates of HCV co-infectivity with HIV are about 10-fold higher than that seen in non–HIV-infected mothers. Perinatal transmission is now the leading cause of HCV transmission to children in middle and high income countries. Cesarean delivery has not been shown to prevent HCV transmission. There is no available vaccine or immune globulin to prevent hepatitis C, and routine prenatal screening is not indicated.

Obstetrical hemorrhagic complications, including DIC and shock and subsequent need for transfusion are more common among HCV infection, with particularly high rates seen peripartum. HCV mothers have higher risk for stillbirth, Cesarean section, preterm birth, SGA. Co-infection with hepatitis B further increases each of these risks.

INFLAMMATORY DISORDERS

Inflammatory autoimmune diseases (IAIDs) have a strong female predilection with onset generally during the childbearing years.

Pregnancy can affect the course of IAIDs with variability: some conditions ameliorate (rheumatoid arthritis), some remain unchanged (Sjögren), and some worsen (SLE). Although all IAIDs are chronic diseases, acute manifestations of IAIDs can be severe, difficult to diagnose and challenging to address in a management plan. Active maternal disease during pregnancy is associated with adverse pregnancy outcomes. These adverse outcomes can be minimized through optimizing disease suppression regimens prior to conception, aggressively managing IAIDs during pregnancy, and aggressively treating emergent complications during pregnancy.

Systemic Lupus Erythematosus

SLE is most common encountered IAID in emergencies related to pregnancy. Maternal complications include lupus flares, hypertension (exacerbation of preexisting disease), nephritis, preeclampsia, and eclampsia. Elevated levels of lupus anticoagulant and antiphospholipid antibodies have emerged as markers of disease activity and are good predictors for adverse pregnancy outcomes. SLE-associated preeclampsia and eclampsia rates, recently as high as 15% to 20%, have been decreasing due to optimal prepregnancy management of active disease and adoption of low-dose aspirin therapy prior to 16 weeks' gestation.[30] Hypertension in SLE-associated pregnancy should lead to careful consideration of lupus glomerulonephritis versus preeclampsia, as both conditions are marked by increasing proteinuria. The presence of abnormal urine sediment, increasing titers of anti-DNA antibody, and decreasing levels of C3 and C4 suggest lupus nephritis.

The most common neurologic complication of SLE in pregnancy is cerebral venous sinus thrombosis. Common presenting symptoms include acute or subacute headache (80%), impaired consciousness (25%), ear complaints (21%), paresis (20%) and epileptic seizures (15%). Neurologic presentations may be associated with a subset of SLE patients who will test positive for antiphospholipid antibodies, and approximately half of these patients will develop thrombosis-related disorders of pregnancy, an antibody-mediated acquired thrombophilia. The most common arterial presentation is stroke; positive antiphospholipid antibody (aPL) test results are found in up to 20% of ischemic stroke patients younger than 50 years of age.

Antiphospholipid syndrome (APS) is characterized by (1) clinical manifestations of deep vessel clotting during pregnancy (2) pregnancy related morbidity, usually fetal or neonatal loss, and (3) confirmatory laboratory tests for lupus anticoagulant, anticardiolipin antibody of IgG and/or IgM isotype, and anti-β2–glycoprotein I antibody of IgG and/or IgM isotype.

The most common thrombotic presentation of APS is deep venous thrombosis (DVT) of the lower extremity. The most serious but rare thrombotic presentation of APS is catastrophic APS (CAPS). This condition is characterized by rapid-onset, small vessel thrombosis, multiorgan dysfunction or failure (renal, hepatic) and a high maternal mortality rate.

Adverse pregnancy outcomes related to IAIDs include fetal death (4%), neonatal death (1%), preterm delivery (9%), and SGA neonate (10%).[31] Baseline predictors of adverse outcomes included presence of lupus anticoagulant, antihypertensive use, an elevated Pregnancy Disease Activity Index score, and low platelet count. Pregnant women with these preexisting measures of active disease had an adverse outcome rate of 58% and neonatal mortality of 22%. Neonates born to patients with lupus are at increased risk of neonatal lupus as well as heart block if born to patients with positive SSA/SSB.

Corticosteroids are the mainstay of therapy for most rheumatologic complications or exacerbations. Aspirin has been advocated for all lupus-related pregnancies of more than 16 weeks' gestational age, and other NSAID regimens remain useful treatments for inflammatory flares. Cytotoxic agents are considered second-line therapy for rheumatic diseases. Cyclophosphamide and methotrexate are both potent teratogens and abortifacients and should be avoided, especially in the first trimester. Azathioprine is a cytotoxic agent that appears to be much better tolerated in pregnancy.

PSYCHIATRIC DISORDERS

Schizophrenia, Bipolar Disorder, and Depression

Similar risks and management principles apply to both schizophrenia and bipolar disorders in pregnancy. In both disorders, abrupt discontinuation of medication leads to high relapse rates in pregnancy. Untreated bipolar disorder and schizophrenia are considered independent risk factors for congenital malformations.

Polypharmacy should be avoided in this patient population during pregnancy in that it contributes to both fetal and maternal risk of adverse outcomes. Sole treatment with second-generation antipsychotics is the recommended management, including intention to control disease with the lowest acceptable dose of any given agent.[32]

Up to 17% of pregnant women experience major depressive disorder, and 25% of pregnant women with bipolar disorder experience mood exacerbation. Anxiety and depression are associated with adverse pregnancy outcomes including preeclampsia, instrument-assisted delivery, and emergency C section.

Adverse neonatal outcomes include low birth weight and preterm delivery. The ill effects of depression in pregnancy can carry into the later newborn period and even into later childhood. Infants of mothers with significant depression show increased cortisol and norepinephrine levels, and decreased dopamine levels. Neonatal outcomes are manifest as altered EEG patterns. reduced vagal tone, and stress/depressive-like behaviors. Adverse pregnancy outcomes include an increased rate of premature deaths and neonatal intensive care unit admissions, and central adiposity in later childhood.[33] Major depressive disorder during pregnancy has had good responses to cognitive behavioral therapy, in addition to pharmacotherapy.

Eating Disorders

The peak incidence of eating disorders occurs during the childbearing years, so the likelihood of anorexia nervosa (AN) or bulimia nervosa (BN) complicating a pregnancy is high. The prevalence of an eating disorder during pregnancy is 7%. The overall prevalence of AN is approximately 1% of young adult women, with a mean age of onset of 17 years, and an overall prevalence of BN of 1% to 3% in the same population. Of all eating disorders, 90% begin before the age 25 years. The high incidence of amenorrhea in AN makes pregnancy less likely than in BN. Medical complications of AN include bradycardia, hypotension, orthostatic changes, hypothermia, mitral valve prolapse, and symptoms associated with electrolyte imbalance. Anemia and transaminitis are also seen.

Pregnancy can frequently precipitate a subclinical eating disorder or exacerbate a condition in remission. The loss of control of body image and weight gain are frequent inciting features for recurrence. Adverse pregnancy outcomes include increased rates of miscarriage, low birth weight, preterm birth, congenital malformations, and increased likelihood of cesarean section births. Inappropriate dieting, with subsequent folate deficiency, increases the rate of congenital neural tube defects. In the postpartum period, depression risk is increased threefold in mothers with a history of eating disorders.

Treatment of eating disorders during pregnancy focuses on the restoration of normal physiologic parameters, electrolyte replacement, and correction of ketosis. There are no recommended pharmacologic interventions for AN by the US Food and Drug Administration, but

antidepressant therapy may be beneficial in those with exacerbations of BN.

Substance Dependence/Use Disorder

The prevalence of substance use disorder in pregnancy has been increasing, with major societal and personal costs. Substance dependence is frequently not identified during pregnancy unless self-reported, or an unplanned pregnancy is discovered during the evaluation of the mother for a substance-related disorder. This is particularly common in the ED, where women of childbearing age are seen frequently for associated complications and pregnancy is coincidentally identified during the visit.

The overall rate of substance use in pregnancy has been steadily increasing in the last 3 decades. According to a national survey conducted in the United States in 2012, 6% of pregnant women use illicit drugs, 9% drink alcohol, and 16% smoke cigarettes, resulting in over 380,000 offspring exposed to illicit substances, over 550,000 exposed to alcohol, and over one million exposed to tobacco in utero. These numbers do not begin to take into account the rapidly rising opioid epidemic un the United States.

The impact of substance use on pregnancy is determined by the following: (1) specific exposure (mono- vs. polysubstance use); (2) gestational timing; (3) duration of exposure; (4) dosing of exposure; and (5) other maternal comorbid conditions (e.g., smoking, general nutritional status). There is a strong association of substance use disorder with psychiatric conditions, particularly depression and psychosis.

Within this context, the terms *use disorder* and *dependence* will be used synonymously, although they are different clinical entities. Both conditions have the same impact on maternal and neonatal health and pregnancy-related complications.

Alcohol

Approximately 50% of women of childbearing age self-identify as alcohol users and 15% are binge drinkers. Nearly 2 million women annually are at risk for alcohol-exposed pregnancies, defined as women who are not using birth control, currently drinking, and are sexually active with a man. Once pregnancy has been identified, the rate of active alcohol consumption in gravid women drops to 7%, and binge drinking to lower than 2%. The true incidence of this disease may be severely underappreciated though. Unfortunately, pregnant women presenting to the ED are 75% less likely to be tested for drug or alcohol use than nonpregnant women.[34] Even when pregnant women present with psychiatric or substance abuse concerns, they are less likely to be screened for alcohol or drug use. Screening for alcohol use in pregnancy is recommended to identify at-risk pregnancies. Screening tools that assume the presence of alcohol intake yield more honest reporting from patients.

There is no safe threshold for alcohol intake during pregnancy, with intake as little as one drink per day being associated with increased rates of IUGR and low birth weight. Heavier consumption of alcohol at more than three drinks/day increases the rate of miscarriage, and more than five drinks/day increases the risk of intrauterine fetal demise two to three times that of nondrinking mothers. Alcohol consumption in pregnancy is the most preventable cause of developmental delay, with alcohol-exposed children having a 1.7-fold greater relative risk of mental retardation and a 2.5 times greater risk of delinquent behaviors.[35]

Congenital abnormalities associated with in utero alcohol exposure can be characterized within the fetal alcohol spectrum disorders. Fetal alcohol syndrome, the most severe of these, has a prevalence of up to 1/1000 births. It is characterized by at least one of a series of morphologic abnormalities in association with a history of heavy alcohol use (>three drinks/day), including midfacial hypoplasia, flat philtrum, low nasal bridge, epicanthal folds, shortened palpebral fissure, low-set ears, and microcephaly. It can also have ocular, cardiac, and skeletal manifestations.

Treatment of an alcohol-dependent mother is difficult. As with nonpregnant patients, withdrawal symptoms are likely to manifest 6 to 24 hours after last alcohol consumption. Any signs of withdrawal should prompt admission and continued management in an inpatient setting. There is a paucity of data on the risk of delirium tremens and major withdrawal in pregnant versus the nonpregnant population. There are also little data on the safety profiles of medications used to ameliorate withdrawal symptoms. The use of naltrexone, acamprosate, or disulfiram or the long-term use of benzodiazepines has not been studied in pregnancy.

Smoking

The long-term deleterious effects of smoking on fetal growth and development have been well documented, up to and including the risk of sudden infant death syndrome (SIDS). Chronic placental insufficiency and vasoconstriction lead to an increased risk of miscarriage, IUFD, preterm birth, IUGR, and clubfoot. Prenatal maternal smoking also has an association with severe bronchiolitis during infancy. Conversely, smoking decreases the risk of preeclampsia.

Treatment for tobacco addiction in pregnancy is largely behavioral and cognitive. Nicotine patches have not been associated with adverse maternal or newborn consequences when used in the second and third trimesters.

Cannabis

Cannabis is the most commonly used recreational drug in pregnancy. There is a maternal association with cannabis use and maternal anemia. Although marijuana use in pregnancy is not associated with any major congenital malformations or increased risk of IUFD, there is an association with low birth weight and need for placement into a neonatal ICU. Infants born to cannabis-using mothers show increased tremulousness, exaggerated startle responses, and high-pitched cries. These are some of the same features associated with neonatal abstinence syndrome (NAS) or Neonatal Opioid Withdrawal Syndrome (NOWS) discussed later in more detail (see "Opioids"). Cannabis is excreted in breast milk and has been associated with neurologic impairment during continued exposure.

Cocaine and Methamphetamines

The prevalence of stimulant use in pregnancy is likely being underrecognized. Maternal cocaine, methamphetamine, and stimulant use is independently linked to IUGR from impaired placental circulation and preterm birth less than 36 weeks' gestation, preeclampsia, IUFD, and increased incidence of cesarean section, gestational hypertension, and gestational diabetes mellitus. Cocaine use also increases the risk of placental abruption and infarction.

Infants of methamphetamine-addicted mothers have lower Apgar scores and increased rates of neonatal mortality and jaundice, but also morphologic difference in brain anatomy, with reduced subcortical volumes. The potential for adverse outcomes is increased in the presence of polysubstance use disorder or other confounding maternal risks, such as poor nutrition. Neonatal congenital abnormalities do not seem to be significantly increased with cocaine use, although there is a slight increased risk of cleft palate with cocaine exposure.

Discontinuation and abstinence are generally the main goals of treatment for pregnant persons addicted to methamphetamines, but immediate discontinuation can cause depression, fatigue, and psychosis. Treatment of a gravid patient who is acutely intoxicated with cocaine or methamphetamine may involve the judicious use of

benzodiazepines and antipsychotics, weighing the risk-benefit ratio for treatment against the medical and psychiatric instability of the patient, but this is not always necessary. Methamphetamine is excreted in breast milk, so infant exposure continues after pregnancy.

Opioids

Roughly 7% of all pregnant patients use opioids, a significant increase over the last decade.[36] This has created a downstream effect of large numbers of addicted infants requiring neonatal intensive care. There is a significant risk of unintended pregnancy among opioid-addicted women, close to 90%, compared to the unintended pregnancy rate in the general population of 40%.[37] The ED is a likely site of entrance of the opioid-addicted gravid patient to the health care system.

There are no well-identified syndromes, congenital abnormalities, or teratogenic effects in infants of opioid-dependent mothers, although there is some association with cleft lip deformities and ventricular septal defects. Neonatal risks include IUGR, specifically symmetric smallness and small head circumference, and an increased risk of SIDS. Maternal risks of postpartum hemorrhage, preterm birth, and increased rates of cesarean section have been documented. The major complication in infants of opioid-addicted mothers is neonatal opioid withdrawal syndrome (NOWS), also known as neonatal abstinence syndrome (NAS), a constellation of physiologic and neurobehavioral changes noted in newborns of addicted mothers secondary to a sudden discontinuation of fetal exposure to substances. The syndrome is characterized by the following: (1) CNS disturbances, including excessive or continuous high-pitched crying, shortened postprandial sleep pattern, hyperactive newborn reflexes, tremulousness, and increased muscle tone, myoclonic jerks, or frank convulsions; (2) metabolic and respiratory abnormalities (e.g., sweating, hyperthermia, yawning, mottling, sneezing, nasal flaring, tachypnea); and (3) gastrointestinal disturbances (e.g., increased sucking, poor feeding, regurgitation or projectile vomiting, loose or watery stools). The Finnegan scale, developed in the 1970s, is still the mainstay of neonatal assessment for NOWS. Treatment of NOWS is supportive. The incidence of NOWS has grown rapidly in the past decade. These infants have a 97% admission rate to neonatal intensive care units.

A new generation of mothers and infants who sustained exposure to methadone, buprenorphine or naltrexone is upon us. Compared to mothers using opioids, those on agonist therapy had improved pregnancy outcomes and decreased risk of NOWS.

CHAPTER 174: REVIEW QUESTIONS AND ANSWERS

1. A 28-year-old G2P1 woman at 26 weeks of gestation presents with a recurrent asthma flare. Vital signs are temperature 36°C, heart rate 110 beats/min, blood pressure 120/60 mm Hg, respiratory rate 28 breaths per minute and O_2 saturation 96%. She has diffuse expiratory wheezes. Arterial blood gas reveals Po_2 90 mm Hg, Pco_2 40 mm Hg, and pH 7.34. Which of the following statements best describes the issues in management with this patient?
- **a.** Corticosteroids are contraindicated.
- **b.** Most patients with asthma improve during pregnancy.
- **c.** She has a metabolic acidosis.
- **d.** Treatment and discharge are likely.
- **e.** Inhaled beta-agonists are first-line therapy.

Answer: E. Beta-agonists followed by corticosteroids are the mainstay of asthma therapy during pregnancy. During pregnancy, one third of asthmatics worsen, one third improve, and one third stay the same. Blood gas interpretation must take into account the "normal" alkemia of pregnancy with a Pco_2 of 30 to 32 mm Hg and a compensatory HCO_3 level of 18 to 20 mEq/L. This patient has a relative "hypoventilation" and may indeed need admission for close observation.

2. A pregnant woman in the second trimester presents to the ED with a complaint of a 5/10 headache and has a blood pressure of 165/100. She reports regular prenatal follow-up. She reports she has a history of mild hypertension dating to before her pregnancy and her blood pressures have been in the 150/90 range during this pregnancy and that she is not on any anti-hypertensive medications. A repeat blood pressure after 15 minutes is 165/100. Which of the following best describes the issues in management of this patient?
- **a.** The patient should have been placed on an anti-hypertensive medication by her OBGYN for her blood pressures of 150/90.
- **b.** A full workup should be completed before treating the patient's hypertension.
- **c.** An IV must be established quickly in order to administer IV anti-hypertensives.
- **d.** Oral nifedipine can be used to lower the patient's blood pressure.
- **e.** ACE inhibitors can be used to lower the patient's blood pressure.

Answer: D. ACOG states that mild chronic hypertension in pregnancy defined as less than a systolic blood pressure of 160 or a diastolic blood pressure of 110 does not need to be treated. Hypertensive emergency in pregnancy is defined as acute-onset persistent hypertension with systolic blood pressure greater than 160 mm Hg or diastolic blood pressure greater than 110 mm Hg that is persistent for greater than 15 minutes. In these cases, antihypertensive therapy should be administered as soon as reasonably possible, and no later than 30 to 60 minutes after diagnosis with a goal blood pressure of 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic. Oral nifedipine, IV hydralazine, and IV labetalol are the drugs of choice in this situation, and IV access attempts should not delay treatment as oral nifedipine can be given. ACE inhibitors are contraindicated in pregnancy.

3. An HIV-positive woman G3P2 at 15 weeks gestation presents with increasing fatigue. She is mildly tachycardia but otherwise with normal vital signs and has normal fetal heart tones. Her labs show a WBC of 10.1, Hgb 6.2, Hct 18, and platelets of 60,000. You should consider what other comorbid condition?
- **a.** Antiphospholipid syndrome
- **b.** Hepatitis B infection
- **c.** Thyrotoxicosis
- **d.** Tuberculosis

Answer: D. The diagnosis of new infection or activation of latent tuberculosis in pregnancy can be challenging, given that common symptoms can be mimicked in normal pregnancy including tachypnea and fatigue. Moderate to severe anemia in an HIV-infected mother should prompt a workup for TB.

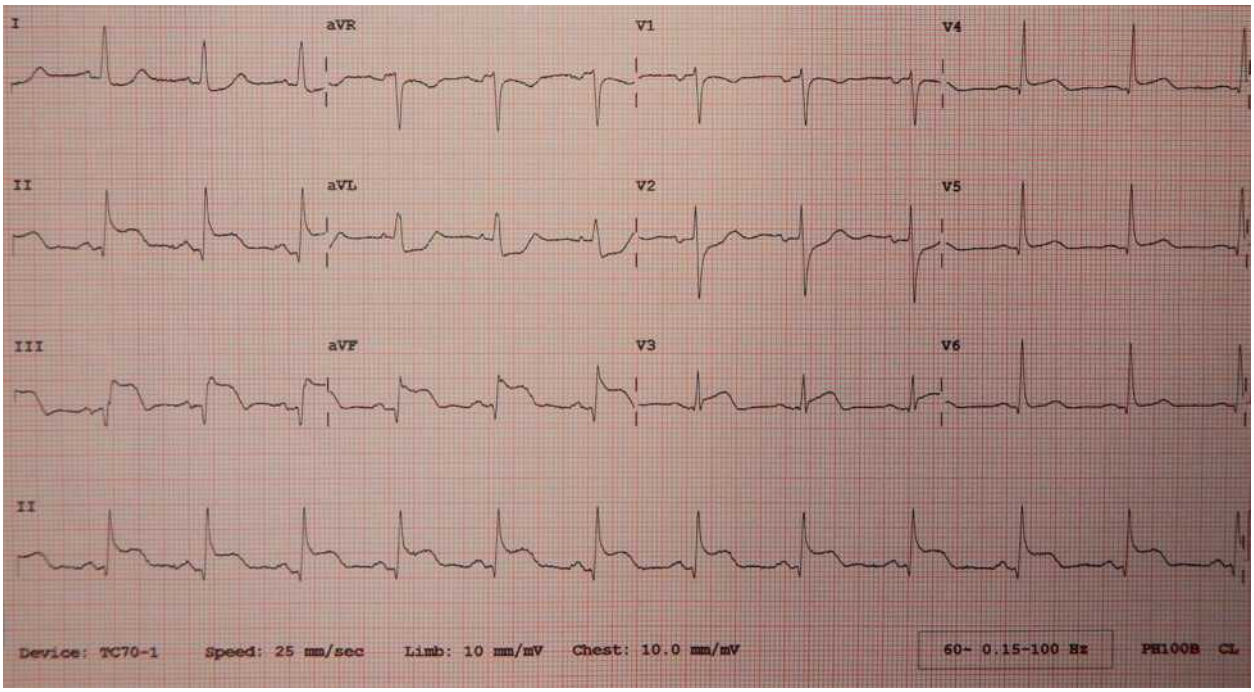
4. A 24-year-old G1P0 woman at 8 weeks' gestation presents with anxiety, sweating, and palpitations. She has a history of Graves disease. She is tachycardic and hypertensive. Her TSH is <0.02 and her free T4 level is 9.2 ng/dl (normal 0.8 to 2.8 ng/dL). Which of the following treatments is most appropriate?
- **a.** Alpha-adrenergic blockade
- **b.** Methimazole
- **c.** Propylthiouracil
- **d.** Radioiodine

Answer: **C.** Radioiodine is strongly contraindicated in pregnancy because it will destroy the fetal thyroid gland. PTU is the treatment of choice in the first trimester because of the risk of adverse congenital drug effects of methimazole during organogenesis. Beta blockade remains the treatment of choice for abnormal vital signs, not alpha-adrenergic blockade.

5. A 20-year-old G2P1 woman at 20 weeks' gestation with a known history of SLE presents with acute onset of R hemiplegia and dysarthria. One hour post onset of symptoms, her head CT is normal. Her symptoms are most likely caused by which of the following?
- **a.** Catastrophic antiphospholipid syndrome (CAPS)
- **b.** Cerebritis
- **c.** Eclampsia
- **d.** Stroke

Answer: D. The most common arterial presentation of neurologic symptoms in lupus patients is stroke; positive aPL results are found in up to 20% of ischemic stroke patients younger than 50 years of age. CAPS is characterized by rapid-onset, small vessel thrombosis, multiorgan dysfunction or failure (renal, hepatic), and a high maternal mortality rate, but not as a large vessel occlusion. Patients with lupus are not at increased risk of cerebritis during pregnancy, and eclampsia does not present as a focal hemiplegic deficit.

6. A 41-year-old G4P3 woman with known hypertension presents at 36 weeks with chest pain and the ECG that follows. Which of the conditions listed below is the most likely diagnosis?
- **a.** Hypertensive emergency
- **b.** Normal physiologic ECG changes of pregnancy
- **c.** Spontaneous coronary artery dissection
- **d.** Stanford type B dissection



English: 12 lead ECG showing inferior and right ventricular infarct

Date 19 May 2014, 06:20:17
Source Own work
Author James Heilman, MD

Answer: C. ECG changes in normal pregnancy include T wave flattening, T wave inversion (mainly in lead III), and nonspecific ST changes during pregnancy, as well as ST depression during labor induction for cesarean section. This ECG demonstrates an inferior MI. Although aortic dissection is more common than ACS in pregnant patients, a type B dissection would not involve the coronary outflow tract. The most common cause of ACS in pregnancy is spontaneous coronary artery dissection.

7. Perinatal maternal complications in women with sickle cell disease include which of the following?
   - **a.** Deep vein thrombosis
   - **b.** Maternal infections
   - **c.** Pain crises
   - **d.** Preeclampsia
   - **e.** All of the above.

Answer: E. Maternal complications are common in patients with SCD; these include preterm labor, premature rupture of membranes, maternal infections, more frequent pain crises, thrombosis, preeclampsia, and increased need for cesarean delivery.[38,39] Due to these complications, pregnant women with SCD have a sixfold increased risk of maternal death compared with controls.

8. A patient with poorly controlled epilepsy is at highest risk of breakthrough seizures during which time period of pregnancy?
   - **a.** 1 to 2 weeks postpartum
   - **b.** During delivery
   - **c.** Post 32 weeks
   - **d.** She is not at increased risk of seizing

Answer: B. Delivery and the first 24 hours postpartum are the most likely times for a seizure to occur, with a nine fold greater incidence of seizure than during pregnancy in general.

9. Which of the following autoimmune disorders most consistently worsens during pregnancy?
   - **a.** Addison disease
   - **b.** Graves disease
   - **c.** Multiple sclerosis
   - **d.** Rheumatoid arthritis

Answer: A. Pregnancy has an immunosuppressive effect. Because of this, pregnancy can have a variable effect on autoimmune disorders. Rheumatoid arthritis consistently improves, Graves disease has a transient worsening in the first trimester but improves later in pregnancy. Patients with MS see a decrease in the frequency and severity of exacerbations. Addison disease is exacerbated, especially in the third trimester, because of the biggest need for cortisol replacement.

Drug Therapy in Pregnancy

Valerie A. Dobiesz and Daniel W. Robinson

KEY CONCEPTS

- Chemically induced birth defects are responsible for approximately 1% to 3% of anomalous births.
- Gestational age is crucial in determination of the impact of any given exposure, especially during organogenesis (days 21–56 of fetal life), when major body organs are formed.
- Human data on teratogenicity and fetal toxicity of medications are often limited, and causal associations are difficult to determine, especially with newer medications.
- In general, the health of the fetus is directly related to the health of the mother, and drugs should be given when the maternal benefits outweigh the risks to the fetus.
- Certain medications should be avoided during pregnancy because they are known teratogens or cause potential toxic effects in the newborn; these include anticonvulsants, warfarin derivatives, NSAIDs, sulfonamides, fluoroquinolones, and ACE inhibitors. If there are no alternatives to these agents, it is recommended to use the lowest dose for the shortest duration possible.

FOUNDATIONS

More than 90% of women take at least one prescription or over-the-counter medication during pregnancy, and overall medication use during pregnancy has increased in the last 3 decades. One study revealed that only 22% of reproductive-aged women have pregnancy testing done when administered or prescribed potentially harmful or teratogenic medications in the emergency department (ED).[1] Unfortunately, the majority of research on the use of medications during pregnancy is insufficient to determine reliable and accurate risks to the mother and fetus, especially for newer agents. Only a few medications have been tested specifically for safety and efficacy during pregnancy. Prescribing medications during pregnancy must account for the physiologic changes associated with pregnancy as well as the benefits and risks to the mother and developing fetus.

The fetal age at exposure to a medication is crucial in determining its impact on the pregnancy. The fetus is most vulnerable to toxic insults during the time of organogenesis (days 21–56 of fetal life). Exposure during this period may result in major anatomic defects. Exposure after the period of organogenesis may affect the growth and development of the fetus. Functional development of the central nervous system (CNS) is affected when it is exposed to a CNS teratogen during the 10th to 17th weeks of pregnancy.

Major birth defects affect 3% to 5% of all live births. Most are of unknown cause, but 1% to 3% of these are thought to be due to pharmaceutical or environmental agents. A teratogen is any chemical, pharmacologic, environmental, or mechanical agent that can cause disruptive development of the conceptus. Included in this definition are functional impairment, growth restriction, and congenital malformations.

The process of establishing teratogenicity is tedious and often flawed. Animal research, although valuable in determining risk initially, is not always applicable to humans, and controlled prospective human studies are generally not performed for ethical reasons. As a result, much of our current knowledge on teratogenicity has been derived from less rigorous studies, which are inherently weak in establishing a causal relationship between a specific exposure and malformations. The genetic background of the fetus, timing and duration of the exposure, environmental factors, multiple exposures, nutritional deficits, maternal illness, and illicit drug use all contribute to the outcome of pregnancy. Large population studies are needed to understand the connection between the outcome of a pregnancy and in utero exposures. Finally, as in the case of diethylstilbestrol, teratogenicity may not be apparent for years after birth.

Classification of Teratogenic Risk

The FDA issued a final rule for drug labeling called the Pregnancy and Lactation Labeling Rule (PLLR) in June 2015. The PLLR changed the content and format of prescription drug labeling to help health care providers better assess the benefits and risks in counseling pregnant and nursing women who are taking medications. The rule requires the removal of letter categories (A, B, C, D, and X) and mandates labeling that includes a summary of data on the risks of a drug used during pregnancy, lactation, and the impacts on male and female reproduction. It requires the provision of current data supporting that summary, and any relevant information to help health care providers make informed decisions and counsel patients. The PLLR also mandates the label be updated when new information becomes available. Drugs already approved before this rule are being phased in. Currently, a number of clinical teratology resources that assign risk are available online, such as Clinical Pharmacology, TERIS, and Micromedex Reprotox (Shepard's *Catalog of Teratogenic Agents*).

Drug Transfer Across the Placenta

Drug transfer across the placenta usually occurs by simple passive diffusion or protein transport. A thin layer of trophoblastic cells is all that separates maternal from fetal circulation. The degree to which a drug gains access to fetal circulation depends on molecular size, ionic state, lipid solubility, and extent of protein binding. Drugs with a molecular mass of less than 5 kilodaltons (kDa) readily diffuse. Anionic substances diffuse through the lipid layer more readily than ionized forms.

A free drug diffuses more readily than a protein-bound drug. Because fetal pH is slightly more alkalotic than maternal pH, weak organic acids may become ion-trapped in the fetal circulation, increasing fetal exposure.

Drug Transfer During Lactation

Generally, drugs that are ingested or injected by the mother diffuse passively into milk and then back into the maternal circulation for excretion. The amount of drug diffusing into milk depends on many factors. Lipid-soluble and nonionic substances diffuse more readily, and highly protein-bound substances diffuse less readily. Whether a substance is concentrated in maternal milk or not, the neonate generally is able to detoxify it with no adverse effects, and only a few drugs pose a serious danger to a breast-feeding infant. The interruption of breast-feeding should not be advocated except in rare situations of known drug toxicity to the infant and in all cases of maternal critical illness.

Drug Therapy During Pregnancy

In general, the health of the fetus is directly related to the health of the mother. Physicians should not withhold lifesaving medications from pregnant patients because of a reported risk to the fetus and should resuscitate pregnant patients according to advanced life support guidelines. Physicians may also prescribe any agent when the maternal benefits outweigh the risks to the fetus. Included in this category are therapeutic medications for asthma, arrhythmias, status epilepticus, life-threatening overdoses, and human immunodeficiency virus (HIV) infection. When prescribing drugs to pregnant and lactating women, the benefits of treatment must be weighed against the inherent risks of treatment or disease. The drug with the lowest known toxicity should be chosen, and used at the lowest effective dose.

PHARMACOLOGIC THERAPY

Analgesic Agents

Over-the-counter analgesics are used commonly during pregnancy, with acetaminophen being used by at least two-thirds of pregnant women. Studies are emerging that call for a reassessment of the safety of these medications. Several studies report increasing use and adverse pregnancy outcomes with opioids, such as neonatal abstinence syndrome and birth defects (Table 175.1).

Acetaminophen

Acetaminophen (paracetamol) is the most widely used analgesic during pregnancy. It has not been associated with congenital malformations

TABLE 175.1 Analgesic Medications

Drug	Breast-Feeding	Clinical Risk Summary
Acetaminophen	Compatible, excreted in breast milk	CP, NHT; studies suggest increased risk of neurodevelopmental problems such as attention-deficit/hyperactivity-hyperkinetic disorder, cryptorchidism, childhood asthma/wheezing
Ibuprofen	Compatible, excreted in breast milk	CP, increased risk of spontaneous abortion at time of conception, association with structural cardiac defects and gastroschisis; risk in third trimester of premature closure of ductus arteriosus and subsequent primary pulmonary hypertension; potential increased risk of asthma with use in pregnancy
Aspirin	Potential toxicity, excreted in breast milk	CP; increased risk of spontaneous abortion at time of conception, avoid chronic or high doses in pregnancy; high doses may increase perinatal mortality, teratogenic effects; increased risk of gastroschisis in first trimester; increased risk of IUGR and fetal and maternal hemorrhage in third trimester; risk in third trimester of premature closure of ductus arteriosus and subsequent primary pulmonary hypertension; near-term use may prolong gestation, labor
Codeine	Potential toxicity Use with caution Excreted in breast milk, metabolized to morphine	LHS; congenital malformation data in humans are inconsistent; avoid prolonged use or high doses near term; may develop respiratory depression and/or withdrawal symptoms, neonatal abstinence syndrome
Oxycodone	Potential toxicity Use with caution Potential for SAR	LHS; use during organogenesis associated with low absolute risk of congenital birth defects; may result in preterm birth, poor fetal outcomes, NOWS
Morphine	Potential toxicity Usually compatible for short-term use Use with caution	CP; use during organogenesis associated with low risk of CBD; may result in preterm birth and poor fetal outcomes; prolonged maternal use during pregnancy may result in NOWS

CBD, Congenital birth defects; *CP,* crosses placenta; *IUGR,* intrauterine growth restriction; *LHS,* limited human studies; *NHT,* no human teratogenicity; *NOWS,* neonatal opioid withdrawal syndrome; *SAR,* serious adverse reactions.

and does not appear to increase the risk of adverse outcomes. There is weak evidence suggesting a link between maternal acetaminophen use in pregnancy with a higher risk of multiple neurodevelopmental problems including hyperkinetic disorders and attention-deficit hyperactivity disorder–like behaviors in children.[1a] Still, it is considered by most clinicians to be the safest analgesic and antipyretic medication currently available during pregnancy and lactation.

Nonsteroidal Antiinflammatory Drugs

Prostaglandin synthesis inhibitors, such as nonsteroidal antiinflammatory drugs (NSAIDs), taken in the first trimester may lead to increased risk of spontaneous abortions, although most of the studies showing this association are limited by not controlling for the conditions for which the medication was taken. The mechanism for this association is inhibition of prostaglandin production by NSAIDs, which is essential for embryonic implantation. Some epidemiologic and animal studies show an increase in ventricular septal defects and gastroschisis with NSAID use during pregnancy. When used in the third trimester, NSAIDs inhibit labor and may be used as tocolytic agents for premature labor. NSAID use in the latter part of pregnancy has been linked to a number of negative effects on the neonate, most notably premature closure of the ductus arteriosus, leading to neonatal pulmonary hypertension, and death.[2] Use in the latter part of pregnancy is therefore discouraged. NSAIDs in general appear to be safe during lactation.

Aspirin

Studies show a proposed increased risk of spontaneous abortion with aspirin use around the time of conception. Chronic or high doses of aspirin during pregnancy should be avoided and may affect maternal and newborn hemostasis and bleeding abnormalities, leading to increased perinatal morbidity and mortality. Aspirin use has been associated with premature closure of the ductus arteriosus causing primary pulmonary hypertension in the newborn, and neonatal death.[2] Low doses of aspirin (60 to 100 mg/day) may be beneficial in pregnancies complicated by systemic lupus erythematosus with antiphospholipid antibodies and those at risk for gestational hypertension and preeclampsia, as well as fetuses with intrauterine growth restriction (IUGR).[3] Aspirin is excreted into breast milk and its use is discouraged during breast-feeding due to risk of Reye syndrome.

Opiate Analgesics

In general, short-term, episodic use of opiates such as oxycodone, hydrocodone, morphine, and fentanyl appear to be safe in pregnancy. Their use near term, however, may result in respiratory depression of the neonate. Prescribing of narcotics for long periods may be associated with preterm birth, low birth weight, reduced infant head circumference, congenital malformations, sudden infant death, and neonatal abstinence syndrome.[4] Neonatal abstinence syndrome is characterized by CNS hyperirritability, autonomic nervous system dysfunction, and higher infant mortality. The short-term use of opiates during lactation appears to be safe, but nursing infants should be closely monitored for respiratory depression.

Rapid Sequence Intubation Agents

Data regarding the use of these agents during pregnancy are limited and have primarily been obtained from animal studies and retrospective human data. None of the agents has been consistently associated with congenital malformations or had adverse effects on the fetus (Table 175.2).

TABLE 175.2 Rapid Sequence Intubation Medications

Drug	Breast-Feeding	Clinical Risk Summary
Fentanyl	Compatible; may cause sedation or respiratory depression	CP; associated congenital birth defects; may cause neonatal respiratory depression, transient neonatal muscular rigidity, NOWS
Etomidate	Probably compatible	CP; animal studies show no teratogenicity; transient decrease in newborn cortisol levels of unknown clinical significance; LHS not harmful when used as induction agent
Propofol	Probably compatible, but not recommended	CP; animal studies show no malformations, LHS with no data on use in first and second trimesters; use at term appears to be safe, but high doses may be associated with neonatal CNS, respiratory depression
Thiopental	Probably compatible; use with caution	CP; LHS; animal studies show no congenital defects, even with high doses; may cause respiratory depression
Ketamine	Probably compatible; plasma levels undetectable after 12 hr	CP; used frequently in obstetrics, not associated with fetal developmental malformations; dose-dependent oxytocic effect; in high doses (>2 mg/kg), associated with uterine tetany; may increase maternal blood pressure and heart rate; may increase neonatal muscle tone or cause apnea and depression of the newborn, SAR usually dose-related
Midazolam	Use with caution Avoid with other CNS depressants	CP; animal studies show no congenital effects, even with high doses; LHS, human observational studies show no malformations, no data on use in first and second trimesters; use near term has resulted in adverse neonatal neurobehavior and neonatal respiratory depression
Succinylcholine	Probably compatible because of rapid hydrolysis	Not embryotoxic or teratogenic in animals; may result in neonatal apnea and partial or complete newborn paralysis in neonates with pseudocholinesterase deficiency
Rocuronium	Probably compatible; LHS	CP; LHS; animal data suggest low risk; newborn neuromuscular blockade is potential complication but probably rare, may have prolonged blockade when used with magnesium
Vecuronium	Probably compatible	CP; LHS; use late in gestation appear to carry little if any risk to the newborn; use lower doses if administering magnesium sulfate

CNS, Central nervous system; *CP,* crosses placenta; *LHS,* limited human studies; *NHT,* no human teratogenicity; *NOWS,* neonatal opioid withdrawal syndrome; *SAR,* serious adverse reactions.

Anticoagulants

Low-molecular-weight-heparin (LMWH) is preferred over unfractionated heparin and warfarin when indicated in pregnancy for therapeutic and prophylactic anticoagulation. Warfarin has the highest teratogenicity of the anticoagulants. The heparins, as a class, do not cross the placenta. All three anticoagulants are considered compatible with breast-feeding (Table 175.3).[5] Oral DTI (dabigatran) and anti-Xa inhibiitors (apixaban, rivaroxaban, edoxaban) have been extensively studied in pregnancy and therefore should be avoided.

Thrombolytic Agents

Alteplase, reteplase, urokinase, and streptokinase have been used successfully in pregnant women in cases of life-threatening pulmonary embolus, myocardial infarction, ischemic stroke, thrombosis of cardiac valve prosthesis, and deep venous thrombosis. Complication rates when used for these indications were similar compared to nonpregnant patients, and none of the live-born children had permanent defects. Recombinant tissue plasminogen activator does not cross the placenta. Poor fetal outcomes have been associated with poor maternal prognosis.

TABLE 175.3 Anticoagulant Medications

Drug	Breast-Feeding	Clinical Risk Summary
Warfarin	Compatible; however, caution advised when breast-feeding premature infants due to increased risk for intraventricular hemorrhage	CP; known dose-dependent teratogen affecting 4%–5% of exposed fetuses; greatest risk at gestational wk 6–9; fetal warfarin syndrome associated with corpus callosum agenesis, hypoplasia of nasal bones, midline dysplasia, optic atrophy and blindness; also associated with fetal osteogenesis, CNS malformations, fetal intraventricular hemorrhage, stillbirths, spontaneous abortions, abnormal development of bones, stippled epiphyses; school-age children exposed in utero had increased incidence of mild neurologic dysfunction
Heparin (UFH)	Compatible	DNCP; associated with maternal osteopenia, immune-mediated thrombocytopenia, maternal hemorrhage at delivery, requiring careful monitoring; has reduced bioavailability, shorter half-life, lower peak plasma concentrations during pregnancy; risk of antepartum bleeding ≈1%
Low-molecular-weight heparin	Compatible	DNCP; lower risk of osteoporosis than UFH has reduced bioavailability, shorter half-life, lower peak plasma concentrations during pregnancy; lower rate of bleeding, HIT, lower allergic response versus heparin; recommended over UFH for VTE

CP, Crosses placenta; *DNCP,* does not cross placenta; *HIT,* heparin-induced thrombocytopenia; *UFH,* unfractionated heparin; *VTE,* venous thromboembolism.
Additional data adapted from: ACOG Practice Bulletin No. 203. Chronic hypertension in pregnancy. *Obstet Gynecol.* 2019;133(1):e26-e50; ACOG Committee Opinion No. 767. Emergent therapy for acute-onset, severe hypertension during pregnancy and the postpartum period. *Obstet Gynecol.* 2019;133(2):e174-e180.

To date, no teratogenic effects have been reported in humans, but intrapartum maternal hemorrhage, fetal hemorrhage, spontaneous abortion, preterm delivery, and fetal death have been reported. Most thrombolytics are thought to be compatible with breast-feeding (Table 175.4).

Antidotes

There are limited human data on the risks of antidote use during pregnancy. Generally, antidotes should be used when there is a clear maternal indication and the potential benefits outweigh the possible risk (Table 175.5). In general, overdoses of medication with higher rates of placental transfer have increased potential for fetal toxicity.

N-Acetylcysteine

N-Acetylcysteine has been used successfully and without untoward effects in pregnant women who have overdosed on acetaminophen. No teratogenic effects have been reported, and pregnant patients who overdose on acetaminophen should be treated the same as nonpregnant patients.[6] It is most likely safe during lactation because it has been used in neonates without untoward effects.

Deferoxamine

Deferoxamine has been associated with developmental effects on ossification in some animal species. Experience in humans is limited, but

TABLE 175.4 Thrombolytic Medications

Drug	Breast-Feeding	Clinical Risk Summary
Alteplase	Compatible Unknown if excreted in breast milk	Embryocidal, not teratogenic, in animal studies; LHS; use if benefits to mother outweigh risks; has been used in human pregnancy with normal fetal outcomes, risk of hemorrhage at any time in gestation
Streptokinase	Use with caution; unknown safety	Use with caution; CP in minimal amounts; no fetal abnormalities reported; antistreptokinase antibodies cross the placenta
Reteplase	Probably compatible Use with caution Unknown if crosses into breast milk	Unknown if CP; risk for bleeding during labor and delivery; abortifacient, but no teratogenicity in animals; LHS; several cases of use with normal infants
Tenecteplase	Hold breast-feeding Unknown safety	Unknown if CP; use with caution, safety unknown; risk of bleeding during labor and delivery; toxicity to mother in animal studies; LHS
Urokinase	Probably compatible Unknown if excreted in breast milk	Probably acceptable in pregnancy; not fetotoxic or teratogenic in animal studies; unknown if CP; placental hemorrhage and separation may occur; increased risk of bleeding during pregnancy; LHS

CP, Crosses placenta; *LHS,* limited human studies.
Additional data adapted from: ACOG Committee Opinion No. 767: Emergent therapy for acute-onset, severe hypertension during pregnancy and the postpartum period. *Obstet Gynecol.* 2019;133(2):e174-e180; ACOG Practice Bulletin No. 212. TABLE 175.5 Antidotes

Drug	Breast-Feeding	Clinical Risk Summary
N-Acetylcysteine	Probably compatible unknown if excreted in milk so consider waiting 30 hr for elimination	CP; not teratogenic or embryotoxic in animal studies; LHS; no adverse fetal outcome when administered IV as antidote in acetaminophen overdose
Deferoxamine	Probably compatible Unknown if excreted in breast milk	LHS; no adverse toxic or teratogenic effects seen; animal studies show toxicity and teratogenicity (delayed ossification, skeletal anomalies)
Digoxin immune fragment	Probably compatible Unknown if excreted in breast milk	Unknown if CP; LHS; no adverse outcomes in fetus or newborn
Dimercaprol	Contraindicated Unknown if excreted in breast milk	Animal studies show teratogenicity; safety in pregnancy unknown; chelates essential elements including zinc, copper, and iron that may alter fetal development but LHS
Flumazenil	Probably compatible Unknown if excreted in breast milk	Unknown if CP, but may occur; animal studies show no teratogenicity or impaired fertility; LHS
Fomepizole	Hold breast-feeding	No animal or human studies; safety unknown
Hydroxocobalamin	Probably compatible, but monitoring of infant recommended	Animal studies showed no teratogenicity; LHS, safety unknown
Methylene blue	Probably compatible Unknown if excreted in breast milk	Epidemiologic evidence of teratogenicity; diagnostic intraamniotic injection resulted in hemolytic anemia, hyperbilirubinemia, methemoglobinemia, jejunal-ileal atresias
Naloxone	Probably compatible Unknown if excreted in breast milk LHS	CP; animal studies show no teratogenicity, no adverse fetal outcomes in human studies
Physostigmine	Probably compatible but safety unknown	Rarely used in pregnancy; no reports linking it with teratogenicity; safety unknown
Pralidoxime	Hold breast-feeding for 6 to 7 hr after dose	Rarely used in pregnancy; safety unknown; limited human case reports, with no adverse outcomes
Pyridoxine	Compatible	High doses appear to pose little risk to the fetus; no increased risk of malformations in first trimester in human trials
Succimer	Contraindicated Heavy metals may be excreted in breast milk, cause harm to newborn	Teratogenic and fetotoxic in animals; avoidance in first trimester recommended for pregnant women unless severe symptoms; LHS

CP, Crosses placenta; *LHS,* limited human studies.

Additional data adapted from: Lai T, Wu M, Liu J, et al. Acid-suppressive drug use during pregnancy and the risk of childhood asthma: A meta-analysis. *Pediatrics*. 2018;141(2):e20170889; McParlin C, O'Donnell A, Robson SC, et al. Asthma outcomes and management during pregnancy. *Chest*. 2018;153(2):515-527; Chambers C. Over-the-counter medications: Risk and safety in pregnancy. *Semin Perinatol*. 2015;39(7):541-544.

has been used in pregnancy without adverse effect on the fetus. The effects of deferoxamine on the nursing infant are not known, but are probably compatible.

Digoxin Immune Fragment

There are very few case reports of the use of digoxin immune fragment (Fab) during pregnancy, so effects on the fetus are inconclusive. In cases of life-threatening digitalis overdose with arrhythmias, the benefits of treatment of the mother outweigh the risk to the fetus. Digoxin fab is probably safe for use during lactation.

Dimercaprol

Dimercaprol, or British antilewisite, is teratogenic in mice and has been associated with increased mortality, growth restriction, cleft facial features, cerebral herniation, and abnormal digits, but experience in humans is limited. In general, with heavy metal poisonings, the maternal benefits of treatment will outweigh the potential risks to the fetus. Breast-feeding is contraindicated in patients poisoned by heavy metals.

Flumazenil

No teratogenic effects have been reported with flumazenil in animals, and there are limited human data. Its use in pregnancy and lactation depends on the potential maternal benefit compared with possible risks to the fetus and nursing infant. Because it has a short half-life, breast-feeding may resume after a few hours.

Fomepizole

Fomepizole use during pregnancy has not been studied in animals or humans. Its safety during pregnancy is not known. In cases of toxic alcohol poisoning, the benefits of treatment of the mother outweigh the possible risks to the fetus or nursing infant. Use of ethyl alcohol in these situations may be considered. Breast-feeding is not recommended during treatment.

Hydroxycobalamin

The effects of hydroxycobalamin on human pregnancy have not been studied, but benefits of its use in cyanide poisoning outweigh any risk to the fetus. Use is considered compatible with breast-feeding.

Methylene Blue

Historically, methylene blue was injected into the amniotic sac to identify twins and detect rupture of the membranes, but these practices were associated with hemolytic disease in the newborn, hyperbilirubinemia, and deep blue staining of the newborn. Methylene blue in pregnancy has also been associated with an increased incidence of intestinal obstruction and atresia in the newborn, primarily with

intra-amniotic or intrauterine administration. Methylene blue has been used successfully in pregnant women with methemoglobinemia; however, the benefits of treatment should outweigh the risks of the therapy and must be considered. The effects of methylene blue on the nursing infant are expected to be minimal.

Naloxone

Naloxone readily crosses the placenta. Although it has not been associated with reproductive abnormalities, its use during pregnancy results in increased fetal wakefulness, increased fetal movement, and increased heart rate, effects attributable to the antagonism of fetal endorphins. In addition, its use in opiate-addicted mothers may precipitate withdrawal in mother and term fetus. The use of buprenorphine with naloxone in pregnant women with opioid use disorder has been found to be safe.[7] It is compatible with breast-feeding.

Physostigmine

Experience during pregnancy is limited, and its effects on the developing fetus are unknown. Use of physostigmine at term has been associated with only mild decreases in Apgar scores at 1 and 5 minutes. Physostigmine is thought to be safe with breast-feeding.

Pralidoxime

Experience with pralidoxime in pregnancy is limited, and its effects on fetal development are not known. In cases of organophosphate poisoning, the benefits to the mother generally outweigh the possible risk to the fetus. Breast-feeding can be resumed after 6 to 7 hours after the last dose.

Pyridoxine

Pyridoxine, vitamin B_6, has not been associated with any adverse developmental effects when given in high doses, and it is safe in lactation.

Dimercaptosuccinic Acid (Succimer)

Succimer has been linked to congenital defects in animal models, possibly because of its negative effects on zinc and copper metabolism. Experience with the use of succimer in human pregnancy is limited to case reports, and adverse effects are unknown. Breast-feeding is contraindicated in heavy metal poisoning.

Antiinfective Agents

Infections during pregnancy potentially affect outcomes as well as fetal development. In the first trimester, infections are a common cause of spontaneous abortion and, in the second or third trimester, they are the most common cause of low birth weight and preterm labor. Antimicrobial agents may also adversely affect the pregnancy. Aminoglycosides, for example, may be nephrotoxic and ototoxic to the mother and newborn, tetracyclines may result in dental staining of the developing fetus, and lincosamides may be skeletotoxic.

The penicillins, cephalosporins, and macrolide antibiotics are the drugs of choice for infections during pregnancy. Alternative classes of antibiotics are prescribed only if these have failed to control the infection or in cases of severe maternal intolerance to these drugs. The choice of antimicrobial therapy will depend on the gestational age of the pregnancy, severity of infection, and maternal tolerance for the drug used. Many drugs are secreted into breast milk. Potential problems for the neonate include direct effects on the neonate, changes in bowel flora, diarrhea, and potential interference with culture results (Table 175.6).

Antibiotics

Aminoglycosides

Aminoglycosides do not appear to have any structural teratogenic effects in humans. Kanamycin and streptomycin have been reported to cause ototoxicity in the mother and her offspring. There are no reports definitively linking in utero exposure to gentamicin, streptomycin,

TABLE 175.6 Antiinfective Medications

Drug	Breast-Feeding	Clinical Risk Summary
Aminoglycosides	Probably compatible Excreted in breast milk Oral absorption poor	No definable structural risk of any aminoglycoside when exposed in utero; streptomycin—low incidence of ototoxicity with careful dosing
• First generation	Compatible	CP; NHT (most studies); conflicting studies on risk of congenital defects in first trimester
• Second generation	Compatible	CP; immune hemolytic reactions observed, especially with cefotetan
• Third generation	Compatible	CP; immune hemolytic reactions observed
• Fourth generation	Compatible	CP; LHS
Chloramphenicol	Potential toxicity (LHS) Excreted in breast milk	CP; may cause grey baby syndrome; idiosyncratic bone marrow suppression
Clindamycin	Compatible Excreted in breast milk	CP; no reports of fetal toxicity or malformations
Fluoroquinolones	Compatible Excreted in breast milk	Ciprofloxacin, ofloxacin, and levofloxacin CP; few reports of arthrotoxicity; risk of major malformations low; caution use during first trimester, risk of cardiac defects
Linezolid	Potential toxicity (LHS) Excreted in breast milk	No studies in pregnancy Use with caution
Macrolides	Compatible Excreted in low concentrations in breast milk	Estolate salt—may induce hepatotoxicity in pregnant patients; no risk of congenital heart malformations or pyloric stenosis, but use of erythromycin in infancy associated with pyloric stenosis
Metronidazole	Compatible Excreted in breast milk—but AAP recommends cessation of breast-feeding during use	CP; in vitro mutagen; NHT
Nitrofurantoin	Compatible	Caution advised with G6PD deficiency—may cause hemolytic anemia; limit use in later pregnancy

Continued

TABLE 175.6 Antiinfective Medications—cont'd

Drug	Breast-Feeding	Clinical Risk Summary
Penicillins	Compatible Small amount excreted in breast milk	CP; long-standing safety data
Sulfonamides	Compatible Excreted in breast milk Caution in newborns, infants with known G6PD deficiency	CP; adverse effects rare; most reports fail to demonstrate congenital malformations; concern for jaundice, hemolytic anemia, kernicterus; trimethoprim is folate antagonist—use with caution
Tetracyclines	Compatible Excreted in breast milk	CP; doxycycline poses little teratogenic risk; adverse effects on fetal bone development; discoloration of adult teeth; oxytetracycline shows neural tube defects, cleft palate, cardiac defects
Vancomycin	Compatible IV form found in breast milk, but, no oral absorption	No toxicity or teratogenicity found
Clotrimazole	Compatible	Systemic absorption from skin minimal; vaginal and topical formulations preferred over oral lozenge; NHT; avoid vaginal use during first trimester; some reports suggest increased risk of spontaneous abortions
Fluconazole	Compatible	High dose in first trimester associated with malformations; If necessary vaginal formulation preferred.
Ketoconazole	Compatible Excreted in breast milk	NHT, but teratogenicity seen in animal studies
Nystatin	Compatible Not excreted in breast milk	Poor systemic absorption from vaginal formulation (preferred route); often first-line therapy in pregnancy
Terbinafine	Potential toxicity Excreted in breast milk	LHS; Likely compatible
Isoniazid	Compatible Excreted in breast milk	CP; benefits of treatment outweigh risks; NHT
Ethambutol	Compatible Excreted in breast milk	CP; benefits of treatment outweigh risks; no adverse effects seen
Rifampin	Compatible Excreted in breast milk	CP; benefits of treatment outweigh risk; hemorrhagic disease of newborn
Acyclovir	Compatible Excreted in breast milk	CP—found in higher concentrations than in maternal blood; systemic use should be avoided unless benefits outweigh the risks; NHT
Valacyclovir	Compatible Excreted in breast milk	CP; LHS
Famciclovir	Potential toxicity	Unknown if crosses placenta or enters breast milk; LHS
Amantadine	Potential toxicity (LHS) Excreted in breast milk	CP; teratogenicity in animals; associated with cardiac malformations.
Oseltamivir	Compatible Excreted in breast milk but in low concentration	Benefits of treatment during gestation likely greatly outweigh risks; no congenital malformations identified

AAP, American Academy of Pediatrics; *CP,* crosses placenta; *G6PD,* Glucose-6-phosphate dehydrogenase; *LHS,* limited human studies; *LS,* limited studies; *NHT,* no human teratogenicity.
Additional data adapted from refs.[24-37]

tobramycin, and neomycin with ototoxicity or nephrotoxicity. Aminoglycosides are probably compatible with breast-feeding.

Cephalosporins

The first- to fourth-generation cephalosporins appear to be safe during pregnancy, although there have been no controlled studies examining their safety. Some cephalosporins are excreted into breast milk and may interfere with culture results in the evaluation of neonatal sepsis.

Chloramphenicol

Chloramphenicol is associated with bone marrow suppression and aplastic anemia. Apart from these complications, its use during pregnancy appears to have no effects on the developing fetus. Exposure to topical chloramphenicol during pregnancy appears to have no adverse effects. However, it is contraindicated at birth because chloramphenicol has been associated with cardiovascular collapse in the neonate, the so-called gray baby syndrome. Chloramphenicol is secreted into the breast milk, and therefore not recommended for use during lactation.

Clindamycin

Clindamycin has not been associated with birth defects in humans or in animal studies. The American Academy of Pediatrics (AAP) considers clindamycin to be compatible with breast-feeding, although there is a rare association with bloody diarrhea in nursing infants.

Fluoroquinolones

Fluoroquinolones are linked to numerous toxic effects on bone and cartilage growth in animal models and are discouraged from use during pregnancy, particularly during the first trimester. Observational studies, however, have failed to demonstrate such a toxic effect on the

human fetus. Meta-analyses have not found an association between fluoroquinolones and fetal malformations, preterm delivery, stillbirth, or spontaneous abortions.[8] Regardless, at this time, they are not recommended in the first trimester until further studies are done. Ciprofloxacin is compatible with breast-feeding, but data are inconsistent for other quinolones, and they are best avoided in lactation.

Linezolid

Linezolid is linked to embryonic death, decreased weight, and abnormalities in cartilage and ossification in animal studies, but human data are lacking. Its use in pregnant women should be limited to cases in which the maternal benefits outweigh possible risks to the fetus. Linezolid is likely compatible with breast-feeding.

Macrolides

Erythromycin is considered safe for use in pregnancy and compatible with breast-feeding. Some reports have linked erythromycin to pyloric stenosis and congenital heart defects. The estolate salt of erythromycin is associated with the development of hepatotoxicity in pregnant women and should be avoided. Clarithromycin is associated with an increased risk of fetal and embryonic death, as well as with congenital malformations in animal studies; this has not been shown in humans. Meta-analyses demonstrate a weak association between macrolides and congenital malformation but data are conflicting.[9] Azithromycin is poorly concentrated in breast milk and may be the preferred agent in lactating mothers.

Metronidazole

Metronidazole is mutagenic and carcinogenic in mice and rats. In humans, a number of studies have failed to demonstrate a clear association between metronidazole and congenital malformations when used in the first trimester of pregnancy. Metronidazole has been used during the second and third trimesters to treat bacterial vaginosis, with no untoward effects.[10] The use of metronidazole during lactation is discouraged because of its potential mutagenic and carcinogenic effects reported in rats, and its slow elimination from infants.

Nitrofurantoin

Though historically considered safe throughout pregnancy, except near term, there is some literature that associates nitrofurantoin use in the first trimester to a number of congenital abnormalities.[11] We recommend to avoid use in the first trimester, but can be used in the second and third trimesters. It is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Penicillins

The first- to fourth-generation penicillins and their derivatives (including procaine, benzathine, clavulanate, sulbactam, and tazobactam) are considered safe for use in pregnancy, as is oral probenecid. Penicillins are considered safe during breast-feeding, but their use may interfere with culture results if evaluation is required for a neonatal fever.

Sulfonamides

Sulfamethoxazole, commonly combined with trimethoprim, is contraindicated in pregnancy because of an increased risk of neural tube defects and other congenital abnormalities, such as cleft palate. There is also an increased risk of cardiovascular and urinary tract malformations in the offspring of women treated with trimethoprim-sulfamethoxazole in the first trimester. Sulfonamides are contraindicated near term because of their association with kernicterus; they are excreted in breast milk and generally tolerated by a healthy neonate. They should be avoided, however, in ill or premature infants and in infants with hyperbilirubinemia or glucose-6-phosphate dehydrogenase deficiency.

Tetracyclines

Tetracycline and doxycycline readily cross the placenta. Tetracycline is associated with the development of fatal fatty liver in pregnant women. It chelates calcium, causing abnormalities in bone growth and staining of decidual teeth. It is associated with fetal genitourinary anomalies, inguinal hernias, and limb abnormalities. Tetracycline should therefore be avoided during pregnancy.

Doxycycline does not bind to calcium and is associated less with stained teeth than tetracycline. It does not appear to cause an increase in any type of congenital malformation. Despite these findings, doxycycline is not recommended in pregnancy.

Because tetracycline binds to breast milk calcium, only a small amount reaches the nursing infant, and it may be used for short periods (<10 days) during breast-feeding. Doxycycline does not bind to breast milk calcium and is present in greater quantities in breast milk. This could theoretically increase its side effects in the newborn. Its use in nursing infants is best avoided.

Vancomycin

Vancomycin has not been linked to birth defects in animals or in humans. Reports of auditory abnormalities and renal insufficiency in neonates of mothers treated with vancomycin are believed to be false positives because these abnormalities were resolved on retesting. Vancomycin is excreted into milk but not well absorbed by the GI tract. Its effects on the nursing infant have not been studied.

Antifungals

Nystatin has a long safety profile during pregnancy and lactation. It is poorly absorbed from skin, mucous membranes, and the GI tract and is considered the antifungal of choice for the treatment of mucocutaneous fungal infections. Clotrimazole, miconazole, and ketoconazole are considered second-line treatment of fungal infections. Fluconazole is teratogenic in high doses (>400 mg/day) and has been associated with spontaneous abortions and stillbirth as well as an increased incidence of craniofacial and cardiovascular defects in offspring and multiple abnormalities of the skeleton and cartilage. There are conflicting reports about the teratogenic effects, but expert recommendations suggest that a single dose of 150 mg one time during pregnancy after the first trimester is unlikely to be associated with teratogenesis.[12]

Ketoconazole, fluconazole, and itraconazole are excreted into breast milk. Because of the safe use of ketoconazole in neonates and the lack of negative reports, it is considered compatible with breast-feeding (see Table 175.6).

Antituberculous Agents

The incidence of tuberculosis is higher during pregnancy and postpartum than in the general population. Untreated tuberculosis places the mother, fetus, and family at greater risk than the use of antituberculous medications. Isoniazid, ethambutol, and rifampin cross the placenta and no association has been reported between these medications and major congenital malformations. Rifampin is associated with hemorrhagic disease of the newborn. Despite this adverse effect, it is considered first-line therapy for the treatment of tuberculosis. All three antituberculous medications are considered compatible with breast-feeding (see Table 175.6).

Antiviral Agents

Antiherpetic Drugs

Acyclovir readily crosses the placenta and reaches higher concentrations in fetal circulation than in maternal circulation. Neither acyclovir nor valacyclovir has been associated with congenital malformations or adverse effects on the offspring. Intravenous (IV) acyclovir is the drug of choice for life-threatening maternal herpes simplex virus infections,

such as disseminated disease, herpes encephalitis, and varicella pneumonia, which carries a maternal mortality of 44% if untreated. For non–life-threatening genital herpes infection in pregnant women, acyclovir or valacyclovir may be used. Experience with famciclovir is limited and therefore it is not recommended for use in pregnancy. Because there are no reported adverse outcomes in infants of mothers taking acyclovir or in infants treated with acyclovir for disseminated herpes, it is considered safe during breast-feeding (see Table 175.6).

Antiinfluenza Drugs

Influenza in pregnancy carries a high risk of morbidity and mortality. Neuraminidase inhibitors, such as oseltamivir and zanamivir, are active against influenza A and B and are associated with improved outcomes. Oseltamivir is considered the treatment of choice for influenza in pregnancy and available safety data report no significant risk to the fetus. Antiviral therapy with M2 ion channel inhibitors, such as amantadine and rimantadine, is also effective against certain subtypes of influenza A but not influenza B. However, amantadine has been linked to various malformations, including cardiac defects in humans, and is considered teratogenic and embryotoxic in rats.

Oseltamivir appears to be safe in lactation. In addition to antiviral therapy, the Centers for Disease Control and Prevention (CDC) recommends that pregnant women receive the inactivated influenza vaccine at any point during pregnancy (see Table 175.6).

Anti-HIV Drugs

Mothers infected with human immunodeficiency virus (HIV) are treated with antiretroviral therapy (ART) in order to decrease mother-to-child HIV transmission as the viral load of the mother directly correlates with the risk of perinatal transmission. No specific pattern of birth defects has been described with the use of anti-HIV drugs,[13] but the drugs' mutagenesis and carcinogenesis and their long-term effects on the liver, heart, and reproductive system are yet to be determined.

Animal and human data suggest that didanosine, lamivudine, stavudine, zidovudine, and zalcitabine present a small risk of structural malformations and mitochondrial dysfunction in the developing fetus, but no specific pattern of birth defects has been described with protease inhibitors, such as ritonavir and nelfinavir. Despite potential risks, it is thought that the benefit from HIV treatment far outweighs the risk of these drugs and should not be withheld. In addition, zidovudine has been shown to reduce vertical and perinatal transmission of HIV from the mother to the fetus. Because of the risk of postnatal HIV transmission through milk, the CDC advises against breast-feeding by HIV-positive mothers.

Cardiovascular Agents

Antidysrhythmics

Atrial and ventricular arrhythmias are common during pregnancy. Most are benign; however, malignant degeneration occasionally occurs. All unstable tachycardias should be treated with electrical cardioversion and Advanced Cardiovascular Life Support (ACLS) guidelines. Stable patients may be treated medically, but the choice of drugs needs to be modified to protect the patient as well as the fetus from the drug's potentially harmful effects (Table 175.7).

Adenosine. Adenosine has been used safely throughout pregnancy and is the drug of choice for termination of maternal supraventricular tachycardia. Adenosine has also been used safely for termination of incessant tachycardia in the fetus. Adenosine is safe in lactation.

Amiodarone. Amiodarone contains large amounts of iodine and is associated with congenital goiter and transient neonatal hyperthyroidism and hypothyroidism. Amiodarone has been linked to many congenital abnormalities, including growth restriction, structural cardiac abnormalities, corneal deposits, and developmental delay. It should be used only in refractory cases of supraventricular or ventricular tachycardias in the mother and incessant tachycardias in the fetus. Because of its high iodine content, excretion into milk, and long elimination half-life, amiodarone should not be used in nursing mothers.

TABLE 175.7 Antidysrhythmic Medications

Drug	Breast-Feeding	Clinical Risk Summary
Adenosine	Compatible	Many reports show compatibility during pregnancy; LHS; effects on fetus unknown, but teratogenicity or malformations not expected
Amiodarone	Contraindicated excreted in breast milk Concern for hypothyroidism	CP; linked to many congenital abnormalities; thyroid abnormalities, congenital goiter have been observed; contains high concentration of iodine; use only in refractory tachydysrhythmias
Digoxin	Compatible excreted in breast milk	CP; NHT; one of the safest antiarrhythmics during pregnancy
Quinidine	Probably compatible (LHS) Excreted in breast milk	CP; no teratogenic effects in humans reported; LHS
Lidocaine	Compatible excreted in breast milk	CP; animal studies—no harm; high doses near term associated with neonatal CNS depression, hypotonia, seizures, bradycardia
Procainamide	Probably compatible (LHS) Excreted in breast milk	LHS
Flecainide	Compatible Concentrated in breast milk	LHS; animal data suggest possible teratogenicity
Ibutilide	Probably compatible (LHS)	Unknown if CP; animal studies show teratogenicity, embryocidal events
Sotalol	Potential toxicity (LHS) Concentrated in breast milk. Conflicting reports	CP; may cause fetal bradycardia and/or IUGR

CP, Crosses placenta; *IUGR,* intrauterine growth restriction; *LHS,* limited human studies; *NHT,* no human teratogenicity.
Data adapted from refs.[38,39]

Digoxin and Quinidine. Digoxin and quinidine are considered safe for use during pregnancy and lactation. Neither has been linked to congenital defects in humans or animals, and they are first-line agents for the treatment of significant maternal dysrhythmias. They have also been successfully used in fetal tachycardia. During lactation, digoxin and quinidine appear compatible with breast-feeding.

Lidocaine. Lidocaine rapidly crosses the placenta and becomes ion-trapped in the fetus. There is no evidence of a link between the use of lidocaine in the first trimester and any fetal developmental malformations. However, high doses used near term are associated with neonatal CNS depression, apnea, hypotonia, seizures, and bradycardia. Lidocaine is considered compatible with breast-feeding.

Procainamide. Procainamide has been safely used in the treatment of stable, wide-complex tachydysrhythmias during pregnancy. It is not associated with fetal developmental abnormalities and appears well tolerated when used for a short duration. It is associated with a high incidence of maternal antinuclear antibodies and the occurrence of a lupus-like reaction in humans. During lactation, procainamide and its metabolite, *N*-acetylprocainamide, are found in breast milk. The AAP considers its short-term use compatible with breast-feeding.

Flecainide. Flecainide has been used safely to terminate maternal and fetal tachycardia, but it is associated with fetal hyperbilirubinemia, hepatotoxicity, and loss of fetal heart rate variability. Flecainide has also been found to be teratogenic in some animal species, resulting in cardiac and musculoskeletal abnormalities. It is present in breast milk and the AAP considers it compatible with breast-feeding, despite limited experience.

Ibutilide. There are only a few case reports of the successful and safe use of ibutilide during the latter part of pregnancy in humans. In animals, however, ibutilide was found to be teratogenic and caused

TABLE 175.8 Antihypertensive Medications

Drug(s)	Breast-Feeding	Clinical Risk Summary
Angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists	Probably compatible, but variable safety	Use in second and third trimesters may cause teratogenicity, severe fetal/neonatal toxicity; reduce fetal renal function; associated with anuria, PDA, IUGR, prematurity, abnormal bone, lung development, renal failure, death
Esmolol	Safety unknown Appears to be low risk	LHS; not thought to cause structural anomalies; may result in persistent beta blockade of fetus or newborn[a]
Labetalol	Probably compatible Low excretion in breast milk	LHS; little risk to fetus except possibly in first trimester; most studies found no effect on fetal growth; IUGR and RPW may occur if used near delivery; newborn should be monitored for 24–48 hr for symptoms of beta blockade[a]
Metoprolol	Conflicting reports Concern for toxicity Excreted in breast milk	CP; LHS; no animal teratogenicity; may cause IUGR, RPW, and persistent beta blockade in newborns[a]
Propranolol	Conflicting reports Concern for toxicity	CP; NHT; fetal and neonatal toxicity may occur; may cause IUGR and RPW if used near delivery; newborn should be monitored for 24–48 hr for symptoms of beta blockade[a]
Amlodipine	Probably compatible, but safety unknown Neonatal myocardium sensitive to changes in calcium status Caution during breast-feeding	LHS; animal studies demonstrated fetotoxicity; safety unknown; case reports of IUGR, fetal death, neonatal rash
Diltiazem	Probably compatible, but safety unknown Neonatal myocardium sensitive to changes in calcium status Caution during breast-feeding	LHS; animal studies demonstrate fetotoxicity, teratogenicity; safety unknown
Nicardipine	Probably compatible but safety unknown LHS	Dose-related embryonic toxicity but not teratogenicity in animals; LHS; neonatal hypotension and acidosis reported, but safety unknown; causes hypotension, reflex tachycardia, PPH, tocolysis, headache, nausea, dizziness, flushing in pregnancy
Nifedipine	Probably compatible but safety unknown Advised to delay breast-feeding for 3–4 hr	LHS; safety unknown; NHT; has been used as a tocolytic agent; may potentiate neuromuscular blocking action of magnesium
Verapamil	Probably compatible	CP; animal studies show adverse effects on fetal growth and fetotoxicity, LHS; appears to be low risk during any stage of pregnancy
Furosemide	Probably compatible Caution advised May suppress lactation	CP; LHS; fetotoxic and teratogenic in animals; no significant alteration of amniotic fluid volume; monitor fetal growth because may cause higher birth weight
Hydrochlorothiazide	Compatible Excreted in breast milk May suppress lactation	CP; NHT; risks to fetus and newborn include hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia, death; may inhibit labor by direct effect on smooth muscle
Nitroglycerin	Probably compatible Monitoring infants recommended	LHS; no adverse effects in animal studies; safety unknown, but appears safe; tocolytic
Nitroprusside	Potential toxicity	CP; LHS; adverse effects in animal studies, caution advised; transient fetal bradycardia noted; accumulation of cyanide in fetus may occur
Clonidine	Probably compatible May alter prolactin and oxytocin levels, affecting lactation	CP; LHS; safety unknown; no observed adverse fetal effects in humans; may develop sleep disorders later in life with prolonged use during pregnancy
Hydralazine	Probably compatible LHS Excreted in breast milk	CP; use with caution, no known congenital defects, but fetal toxicity associated with third-trimester use; meta-analysis on use in preeclampsia demonstrated more hypotension, placental abruption, cesarean section, maternal oliguria, adverse fetal heart rates, lower Apgar scores compared with labetalol or nifedipine
Methyldopa	Probably compatible	Long history of safety and efficacy in pregnancy

[a]Beta blockade = bradycardia, respiratory depression, and hypoglycemia.
CP, Crosses placenta; *IUGR,* intrauterine growth restriction; *LHS,* limited human studies; *NHT,* no human teratogenicity; *PDA,* patent ductus arteriosus; *PPH,* postpartum hemorrhage; *RPW,* reduced placental weight
Data adapted from refs.[40-45]

cardiac septal defects as well as skeletal dysgenesis in rats, especially when high doses were given. Ibutilide should be reserved for refractory cases in which the benefits of therapy outweigh any fetal risk. There are very few data about the risk during breastfeeding, though there is low bioavailability and likely low risk to the infant.

Sotalol. Sotalol has been used in pregnant women to treat atrial arrhythmias successfully and safely, as well as hypertension. It has also been successfully used to terminate fetal atrial tachycardias. It does not appear to have teratogenic effects in animals. Some of the negative effects of sotalol include bradycardia in the newborn, persisting for 24 hours. Sotalol is concentrated in milk but does not appear to result in bradycardia or hypotension in the nursing infant and, according to the AAP, it is compatible with breast-feeding.

Antihypertensives

Labetalol is the agent of choice for hypertensive emergencies in pregnancy (Table 175.8).[14]

Angiotensin-Converting Enzyme Inhibitors. Angiotensin-converting enzyme (ACE) inhibitors are contraindicated for use during pregnancy. Furthermore, ACE inhibitors are embryocidal in animals and increase the rate of stillbirths in some animal species. In humans, the most significant adverse fetal effects occur when used in the second and third trimesters. ACE inhibitor use in the first trimester is controversial; some studies suggest no increased risk whereas ACOG recommends against its use. Captopril and enalapril are considered compatible with breast-feeding.

Angiotensin II Receptor Antagonists. Angiotensin II receptor antagonists should be avoided during pregnancy because their use has been reported to result in fetal abnormalities similar to the abnormalities seen with ACE inhibitors, including renal agenesis, neonatal anuria, oligohydramnios, intrauterine growth restriction, persistent patent ductus arteriosus, abnormal ossification, and death. Their safety in lactation is unknown.

Beta Blockers. Beta blockers are a first-line treatment of hypertension in pregnancy.[15] They have not been associated with fetal malformations and appear to be safe when used for short periods. Adverse fetal effects include intrauterine growth restriction and a low placental weight. Beta blockers lacking intrinsic sympathomimetic activity, such as acebutolol, atenolol, nadolol, and propranolol, are more likely to be associated with these adverse effects. When beta blockers are given near term, they have been associated with persistent beta blockade in the newborn. Nonselective beta blockers, such as propranolol, also have resulted in neonatal hypoglycemia, respiratory depression, and hyperbilirubinemia in the newborn. These adverse effects are less common when a cardioselective beta blocker, such as atenolol or metoprolol, is used. Esmolol has been associated with fetal bradycardia, neonatal bradycardia and hypotonia, and fetal distress requiring emergent cesarean section. Beta blockers have variable effects on the nursing infant, and close monitoring of the infant for adverse effects is recommended.

Calcium Channel Blockers. Calcium channel blockers are effective treatments for hypertension and the termination of supraventricular rhythm disturbances during pregnancy. IV verapamil is useful to terminate fetal tachycardia, and IV nicardipine has been used for severe preeclampsia. In addition, some calcium channel blockers, such as nifedipine and diltiazem, are used as tocolytic agents. In laboratory animals, calcium channel blockers in the first trimester have been associated with a dose-dependent increase in embryonic mortality and skeletal abnormalities. To date, however, these abnormalities have not been seen in humans. Complications of calcium channel blocker use during pregnancy include maternal hypotension, tachycardia, and fetal distress, especially pronounced when sublingual nifedipine or IV nicardipine is used. The AAP considers these drugs compatible with breast-feeding.

Diuretics

Loop diuretics such as furosemide are indicated in the treatment of pulmonary edema due to congestive heart failure. In laboratory animals, furosemide has been linked to renal and skeletal abnormalities when used in pregnancy. These effects have not been seen in humans, but a slightly increased risk of hypospadias has been reported. Furosemide is secreted into breast milk but is considered compatible with breast-feeding.

Thiazide diuretics have been associated with hypoglycemia and electrolyte abnormalities in neonates when given near term and with an increase in meconium staining and perinatal mortality. Moreover, thiazide diuretics may have a direct effect on smooth muscle and inhibit labor. In general, these agents are considered safe during breast-feeding.

Nitrates. Nitroglycerin has not been shown to cause fetal harm in animal studies. Limited reports in humans have not shown any major effects on the fetus or neonate. Nitroglycerin is rarely used during pregnancy, but it appears to be a safe, effective, rapidly acting, and short-acting agent. Nitroprusside for the treatment of hypertensive emergencies in pregnancy has the same advantages and disadvantages as in nonpregnant patients. During prolonged administration of high doses, nitroprusside may result in cyanide toxicity and severe acidosis. It readily crosses the placenta, and fetal levels of cyanide can increase as high as twice maternal levels. Standard doses do not seem to subject the fetus to a major risk of toxicity but, with the availability of safer alternatives, notably labetalol, nitroprusside is considered a last resort agent. No data are available on its use during lactation

Clonidine. Clonidine has been safely used throughout pregnancy, but experience during the first trimester remains limited. It does not appear to be teratogenic in laboratory animals and does not increase fetal mortality. Transient neonatal hypertension has been reported with the use of clonidine in the treatment of neonatal abstinence syndrome. Its effects on breast-feeding neonates are unknown, but it is considered compatible with breast-feeding.

Hydralazine. Hydralazine use is associated with higher rates of maternal hypotension, placental abruption, and neonatal distress compared with labetalol. It is therefore no longer recommended as a first-line agent in the treatment of severe acute hypertension in pregnancy.[15] It may still be used as a second-line agent. Hydralazine is considered compatible with breast-feeding.

Methyldopa. Methyldopa has been safely used throughout pregnancy, and most reviews have not linked it to any teratogenic effects on the offspring or adverse effects on the pregnancy. The use of methyldopa has been associated with depression, which may limit its use in the peripartum phase. Methyldopa is compatible with breast-feeding.

Vasopressors

Vasopressors all have the potential to increase uterine vascular resistance, resulting in a proportional decrease in placental blood flow. ACOG currently recommends epinephrine as the vasopressor of choice in the treatment of vascular collapse during pregnancy (Table 175.9).[16]

Endocrine Agents

Diabetes Medications

Diabetes mellitus is associated with a number of congenital malformations involving multiple organ systems, as well as with a significant increase in perinatal morbidity. Glycemic control in pregnancy is therefore important and should be accomplished in a controlled manner, because hypoglycemia is also associated with adverse pregnancy outcomes. Insulin is the drug of choice for diabetes mellitus types 1 and 2 in pregnancy and gestational diabetes, if treatment is needed. Metformin is generally well tolerated but has rare serious adverse effects in non-pregnant and pregnant adults, including life-threatening metabolic acidosis and hepatitis. It has not been associated with fetal malformations in animals and humans (Table 175.10).[17]

TABLE 175.9 Vasopressors

Drug	Breast-Feeding	Clinical Risk Summary
Dobutamine	Probably compatible (LHS)	CP; LHS; animal data suggest low risk; no adverse effects on human fetuses found
Dopamine	Probably compatible (LHS)	LHS; used in maternal shock, including spinal shock due to spinal anesthesia; low-dose dopamine can be used to improve cardiac and urine output in patients with preeclampsia and oliguria, but has not been shown to improve mortality or renal function; animal studies suggest maternal toxicity, but no fetal teratogenicity found; decreases uterine blood flow
Epinephrine	Potential toxicity (LHS)	CP; NHT; preferred treatment agent for anaphylaxis, used for status asthmaticus and shock during pregnancy; associated with fetal anoxic injury, intracranial hemorrhage, and increased incidence of inguinal hernias; decreases uterine blood flow, which may lead to fetal anoxia
Norepinephrine	Potential toxicity (LHS)	CP; animal studies demonstrate malformation—situs inversus, cataracts, hemorrhages, bone abnormalities; increased incidence of cerebral hemorrhage; decreased placental flow and fetal anoxia, but overall effects unknown
Ephedrine	Potential toxicity	CP; NHT; effective in treatment of shock in pregnancy; compared to phenylephrine, ephedrine associated with higher heart rates, gastric upset, increased incidence of fetal acidosis; no major or minor malformations shown
Phenylephrine	Probably compatible (LHS)	Preferred agent to treat shock during pregnancy; severe hypertension during delivery when reacting to oxytocics or ergots; malformations when used in first trimester; use during late pregnancy, labor, or cesarean section may cause fetal anoxia, bradycardia due to uterine contractions, decreased uterine blood flow

CP, Crosses placenta; *LHS,* limited human studies; *NHT,* no human teratogenicity.
Data adapted from ref.[44]

TABLE 175.10 Diabetic Medications

Drug	Breast-Feeding	Clinical Risk Summary
Insulin	Compatible Degraded by infant's GI tract	Maternal hypoglycemia; DNCP; no observable effects found
Sulfonylureas	Compatible	Minimal amounts found in fetal circulation; no greater risk of adverse effects compared with insulin therapy; infant 200 g heavier with use of sulfonylureas; stop ≈2 wk before birth to prevent neonatal hypoglycemia
Metformin	Compatible Excreted in breast milk Monitoring advised	CP; NHT Less likely to experience maternal and neonatal hypoglycemia

CP, Crosses placenta; *DNCP,* does not cross placenta; *GI,* gastrointestinal; *NHT,* no human teratogenicity.
Data adapted from refs. [46,47,64]

TABLE 175.11 Thyroid Medications

Drug	Breast-Feeding	Clinical Risk Summary
Levothyroxine	Compatible Excreted in breast milk	Minimal transfer across placenta; treatment of choice for hypothyroidism in pregnancy; minimal side effects; maternal benefits outweigh risks to fetus
Potassium iodide	Compatible Excreted in breast milk	CP; reserved for thyrotoxic patients; easily taken up by fetal thyroid, resulting in prolonged fetal hypothyroidism and goiter
Propylthiouracil (PTU)	Compatible Excreted in breast milk	CP; causes fetal goiter, hypothyroidism, hepatic injury, death; preferred drug in the first trimester for hyperthyroidism in pregnancy; maternal benefits outweigh risk to fetus
Methimazole	Compatible Excreted in breast milk	CP; may cause a methimazole embryopathy—congenital skin defects, umbilical defects, preferred drug in the second and third trimesters

CP, Crosses placenta.

Thyroid Medications

Maternal hyperthyroidism is associated with an increased risk of spontaneous abortion, preterm labor, placental abruption, and maternal congestive heart failure. Effects of the disease on the offspring include intrauterine growth restriction, intrauterine fetal death, and neonatal goiter. Propylthiouracil (PTU) is the drug of choice in the first trimester and should be replaced with methimazole in the second and third trimester. Methimazole is associated with higher rates of congenital malformations such as choanal and esophageal atresia and therefore not recommended in the first trimester. PTU is associated with maternal hepatotoxicity. When used close to term the newborn may display hypothyroidism and a goiter. Methimazole and carbimazole have been associated with abnormal development of the skin, albeit inconsistently. Hypothyroidism in pregnancy may result in an increased risk for spontaneous abortion, intrauterine growth restriction, placental abruption, and fetal demise and has been associated with severe neurologic impairment of the offspring. Levothyroxine is the treatment of choice for hypothyroidism in pregnant women (Table 175.11).

Gastrointestinal Agents

Gastroesophageal reflux disease (GERD) occurs in up to 80% of pregnancies and peaks in the third trimester (Table 175.12). Another common condition during pregnancy is nausea and vomiting of pregnancy (NVP), which can affect up to 80% of women during pregnancy. NVP typically presents after 4 to 5 weeks' gestation and resolves before the beginning of the second trimester (see Antiemetic Medication section).

Antacids

H2 Receptor Antagonists. None of the H2 receptor antagonists has been linked to congenital malformation, and they all appear to be safe for the nursing infant. There are multiple reports in the literature, however,

TABLE 175.12 Gastrointestinal Medications

Drug	Breast-Feeding	Clinical Risk Summary
Famotidine	Probably compatible Secreted less than other H2 blockers Considered low risk	CP; no fetal toxicity or teratogenicity in animal studies[a]
Ranitidine	Probably compatible Considered low risk	CP; no toxicity or teratogenicity in animal studies; considered H2 blocker of choice due to efficacy and safety data; ranitidine-induced anaphylactoid shock has been reported[a]
Cimetidine	Compatible Has antiandrogenic activity, so use with caution	CP; no toxicity in animal studies, has some weak anti-androgenic activity that could result in feminism of male fetuses but no documented cases in humans[a]
Omeprazole	Potential toxicity LHS	CP; animal data show dose related embryonic and fetal mortality; low risk of fetal harm or teratogenicity; overall slightly higher rates of congenital malformations and stillborns after exposure in first trimester of pregnancy, but studies limited/unconfirmed[a]
Esomeprazole	Potential toxicity LHS Wait 5–7.5 hr after dose for breast-feeding to limit exposure Strontium formulations—should not be used	CP; LHS; some changes in bone morphology observed in animal studies; should be used with caution[a]; esomeprazole magnesium preferred over esomeprazole strontium
Lansoprazole	Potential toxicity Should be avoided	Unknown whether CP but likely; carcinogenic in animals; LHS; should be avoided in first trimester[a]
Pantoprazole	Probably compatible Potential for tumorigenicity and carcinogenicity in animals Caution advised	Animal and human data suggest low risk in pregnancy[a]

[a]Several studies have shown a possible link between in utero exposure to gastric acid suppressors and childhood allergy and asthma.
CP, Crosses placenta; *LHS,* limited human studies.
Data adapted from ref.[48-50]

TABLE 175.13 Antiemetic Medications

Drug	Breast-Feeding	Clinical Risk Summary
Pyridoxine	Compatible Excreted in breast milk	High doses pose little risk to fetus; vitamin B_6 deficiency common during pregnancy—pyridoxine required for good maternal and fetal health
Doxylamine, pyridoxine	Probably compatible, but sedative and antihistamine actions are potential concern	Safe in pregnancy, including first trimester; several meta-analyses demonstrated no increased risk of malformations, fetal abnormalities
Metoclopramide	Potential toxicity Concern for CNS effects but data lacking	CP; no association with adverse fetal and neonatal outcomes while with used during all stages of pregnancy
Prochlorperazine	Potential toxicity Use caution—may cause sedation, lethargy in infant	CP; LHS; fetal toxicity, teratogenicity in animals; adverse effects of extrapyramidal effects, agitation, hypertonia, hypotonia, tremor, somnolence, respiratory distress, feeding disorder reported in infants exposed during third trimester; considered low risk for mother and fetus if used occasionally in low doses
Promethazine	Probably compatible May cause sedation in infant	CP; LHS; reports of embryonic and fetal harm may be considered low risk for embryo, fetus; theoretical increased risk of respiratory depression in the newborn if given close to delivery, of unknown clinical significance
Ondansetron	Probably compatible Unknown safety	CP; animal, human data suggest low risk of birth defects; studies show inconsistent data on increased risk of cardiac anomalies and cleft palates

CP, Crosses placenta; *LHS,* limited human studies.
Additional data adapted from refs.[52,53]

linking in utero gastric suppression to an increased incidence of asthma and allergies during childhood, which require confirmation.[18]

Proton Pump Inhibitors. Studies on proton pump inhibitor (PPI) use in pregnancy are limited but several studies and a meta-analysis have found no association with an increased risk for major congenital birth defects, spontaneous abortions, or preterm delivery. Esomeprazole, lansoprazole, pantoprazole, and rabeprazole may be used during pregnancy. There are reports, however, of an increased incidence of GI, hepatic, and thyroid cancers in rats and mice. Several studies have demonstrated a possible link between in utero exposure to gastric acid suppressors and childhood allergic disorders and asthma. There are limited data in humans on the effects of PPIs on nursing infants. Breast-feeding should be avoided while taking PPIs.

Antiemetic Medications

Nausea and vomiting occur in up to 85% of all pregnant women between 6 and 12 weeks of gestation, but these symptoms are usually self-limiting. One-third of women with nausea and vomiting of pregnancy have clinically significant symptoms, and 3% will progress to hyperemesis gravidarum, which poses health risks to the mother and fetus. Despite these symptoms being common in pregnancy, there is a lack of high-quality evidence to support any particular intervention (Table 175.13).

Pyridoxine (Vitamin B_6), Doxylamine-Pyridoxine Combination. Pyridoxine is used alone, or in combination with doxylamine, an antihistamine, for the treatment of nausea and vomiting of pregnancy. Combination therapy of doxylamine and pyridoxine is FDA approved and fetal safety has been demonstrated in multiple epidemiologic studies.[19]

Phenothiazines. Phenothiazines, such as metoclopramide, prochlorperazine, and promethazine, are dopamine antagonists commonly used in the treatment of nausea and vomiting during pregnancy. Although there have been reports of increased risk of cardiac defects, these reports did not consider other factors, such as the mother's health, when the drug was reviewed. The bulk of evidence does not support a link to congenital abnormalities. The AAP cautions against their use in nursing mothers because they may cause sedation and other untoward effects.

Serotonin 5-HT$_3$ Receptor Antagonists. Dolasetron, granisetron, and ondansetron have not been consistently linked to any fetal malformations, although experience with the newer agents remains limited. Recent studies of ondansetron have suggested a low teratogenic risk; however, an increased risk for a cardiac septum defect and cleft palate is possible, but data are inconsistent, and has not been confirmed in other studies. The AAP considers these agents compatible with breast-feeding.

Neurologic Agents

Anticonvulsants

Maternal mortality is ten times higher in women with a seizure disorder. Pregnant women with a seizure disorder are at increased risk of spontaneous miscarriage, antepartum and postpartum hemorrhage, hypertensive disorders, induction of labor, cesarean sections, preterm birth, and fetal growth restriction. Pregnant women exposed to antiepileptic drugs (AEDs) have an increased risk of postpartum hemorrhage, induction of labor, fetal growth restriction, and admission to the NICU.

Newer-generation AEDs, lamotrigine and levetiracetam, have not been associated with increased risk of congenital malformations compared to controls but data are limited. Several anticonvulsants are known teratogens, and 30% of neonates exposed to commonly used anticonvulsants exhibit congenital anomalies. Monotherapies shown to have increased risk of congenital malformations are carbamazepine, ethosuximide, phenobarbital, phenytoin, topiramate, and valproate.

The risks for birth defects increase with the duration of exposure and with the number of agents used. Valproate is associated with the most frequent serious adverse effects on the pregnancy and fetus (20% incidence of serious adverse outcomes) compared with phenytoin, carbamazepine, and lamotrigine (11%, 8%, and 1%, respectively). Despite the risks, most practitioners believe that it is important to control seizures during pregnancy. Generalized seizures during pregnancy are associated with an increased risk of spontaneous abortion, hypoxic injury to the fetus, and impaired neuropsychological functioning. Monotherapy is the most appropriate option and is recommended at the lowest effective anticonvulsant dose. Dividing the daily dose to decrease peak plasma levels may be considered. Adjustment of the dosage upward may be required to maintain adequate seizure control.

Antipsychotics

These agents sometimes cause extrapyramidal side effects of the infants when exposed in utero. These effects are seen with use of the first- and second-generation antipsychotics. Haloperidol may cause limb defects when the mother is exposed during the first trimester, but data are inconsistent. This effect is not seen with other first-generation antipsychotics. Most second-generation antipsychotics do not show teratogenicity. The most commonly prescribed antipsychotics are olanzapine, risperidone, and quetiapine, which do not appear to cause consistent congenital defects (Table 175.14).

Migraine Medications

Ergot Alkaloids

Neither ergotamine nor dihydroergotamine are associated with teratogenic effects but are contraindicated in pregnancy because of their oxytocic effects and effects on uterine blood flow. In a number of animal studies, these alkaloids have been associated with intrauterine growth restriction, probably because of reductions in uteroplacental blood flow. They are also contraindicated during breast-feeding because of possible ergot poisoning of the nursing infant manifested by convulsions and gastrointestinal symptoms.

Triptans

Triptans have been found to be teratogenic in a number of animal species, but recent human studies appear to favor their safety during pregnancy. The AAP considers sumatriptan to be compatible with breast-feeding, especially if the breast milk is not used for 8 hours after the last dose.

Respiratory Agents

Antihistamines

Approximately 10% to 15% of women reportedly take an antihistamine during pregnancy. Chlorpheniramine, diphenhydramine, doxylamine, hydroxyzine, and meclizine are safe for the treatment of allergic reactions and as antiemetics in the treatment of nausea and vomiting during pregnancy. First-generation antihistamines are not recommended during breast-feeding because they are thought to inhibit lactation. In addition, serious adverse CNS effects, including seizures, have been reported to develop in neonates receiving antihistamines, especially when they are premature.

The newer-generation antihistamines, such as cetirizine and loratadine, also appear safe during pregnancy. These may be acceptable alternatives if the first-generation antihistamines are not tolerated or if the patient has severe allergies. The AAP has classified these drugs as compatible with breast-feeding (Table 175.15).

TABLE 175.14 Antipsychotic Medications

Drug	Breast-Feeding	Clinical Risk Summary
First Generation		
Haloperidol	Potential toxicity (LHS) Excreted in breast milk	CP; extrapyramidal symptoms can be seen in infants exposed in utero in the third trimester; limb defects seen with first-trimester exposure but data inconsistent
Droperidol	Potential toxicity (LHS)	CP; no effect on respiratory drive when given perinatally; no observed fetal or maternal SAR, risk of extrapyramidal signs with exposure in the third trimester
Second Generation		
Olanzapine	Potential toxicity (LHS) Concentrated in breast milk	CP; no teratogenicity or mutagenicity in animal studies; extrapyramidal effects noted in infants exposed in third trimester
Risperidone	Potential toxicity (LHS)	CP; extrapyramidal effects noted in infants exposed in third trimester

CP, Crosses placenta; *LHS,* limited human studies; *SAR,* serious adverse reactions.
Additional data adapted from refs.[58,59]

Asthma Medications

Asthma is the most common respiratory disorder in pregnancy. The prevalence of asthma in pregnancy is 8%, and one-third of pregnant asthmatics experience a worsening of their asthma that may progress to a critical asthma syndrome, including status asthmaticus and near-fatal asthma. Pregnant women with asthma are at risk for neonatal death, preterm birth, low-birth-weight infants, preeclampsia, and small-for-gestational-age infants. Asthmatic mothers may also have higher rates of antepartum/postpartum hemorrhage, placenta previa, placental abruption, chorioamnionitis, gestational diabetes, hypertensive disorders of pregnancy, cesarean section, and prolonged hospital stay compared with control mothers. Active asthma management during pregnancy is associated with improved maternal and fetal outcomes.[20]

Albuterol has the most safety data and is the treatment of choice for asthma in pregnancy. None of the β-adrenergic medications has been linked to fetal or congenital malformations, but some have been associated with significant cardiovascular and metabolic effects, which are transient and generally well tolerated by the fetus. Transient hyperglycemia followed by insulin secretion may also occur, resulting in neonatal hypoglycemia, especially in diabetic patients. Terbutaline, when used IV or orally in pregnant women, may result in maternal and fetal arrhythmias, maternal pulmonary edema, and death. The FDA has recommended a label change to add a warning against its use in preterm labor because safer β_2-agonists and tocolytic agents are available. Long-acting β-agonists also appear to be safe during pregnancy. Albuterol is compatible with breast-feeding.

Ipratropium has not been found to be teratogenic in numerous animal models, but there are few data regarding its safety in human pregnancy. It is considered compatible with breast-feeding. Data on the use of leukotriene antagonists in pregnancy are limited (Table 175.16).

Corticosteroids

Inhaled corticosteroids are the main therapy for the prevention of asthma exacerbations during pregnancy. Budesonide has the greatest

TABLE 175.15 Antihistamine Medications

Drug	Breast-Feeding	Clinical Risk Summary
Chlorpheniramine	Probably compatible; use with caution: may cause sedation, irritability, disturbed sleep, hyperexcitability, excessive crying	LHS; no known congenital defects, low risk in pregnancy; recommended antihistamine in pregnancy, especially in first trimester[a]
Diphenhydramine	Probably compatible; use with caution, can be sedating; parenteral use contraindicated	LHS; animal and human studies demonstrate safety in pregnancy; association with cleft palate in one study; drug of choice if parenteral antihistamine is indicated[a]
Hydroxyzine	Probably compatible, LHS; not recommended with breast-feeding: may interfere with establishment of lactation	Contraindicated in 1st trimester; lower risk in 2nd and 3rd trimesters, if necessary to use; CP; teratogenic in animals, with high doses associated with developmental toxicity; low potential risk for fetus in humans; withdrawal or seizures noted in newborn exposed near term; possible increased risk of oral clefts, but limited data[a]
Meclizine	Probably compatible Safety unknown Occasional dose should not pose risk	Teratogenic in animals but not in humans; frequently used as antiemetic; considered low risk in pregnancy[a]
Cetirizine	Probably compatible Excreted in breast milk Not recommended—safety unknown	Animal studies—no teratogenicity; LHS; no evidence of increased risk of adverse fetal outcomes; may be used as alternative to oral first-generation antihistamine
Fexofenadine	Probably compatible excreted in breast milk	Animal studies—embryonic and fetal toxicity; no human studies available
Loratadine	Probably compatible considered antihistamine of choice in breast- feeding	Unknown if CP, but expected; no evidence of teratogenicity in animals or humans

[a]H1 blockers are not recommended for use in last 2 wk of pregnancy due to association with retrolental fibroplasia in premature neonates.
CP, Crosses placenta; *LHS,* limited human studies.
Data adapted from refs.[51]

TABLE 175.16 Asthma Medications

Drug	Breast-Feeding	Clinical Risk Summary
Ipratropium	Probably compatible, LHS May appear in breast milk	LHS; NHT; no teratogenicity in animals; recommended for use in severe asthma as additional therapy
Albuterol	Probably compatible, LHS Unknown if excreted in breast milk	May act as tocolytic; drug of choice for treatment of asthma; association with functional and neurobehavioral toxicity with prolonged use; may cause maternal and fetal tachycardia, hyperglycemia
Epinephrine	Potential toxicity, LHS Not known if excreted in breast milk	CP; teratogenic in animals; avoid during active labor and delivery—can delay labor progression; may lead to decrease in uterine blood flow with placental, uterine vasoconstriction
Terbutaline	Probably compatible Excreted in breast milk in small amounts	CP; NHT; may act as tocolytic; association with autism spectrum disorders (if used >2 wk); cardiac defects in first trimester; fetal tachycardia and hypoglycemia after parenteral use; avoid in early gestation, continuous use in second and third trimesters; may cause serious maternal cardiovascular events (e.g., increased heart rate, hyperglycemia, hypokalemia, cardiac arrhythmias, pulmonary edema and MI), death; black boxed warnings against use for prevention or prolonged use (beyond 2–3 days) of preterm labor

CP, Crosses placenta; *LHS,* limited human studies; *MI,* myocardial ischemia; *NHT,* no human teratogenicity.
Additional data adapted from refs.[60,61]

amount of safety data but others are also considered safe. Oral corticosteroids are the mainstay of therapy for acute exacerbations of asthma. Although they are not considered human teratogens, there may be a slightly increased incidence (0.1% to 0.3%) of orofacial clefts when systemic steroids are used during the first trimester. Furthermore, their use in the third trimester has been linked to an increased incidence of preterm delivery, low birth weight, preeclampsia, and cataracts in the newborn. Prednisone is considered safe during breast-feeding.

Decongestants

Decongestants with strong vasoconstrictive properties, such as phenylpropanolamine, phenylephrine, and pseudoephedrine, cause placental vasoconstriction and are not recommended during pregnancy. Pseudoephedrine is one of the most commonly used over-the-counter medications in pregnancy, with 8% to 12% of pregnant women using it in the first trimester. They are often used as a combination product and therefore difficult to study. There are limited data suggesting that their use in the first trimester may result in an increased incidence of abnormalities typically associated with placental vascular disruption, such as gastroschisis and intestinal atresia. Recent evidence has supported the association of phenylephrine and endocardial cushion defect, phenylpropanolamine and ear defects, and phenylpropanolamine and pyloric stenosis with oral and intranasal decongestant use in the first trimester.[21] The risk, however, appears to be low. The AAP classifies pseudoephedrine as compatible with breast-feeding.

CHAPTER 175: QUESTIONS AND ANSWERS

1. Which of the following statements is true regarding the teratogenic risk of medications administered during pregnancy?

- **a.** A drug should be given when maternal benefits outweigh the risks to the fetus.
- **b.** The FDA assigns one of five letters (A, B, C, D, and X) to classify teratogenic risk.
- **c.** The fetus is at greatest risk of anatomic defects during the third trimester.
- **d.** Most drugs do not enter the breast milk due to protein binding.
- **e.** Most drugs have epidemiologic studies confirming the risks in pregnancy.

Answer: A. In general, the health of the fetus is directly correlated with the health of the mother and necessary medications should not be withheld for fear of harming the fetus. The FDA no longer uses letter categories to describe teratogenic risk, which was a flawed system. The Pregnancy and Lactation Labeling Rule (PLLR), effective in 2015, changed the content and format for prescription drug labeling to better summarize the risks of drugs in pregnancy, lactation, and reproduction. The fetus is at greatest risk during organogenesis in the first trimester and functional development of the CNS in the 10th to 17th weeks of pregnancy. Unfortunately, current studies are insufficient to determine reliable and accurate risks in the use of medications in pregnancy. Most drugs passively diffuse into the breast milk.

2. Which of the following drugs is a known teratogen?

- **a.** Albuterol
- **b.** Hydroxycobalamin
- **c.** Penicillin VK
- **d.** Pyridoxine
- **e.** Valproic acid

Answer: E Several antiepileptic drugs (AEDs) are known teratogens, including valproic acid, carbamazepine, ethosuximide, phenobarbital, phenytoin, and topiramate. Valproic acid is associated with the most frequent serious adverse effects on the pregnancy and fetus compared with other AEDs. Newer-generation AEDs, such as lamotrigine and levetiracetam, have not been associated with increased risk of congenital malformations compared to controls but the data are limited. Maternal mortality is higher in women with a seizure disorder and control of seizures is felt to be important. Use of monotherapy in the lowest effective anticonvulsant dose is optimal. The other drugs are safe in pregnancy.

3. A 28-year-old woman who is 7 months pregnant was well until she experienced sudden onset of shortness of breath and left-sided sharp chest pain one hour prior to arrival. The pain is worse on inspiration and is not related to exertion, although her dyspnea becomes worse with any activity. She is alert and appears in mild distress. Her pulse is 112 beats/min, RR is 24 breaths/min, and BP is 110/68 mm Hg. Her temperature is 100.8°F (32°C), and O_2 saturation is 92%. Lung examination reveals diminished breath sounds on the left base with scattered wheezes. Cardiac examination reveals tachycardia. Chest radiograph reveals elevated right hemidiaphragm but no infiltrates. ECG reveals generalized T wave inversions. Which of the following treatments is most appropriate?

- **a.** Administer a low-molecular-weight heparin subcutaneously and start oral warfarin.
- **b.** Administer intravenous ceftriaxone and azithromycin.
- **c.** Administer nebulized bronchodilators and start prednisone.
- **d.** Administer oxygen and start low-molecular weight heparin
- **e.** Place a central line, and start early goal-directed therapy for sepsis.

CHAPTER 175: QUESTIONS AND ANSWERS—cont'd

Answer: D On the basis of the information provided, the patient most likely has a pulmonary embolus. The patient is hypoxic and requires oxygen administration and anticoagulation. This may be accomplished with heparin, low-molecular-weight heparin (LMWH), or warfarin. Warfarin, a vitamin K antagonist, is teratogenic and is contraindicated in pregnancy. The treatment of pulmonary embolism is LMWH preferentially or heparin. Heparin is preferred if the patient is hemodynamically unstable due to its rapid onset and short half-life. The patient has no symptoms of an infectious process; choices B and E are therefore not appropriate. Bronchodilators and steroids are indicated for asthma but not for thromboembolic disease. Choice C is therefore not appropriate.

4. Which of the following drugs may be associated with complications in the newborn when used at term?
   - **a.** All of these
   - **b.** Nitrofurantoin
   - **c.** Nonsteroidal antiinflammatory drugs
   - **d.** Propranolol
   - **e.** Sulfonamides

Answer: A. All the choices have been associated with complications in the newborn when used at term. Sulfonamides compete with bilirubin for protein-binding sites, leaving large amounts of free bilirubin to diffuse freely into the brain. This results in bilirubin deposition in the infant's brain, thus causing kernicterus. Nitrofurantoin at term has been associated with hemolytic disease of the newborn. Nonsteroidal antiinflammatory drugs are associated with premature closure of the ductus arteriosus. Propranolol at term has been associated with neonatal hypoglycemia, respiratory depression, and neonatal jaundice.

5. A 7-week pregnant (by LMP) patient arrives in the emergency department. She is complaining of severe nausea and vomiting. She is unable to keep any solids or liquids down. Her heart rate is 115, BP 110/75, Temp 98.8°F, RR 15, and glucose is 98. The patient is given IV fluids and antiemetics with improvement of her symptoms. Which of the following medications is the most appropriate for the outpatient management of this patient once her symptoms are controlled and she is tolerating fluids well?
   - **a.** Doxylamine 10 mg and pyridoxine 10 mg once per day
   - **b.** Haloperidol 2 mg twice a day
   - **c.** Omeprazole 20 mg every morning
   - **d.** Ondansetron orally disintegrating tablets 4 mg every 8 hours
   - **e.** Prochlorperazine 10 mg three times per day

Answer: A. This patient's symptoms likely represent nausea and vomiting of pregnancy or possible hyperemesis gravidarum. The preferred initial home treatment is Diclegis, which is a combination drug of doxylamine and pyridoxine (10 mg/10 mg). The non-combination version is: half-tab (21.5mg) of OTC Unisom and 10 mg pyridoxine (Vitamin B_6). There are some inconsistent studies suggesting a possible link with long term use of Zofran (Ondansetron) and cardiac abnormalities and cleft palates. Omeprazole is not first-line treatment for hyperemesis gravidarum, it is for the treatment of GERD. Prochlorperazine is teratogenic in animals and is not considered first-line treatment. Haloperidol is an antipsychotic and not indicated in this patient.

6. In determining a causal link between a specific drug and congenital malformations, which of the following may be viewed as confounding factors?
   - **a.** Genetic background of the fetus
   - **b.** Maternal illicit drug use
   - **c.** Presence of maternal illness
   - **d.** Presence of nutritional deficits
   - **e.** All of the above.

Answer: E. The process of establishing teratogenicity of a substance is often flawed. Much of our current knowledge on teratogenicity has been derived from case reports, case-controlled studies, and cohort studies, which are inherently weak in establishing a causal link. These reports are often complicated by a number of confounding factors, which make a causal link difficult to establish. The presence of any of the listed choices may confound results. In the presence of maternal illness, for example, the outcome of pregnancy may be related to the medical condition and not the medication.

Labor and Delivery

Jeremy Rose and Erick Eiting

KEY CONCEPT

- Most ED deliveries require only basic equipment to cut and clamp the umbilical cord and dry and suction the infant. However, the ED should have additional equipment and trained staff should be available to care for a newborn requiring further resuscitation.
- Women in labor who present to the ED are generally best cared for in the obstetric suite. Women with the urge to push or with the head of the infant crowning are at imminent risk of delivery, which should take place in the ED.
- The Braxton Hicks contractions of false labor do not escalate in frequency or duration like the contractions of true labor. When in doubt, external electrical monitoring of uterine activity can rule out true labor.
- Preterm labor is defined as uterine contractions with cervical changes before 37 weeks of gestation. Treatment includes tocolytics and fetal maturation therapy combined with bed rest and hydration.
- Premature rupture of membranes (PROM) occurs after 37 weeks' gestation. Its management depends on several factors, including gestational age and fetal maturity, presence of active labor, presence of infection or placental abruption, and degree of fetal well-being or distress.
- Preterm PROM should be treated with antibiotics to prevent infection (chorioamnionitis).
- The first stage of labor averages 8 hours in nulliparous women and 5 hours in multiparous women. Throughout labor, ongoing assessment of fetal well-being is important, and continuous external electrical monitoring helps identify fetal distress.
- Ultrasonography provides crucial information regarding pending delivery, including fetal viability, lie, and presentation.
- The fourth stage of labor refers to the first hour after delivery of the placenta and is a critical period during which postpartum hemorrhage is most likely to occur.
- Deliveries complicated by dystocia, malpresentation, or multiple gestations are life-threatening emergencies. The emergency clinician should develop strategies to treat each of these potential complications of delivery. Please see the following link for a video demonstration of maneuvers used to treat shoulder dystocia: https://www.hopkinsmedicine.org/gynecology_obstetrics/education/training/shoulder-dystocia.
- When a prolapsed cord occurs with a viable infant, cesarean section is the delivery method of choice. If surgical delivery is available, maneuvers to preserve umbilical circulation should be instituted immediately. The mother is placed in the knee-chest position, with the bed in the Trendelenburg position, and instructed to refrain from pushing to avoid further compression of the cord. The presenting part is then manually elevated off the cord. Elevation is maintained until the baby can be delivered surgically.
- Uterine atony accounts for 75% to 90% of cases of postpartum hemorrhage. Administration of a uterotonic, such as oxytocin in conjunction with massage usually provide enough stimuli to control bleeding.
- Approximately 10% of postpartum hemorrhage cases are due to retained placental tissue. Treatment requires manual removal of the remnant placental tissue.
- Pelvic bleeding postpartum can be difficult to control without hysterectomy. When available, embolization of bleeding vessels by an interventional radiologist has reported success rates of 95% to 100%.
- Maternal complications of labor and delivery include obstetric trauma, uterine inversion and rupture, amniotic fluid embolism, coagulation disorders, and infections. Many of these problems can initially be managed in the ED while awaiting obstetric consultation.

FOUNDATIONS

Births in the emergency department (ED) remain a rare event. However, hospital closures and health system consolidation of services has left more hospitals without obstetric coverage, especially in rural areas. These practices have stressed the need for emergency clinicians to be familiar with labor, delivery, and their complications.

Limitations of the Emergency Department

The ED is a suboptimal location for the management of a complicated delivery. Unlike the obstetric suite, the ED may be lacking in appropriate resources, certain specialized equipment, and information about the patient's prenatal care. Cesarean section may be indicated to ensure a successful delivery in dire perimortem circumstances.

Epidemiology of Emergency Delivery

From 2014 to 2016, the perinatal mortality rate in the United States (US) was 6.00/1000 live births.[1] This is remarkably high, almost three times the rate of other similar countries in the developed world. Delivery complications and mortality occur with greater frequency in the ED, where the perinatal mortality rate is approximately 8% to 10%. There are multiple features of the high-risk ED delivery profile. The ED as a care environment is often selected by an obstetric population that subsequently may have unexpected complications. Psychosocial

factors, such as drug or alcohol abuse, domestic violence, and lack of access to medical care, contribute to precipitous deliveries in pregnant women with little or no prenatal care. Antepartum hemorrhage, premature rupture of membranes (PROM), eclampsia, premature labor, abruptio placentae, malpresentation, and umbilical cord emergencies are overrepresented in the ED population.

Patient Transfer Considerations

Because of the high risk associated with ED delivery, patients should be transported to a facility that has obstetric and neonatal resources whenever possible. The transfer of a woman with an impending high-risk delivery to such a facility should be based on careful consideration of the risks and benefits. Transferring a pregnant patient with impending delivery can be disastrous for the mother and fetus and may actually violate federal law. Further consideration should be given to the level of care that the neonate will require after delivery, particularly in preterm (<36 weeks of gestation) deliveries, in which interval transfer for a higher level of care may be necessary.

NORMAL DELIVERY

Initial Presentation

Although the epidemiology and high complication rate associated with ED births demand caution, most are normal deliveries. Knowledge of normal labor and delivery mechanics aids safe vaginal delivery and facilitates the identification of complications.

Whenever a woman in the third trimester of pregnancy seeks treatment in the ED, the possibility that she is in labor must be considered. A wide array of nonspecific symptoms may herald the onset of labor. Abdominal pain, back pain, cramping, nausea, vomiting, urinary urgency, stress incontinence, and anxiety can be symptoms of labor. After 24 weeks' gestation, fetal viability is established and thus a medical screening exam should include assessment of both the mother and fetus. Risk factors for preterm labor include older maternal age and presence of systemic disease. This should be considered when treating pregnant patients, even with non–pregnancy-related complaints such as asthma.

Distinguishing False From True Labor

Braxton Hicks contractions, or false labor, must be differentiated from true labor. After 30 weeks of gestation, the previously small and uncoordinated contractions of the uterus become more synchronous and may be perceived by the mother. Braxton Hicks contractions do not escalate in frequency or duration, in contrast to the contractions of true labor. By definition, these contractions are associated with minimal or no cervical dilation or effacement. Examination should also reveal intact membranes. Care not to rupture the membranes is important to avoid inducing labor prematurely. Examination should be done in a sterile fashion to avoid introducing infection if the membranes have ruptured. If the diagnosis remains in doubt, external electrical monitoring of uterine activity can rule out true labor. Any discomfort associated with false labor is usually relieved with mild analgesia, ambulation, or change in activity.

Unlike false labor, true labor is characterized by cyclic uterine contractions of increasing frequency, duration, and strength, culminating in delivery of the fetus and placenta. In contrast to Braxton Hicks contractions, true labor causes cervical dilation to begin, marking the first stage of labor.

Bloody Show

At the onset of labor, the cervical mucous plug may be expelled, resulting in what is termed a *bloody show*. The bleeding associated with this process is slight (usually only a few dark red spots admixed with mucus) and is due to the increase in cervical vascularity that occurs in pregnancy. Bloody show is not a contraindication to vaginal examination for the determination of cervical effacement and dilation. If bleeding continues or is of a larger volume, more serious causes should be suspected, such as placenta previa and placental abruption, which are contraindications for a vaginal examination.

Stages of Labor

First Stage of Labor

The first stage of labor is the cervical stage, ending with a completely dilated, fully effaced cervix. It is divided into a latent phase, with slow cervical dilation, and an active phase, with more rapid dilation. The active phase begins once the cervix is dilated to 3 cm. Most women who deliver in the ED arrive while in the active phase of stage 1 or early stage 2 labor (Fig. 176.1). The duration of the first stage of labor averages 8 hours in nulliparous women and 5 hours in multiparous women. During this time, frequent assessment of fetal well-being is important, and continuous external electrical monitoring may help identify fetal distress, allowing for appropriate intervention.

The maternal examination provides a rough guide to gestational age. At 20 weeks' gestation, the uterine fundus reaches the umbilicus. Approximately 1 cm of fundal height is added per week of gestation until 36 weeks. At that time, the fundal height decreases as the fetus drops into the pelvis (Fig. 176.2). These estimates help establish gestational age rapidly.

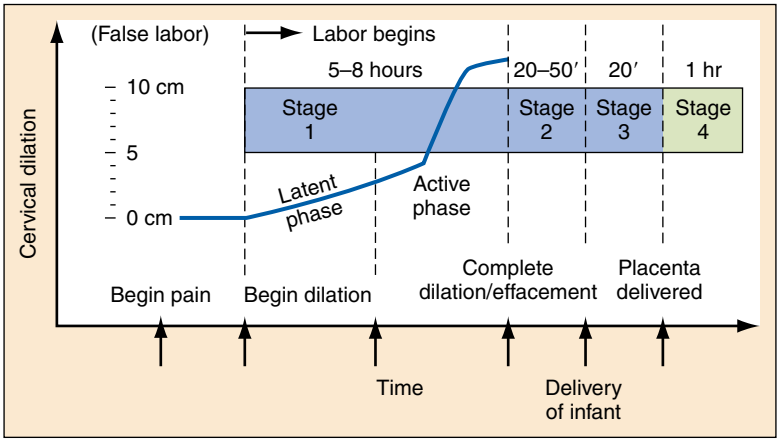

Fig. 176.1 Stages of labor and delivery. Stage 1, cervical stage; stage 2, fetal expulsion; stage 3, placental expulsion (20 minutes); stage 4, uterine contraction (1 hour postpartum).

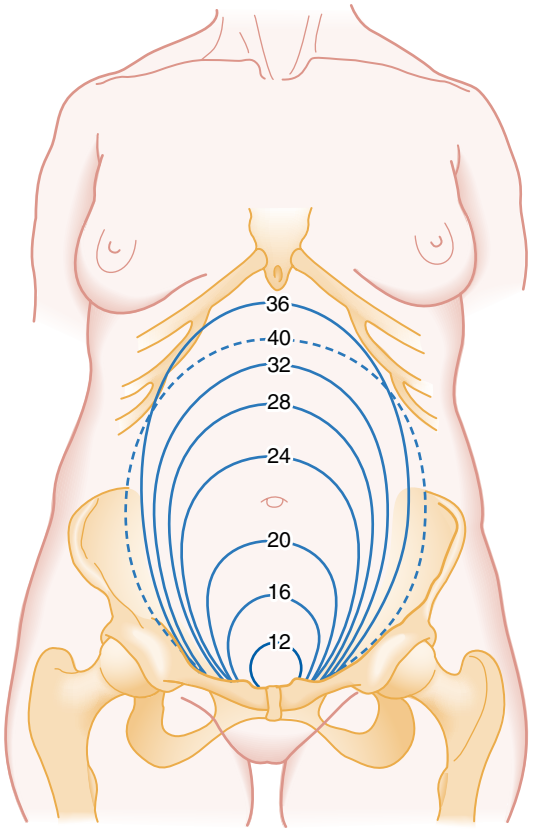

Fig. 176.2 Height of fundus by weeks of normal gestation with a single fetus. The dotted line indicates height after lightening. (Adapted from: Barkaukas V, et al. *Health and Physical Assessment*. St. Louis: Mosby; 1992.)

The abdominal examination with Leopold maneuvers may confirm the lie of the fetus (Fig. 176.3). Bedside ultrasound can be especially useful in determining fetal position. The determination of the stage of labor depends on examination of the cervix. A sterile approach using sterile gloves, sterile speculum, and povidone-iodine solution is indicated to prevent ascending infection. On pelvic examination, the clinician should determine the following:

- *Effacement* refers to the thickness of the cervix. A paper thin cervix is 100% effaced.
- *Dilation* indicates the diameter of the cervical opening in centimeters. Complete, or maximum, dilation is 10 cm.
- *Position* describes the relationship of the fetal presenting part to the birth canal. The most common position of the head is occiput anterior.
- *Station* indicates the relationship of the presenting fetal part to the maternal ischial spines (Fig. 176.4).
- *Presentation* specifies the anatomic part of the fetus leading through the birth canal.

In 95% of all labors, the presenting part is the occiput, or vertex. On digital examination, a smooth surface with 360 degrees of firm bony contours and palpable suture lines is noted. Palpation of the suture lines and the fontanels where they join allows the examiner to determine the direction the fetus is facing. Three sutures radiate from the posterior fontanel, and four radiate from the anterior fontanel (Fig. 176.5). The lateral margins are examined carefully for fingers or facial parts that indicate compound or brow presentations.

When the clinician suspects rupture of membranes, a sterile speculum examination is performed. This may reveal pooling of amniotic fluid, a fernlike pattern when the fluid is allowed to dry on a microscope slide, and the use of Nitrazine paper, which should turn blue, indicating an alkaline amniotic fluid (pH > 6). Although vaginal blood, cervical mucus, semen, and infection can interfere with results, sensitivities of Nitrazine paper and ferning for the detection of amniotic fluid are nearly 90%. If vaginal bleeding is evident, digital and speculum examination of the pelvis should be deferred until an ultrasound study can be obtained to rule out placenta previa.

Second Stage of Labor

The second stage of labor is characterized by a fully dilated cervix and accompanied by the urge to bear down and push with each uterine contraction. The median duration of this stage is 50 minutes in nulliparous women and 20 minutes in multiparous women, with the anticipation of a more rapid progression for low-birth-weight premature infants. A prolonged second stage of labor is associated with an increase in maternal complications, including postpartum hemorrhage, infection, and severe vaginal lacerations.

Antenatal Fetal Assessment. During labor and delivery, the identification of fetal distress and appropriate intervention can reduce fetal morbidity and mortality. There are currently three methods of assessing a fetus in utero: (1) clinical monitoring; (2) electrical monitoring; and (3) ultrasonography. External electrical monitoring and ultrasonography merit consideration for use in the care of women laboring in the ED. Both modalities provide real-time information that is helpful for the diagnosis of fetal distress and assistance with intrapartum decision making.

Electronic Fetal Monitoring. Electronic fetal monitoring uses tracings of the fetal heart rate and uterine activity. Documentation of organized cyclic uterine contractions helps confirm true labor and may help diagnose fetal distress. In combination with clinical data, this can portend fetal distress due to hypoxia and provide a window for intervention.

Uterine activity is measured transabdominally by a pressure transducer, creating a recording of the contraction frequency. Because the measurements are indirect, the strength of the contractions correlates poorly with the tracing. The tracings are position and placement sensitive.

Fetal heart rate tracings have several components that can be assessed—baseline heart rate, variability, accelerations, decelerations, and diagnostic patterns.

Baseline Heart Rate. This is the average fetal heart rate during a 10-minute period (in the absence of a uterine contraction) and is the most important aspect of fetal heart rate monitoring. Fetal bradycardia is defined as a baseline rate of less than 110 beats/min; fetal tachycardia is defined as a baseline rate of more than 160 beats/min.

Variability. This can be instantaneous (beat to beat) or long term (intervals ≥ 1 minute). Both types of variability are indicators of fetal well-being. Accelerations occur during fetal movement and reflect an alert mobile fetus. Decreased variability may indicate fetal hypoxemia and acidemia, or it may be a side effect of a wide array of drugs, including analgesics, sedative-hypnotics, phenothiazines, and alcohol.

Decelerations. Decelerations in fetal heart rate are more complicated and should be interpreted according to the clinical scenario. There are three types of deceleration—variable, early, and late (Fig. 176.6). These terms refer to the timing of the deceleration relative to the uterine contraction.

Variable and early decelerations are common and normally represent physiologic reflexes associated with head compression in the birth canal or intermittent cord compression. Variable decelerations that are persistent and repetitive usually indicate repeated episodes of umbilical cord compression. The resultant hypoxia and acidosis may cause fetal distress. Attempts to shift maternal and fetal weight off the umbilical cord by changing position are indicated. If variable decelerations continue, the

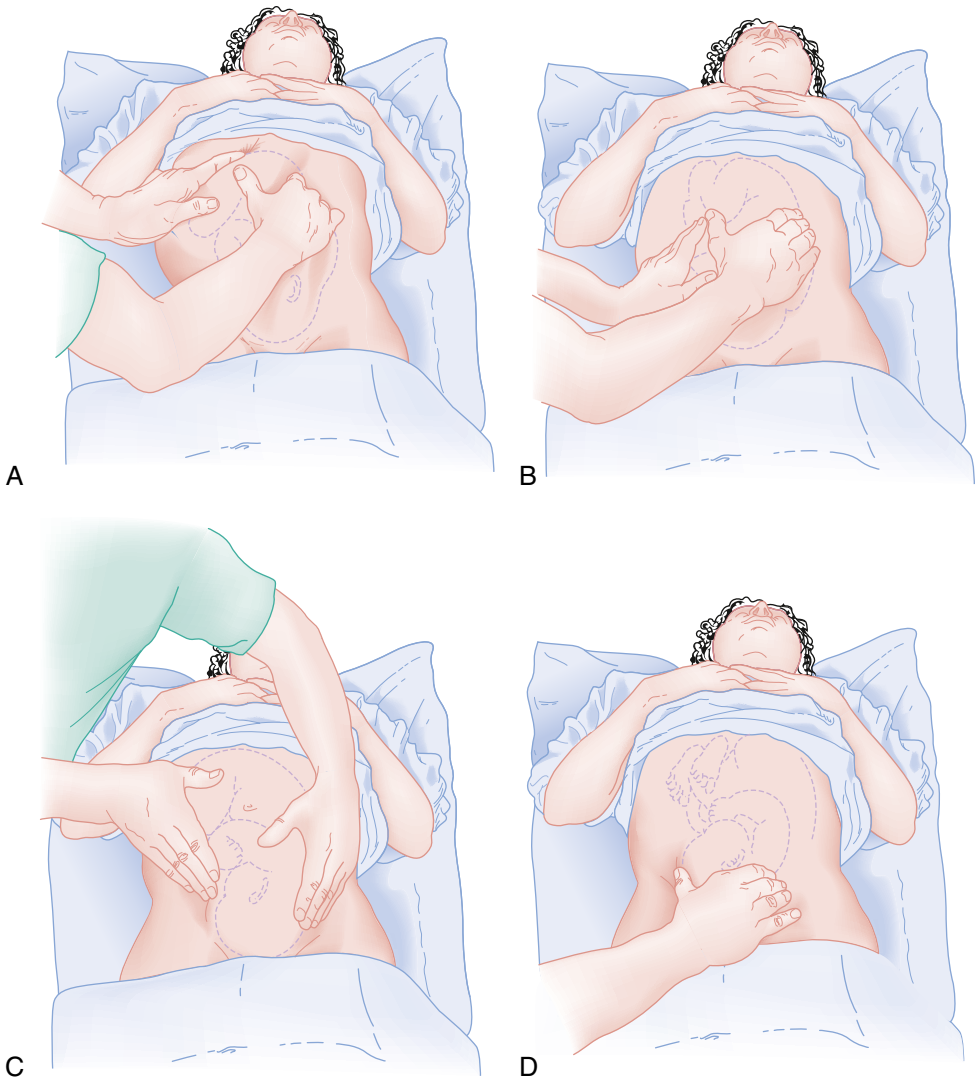

Fig. 176.3 Leopold maneuvers. (A) The first Leopold maneuver reveals which fetal part occupies the fundus. (B) The second Leopold maneuver reveals the position of the fetal back. (C) The third Leopold maneuver reveals which fetal part lies over the pelvic inlet. (D) The fourth Leopold maneuver reveals the position of the cephalic prominence. (Adapted from: Willson JR, et al. *Obstetrics and Gynecology*, ed 9. St. Louis: Mosby; 1991.)

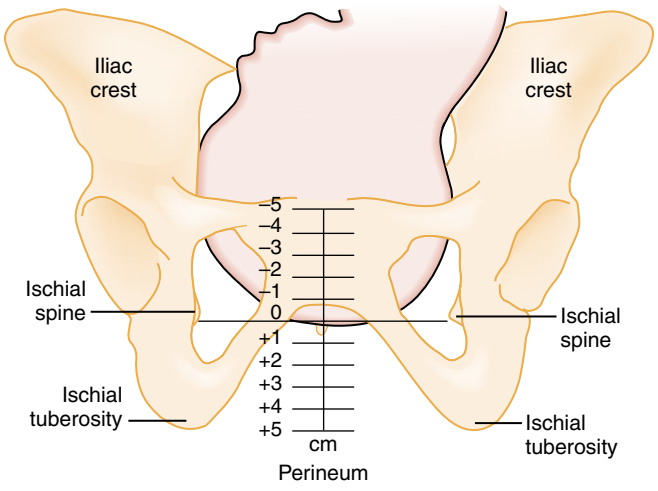

Fig. 176.4 Fetal stations. The level of the ischial spines is considered 0 station. The silhouette of the infant's head is shown approaching station +1. (Courtesy Ross Laboratories, Columbus, OH.)

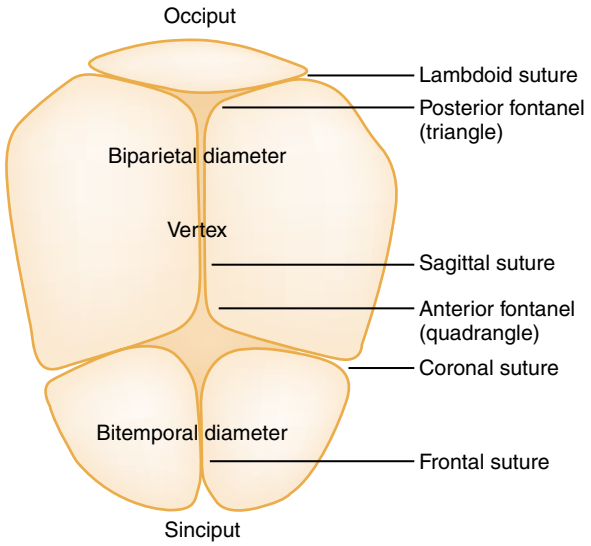

Fig. 176.5 Bony landmarks of the fetal skull. (Adapted from: Willson JR, et al. *Obstetrics and Gynecology*, ed 9. St. Louis: Mosby; 1991.)

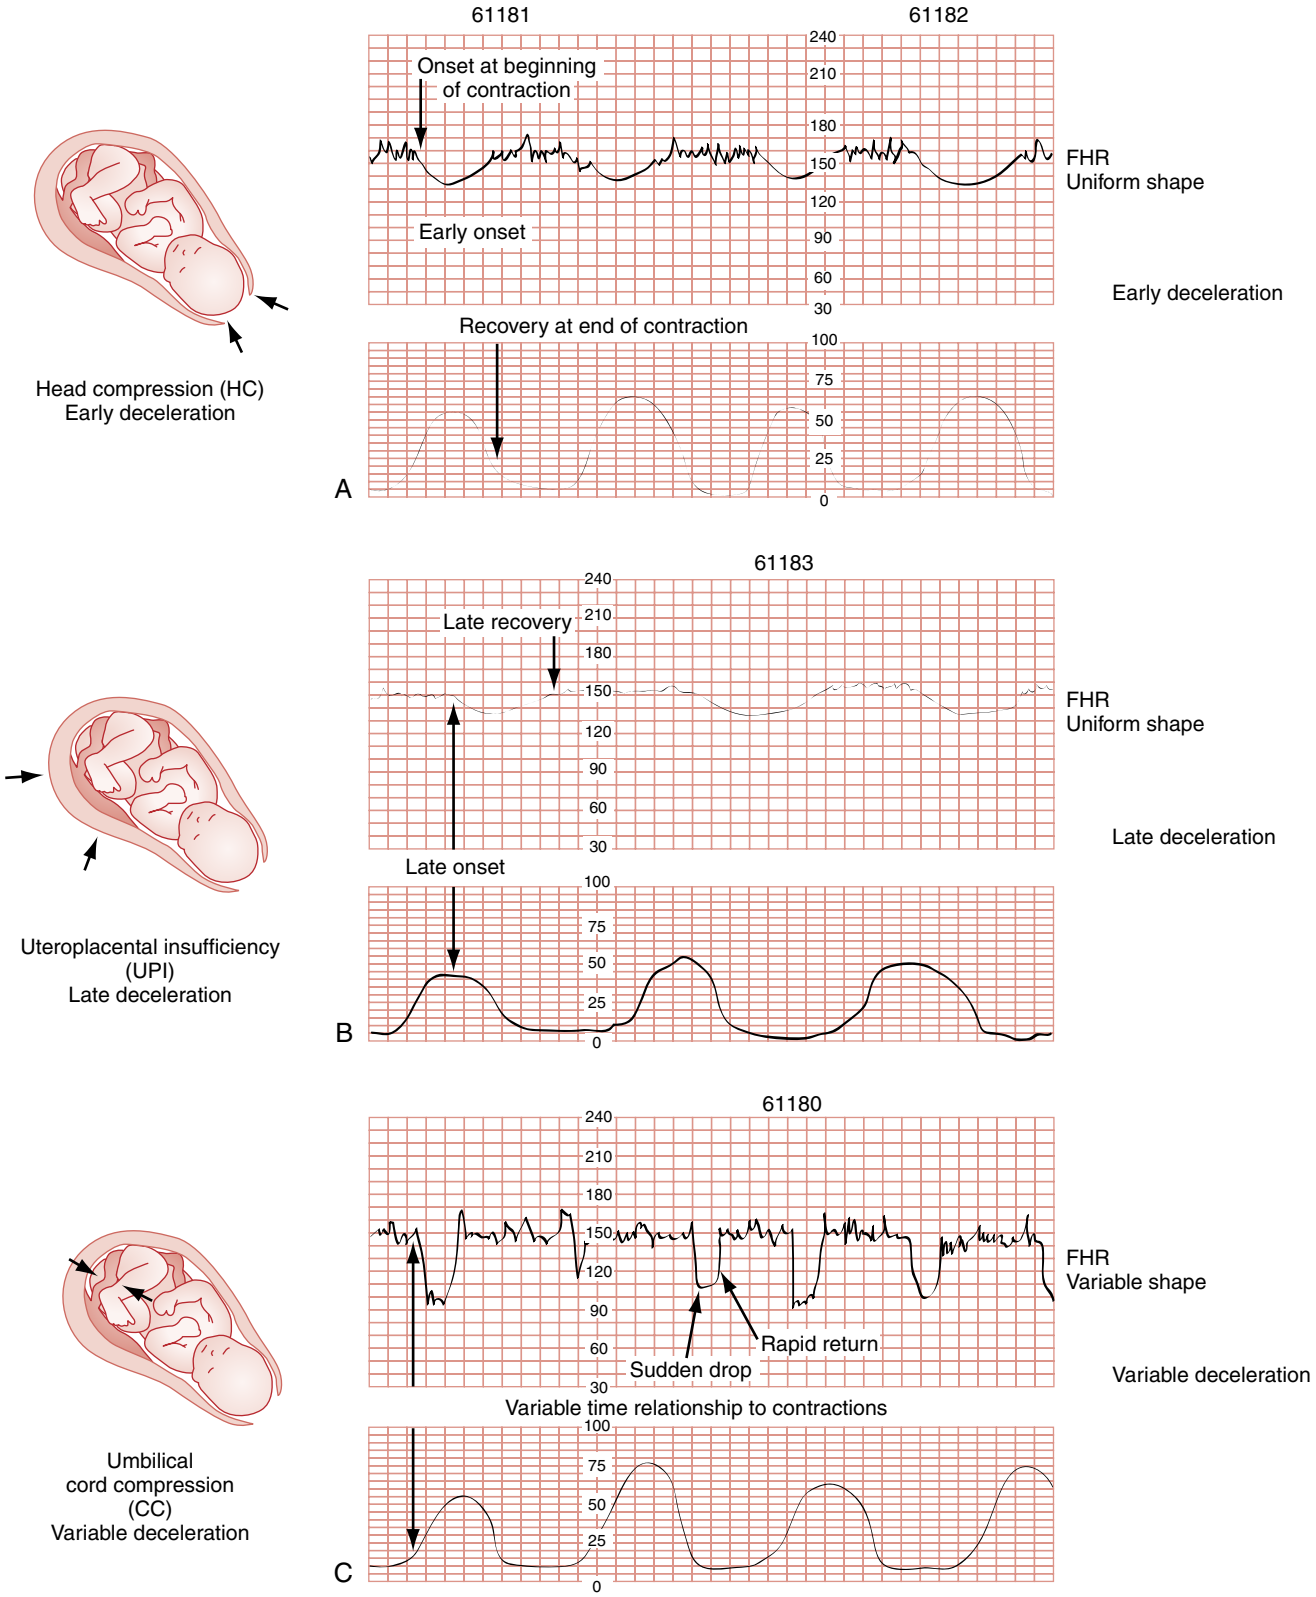

Fig. 176.6 Deceleration patterns of the fetal heart rate (FHR). (A) Early deceleration caused by head compression. (B) Late deceleration caused by uteroplacental insufficiency. (C) Variable deceleration caused by cord compression. (Modified from: Lowdermilk DL, et al. *Maternity and Women's Health Care*, ed 6. St. Louis: Mosby; 1997.)

situation warrants efforts to hasten the delivery or, if obstetric backup becomes available, to perform an emergency cesarean section.

Late decelerations are more serious and most often indicate uteroplacental insufficiency. The tracing contours are generally smooth, with the heart rate nadir occurring well after a maximal uterine contraction (typically, ≥30 seconds afterward). The lag, slope, and magnitude of late decelerations correlate with increasing fetal hypoxia. Late decelerations are particularly ominous in association with poor variability, nonreactivity, and baseline bradycardia. When these findings are present, immediate obstetric consultation for delivery is indicated to prevent further hypoxia.

Diagnostic Patterns. Finally, the emergency clinician should be aware of the significance of sinusoidal tracings. Tracings of this type have low baseline heart rates and little beat to beat variability. The sinusoidal tracing is an ominous finding that is often premorbid. The differential diagnosis includes erythroblastosis fetalis, placental abruption, fetal hemorrhage (trauma), and amnionitis.

Ultrasonography. In the third trimester or during labor, ultrasonography can provide crucial information pertaining to impending delivery, such as the number and position of fetus(es) and fetal heart rate. When a technician and radiologist are available, and if time permits, the gestational age, biophysical profile, amniotic fluid index, and a survey of fetal and placental anatomy may be obtained. The American College of Obstetricians and Gynecologists (ACOG) has published recommendations regarding the indications for ultrasonography in the third trimester (Box 176.1). The parameters of immediate interest in the ED are fetal viability (specifically in utero gestation and fetal heart rate), lie, and presentation. Transvaginal ultrasonography is relatively contraindicated in the peripartum period, particularly in the cases of premature rupture of membranes (PROM) and placenta previa.

Delivery. As stage 2 of labor progresses, preparation for delivery should be under way. A radiant warmer should be available and heated. Neonatal resuscitation adjuncts should be available, including a towel, scissors, umbilical clamps, bulb suction, airway equipment (oxygen, bag-mask device with appropriate-sized masks, and tools for endotracheal intubation), and equipment to achieve vascular access. Most deliveries require only basic equipment to cut and clamp the umbilical cord, suction the mouth and nose, and dry and stimulate the infant. A nurse should be at the bedside to coach and provide reassurance to the mother.

The mother is placed in the dorsal lithotomy position and prepared for delivery. The Sims position, or left lateral position with knees drawn toward the mother's chest and back to the physician, is also an acceptable position. The vulva and perineum are cleared and gently scrubbed with sterile water or saline. A repeated sterile examination to assess labor progression and confirm presentation may be performed. Firm digital stretching of the perineum, particularly posteriorly, may prevent tears and lacerations later in delivery.

BOX 176.1 Third-Trimester Ultrasonography: Possible Indications

Determine number of fetuses.
Establish fetal presentation.
Identify fetal heart motion.
Locate placenta.
Measure amniotic fluid.
Determine gestational age.
Survey fetal anatomy.
Diagnose cord prolapse.
Diagnose cause of third-trimester bleeding.
Rule out placental abruption.

Controlled coordinated expulsion with coaching to sustain each push aids with crowning and delivery of the head. The most vulnerable moment is when the fetal head begins to stretch and distend the perineum. Instructing the mother to pant and not push slows the passage of the head and shoulders. The modified Ritgen maneuver may be used to support the perineum and prevent maternal injury: In this technique, a towel-draped, gloved hand is used to stretch the perineum and gently exert pressure on the chin of the fetus. The second hand places pressure on the occiput superiorly, guiding the head into slight extension and positioning it so that its smallest diameter passes through the pelvic outlet. Calm communication between the physician and mother is the best way to maintain control of the delivery.

After the head is delivered, the physician allows the head to rotate toward the maternal thigh and clears the fetal face and airway. Next, the shoulders, usually anterior shoulder first, clear the perineum. The shoulders often deliver spontaneously, with little effort by the physician. Gentle downward traction on the head promotes delivery of the anterior shoulder. A subsequent upward motion pulls the posterior shoulder through the pelvic outlet. If delay occurs in delivery of the shoulders, the potential for shoulder dystocia should be considered.

As the infant clears the perineum, attention focuses on the umbilical cord. The infant should be kept low or at the level of the perineum to promote blood flow into the infant from the placenta. The cord is clamped and cut. Clamps should be placed 4 or 5 cm apart, with the proximal clamp 10 cm from the infant's abdomen. The cord should be cut at least 1cm from the skin to ensure venous access if the neonate requires resuscitation. Suctioning of the nose and mouth at this time may reduce secretions that can cause increased airway resistance.

The infant is now clear of the mother and can be wrapped in towels and moved to the warmer. Gentle drying with a towel and suctioning usually provide sufficient respiratory stimulation. If not, flicking the soles of the feet and rubbing the back are other modalities. Apgar scores at 1, 5, and 10 minutes after birth should be documented.

Episiotomy. With a controlled delivery, routine performance of an episiotomy is not recommended. It should be performed only for specific indications, such as shoulder dystocia or breech delivery. An episiotomy should be done before excessive stretching of the perineal muscles occurs but near the time of delivery to avoid excessive bleeding. Common practice is to cut the episiotomy when the head is visible during a contraction and the introitus opens to a diameter of 3 or 4 cm. The literature currently recommends a mediolateral incision to avoid perineal tears and rectal involvement (Fig. 176.7).

Third Stage of Labor

The third stage of labor involves the delivery of the placenta and frequent checks of the tone and height of the uterine fundus. Signs of placental separation include the following: the uterus becomes firmer and rises; the umbilical cord lengthens 5 to 10 cm; or there is a sudden gush of blood.

These signs usually occur within 5 to 10 minutes of the delivery of the infant but may extend to 30 minutes. Beyond 18 minutes, the risk of postpartum hemorrhage increases and is up to six times more likely after 30 minutes. Although the placenta may be delivered expectantly, active management reduces the length of the third stage of labor and thereby decreases the risk of postpartum hemorrhage. Active management includes the administration of uterotonic gentle traction of the clamped umbilical cord with mild pressure applied above the symphysis pubis and uterine massage after delivery. Any attempt to deliver the placenta before it separates is contraindicated.

Examination of the umbilical cord and placenta is an essential part of the delivery process and any abnormalities should be noted at this

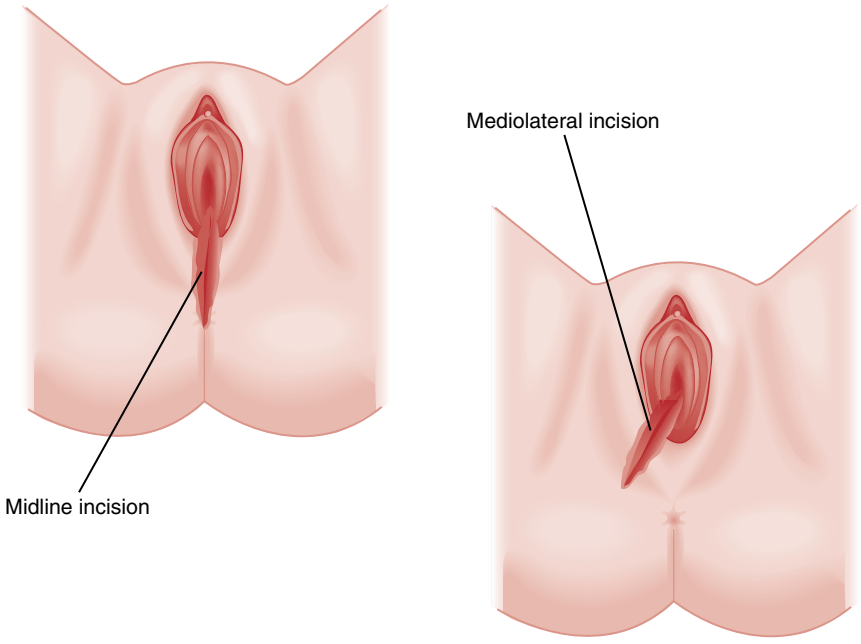

Fig. 176.7 A mediolateral episiotomy incision is preferred to a strictly midline incision. (Adapted from www.aurorahealthcare.org/healthgate/images/exh44028a_ma.jpg.)

time. The umbilical cord is normally a three-vessel structure, with two umbilical arteries on either side of the single umbilical vein. A two-vessel cord (one umbilical artery) occurs in 1 of 500 deliveries. Common abnormalities of the placenta include accessory lobes and abnormal cord insertion. Visible clots adherent to the uterine aspect may indicate placental abruption and the discovery of an incomplete placenta or membranes should alert the clinician to the possibility of postpartum complications.

Fourth Stage of Labor

The fourth stage of labor refers to the first hour after delivery of the placenta and is a critical period during which postpartum hemorrhage is most likely to occur. The cervix and vaginal fornices should be inspected for deep lacerations as a result of delivery, and repair of any vaginal lacerations should be performed at this time.

Finally, oxytocin is infused to promote contraction of the uterus and control hemorrhage. The uterus is evaluated frequently for tone and massaged transabdominally if any sign of relaxation exists. Oxytocin should not be given before delivery of the placenta because this could result in the trapping of placental fragments or may hinder the delivery of an undetected twin.

THIRD-TRIMESTER COMPLICATIONS ASSOCIATED WITH DELIVERY

Obstetric problems in the third trimester often result in the initiation of labor. Premature labor, PROM, and third-trimester bleeding are relatively common complications. The fundamental question to be addressed in these settings is whether the fetus would fare better in utero or delivered.

Premature Labor

Premature or preterm labor and fetal immaturity are the leading causes of neonatal mortality. Preterm labor is defined as uterine contractions with cervical changes before 37 weeks of gestation. Many underlying conditions result in preterm labor, which is associated with 5% to 18% of all pregnancies and is the leading cause of neonatal death. Factors linked to this problem include substance abuse, history of preterm delivery, multiple gestations, placental anomalies, infections, and lifestyle or psychosocial stressors (Box 176.2). The unexpected nature of premature labor often results in an ED visit. When delivery is not imminent, the patient can be moved to the obstetrics unit for further care.

BOX 176.2 Factors Linked to Preterm Labor

Demographic and Psychosocial
Extremes of age (>40 yr, teenagers)
Lower socioeconomic status
Tobacco use
Cocaine abuse
Prolonged standing (occupation)
Psychosocial stressors

Reproductive and Gynecologic
Prior preterm delivery
Diethylstilbestrol exposure
Multiple gestations
Anatomic endometrial cavity anomalies
Cervical incompetence
Low pregnancy weight gain
First-trimester vaginal bleeding
Placental abruption or previa

Surgical
Prior reproductive organ surgery
Prior paraendometrial surgery other than genitourinary (appendectomy)

Infectious
Urinary tract infections
Nonuterine infections
Genital tract infections (bacterial vaginosis)

Clinical Features

The diagnosis of preterm labor requires the identification of uterine activity and cervical changes before 37 weeks of gestation. Early maternal signs and symptoms include an increase or change in vaginal discharge, pain resulting from uterine contractions (sometimes perceived as back pain), pelvic pressure, vaginal bleeding, and fluid leak.

Diagnostic Testing

If uterine contractions and cervical changes are present, and the estimated fetal weight on ultrasonography is less than 2500 g, the diagnosis of premature labor is likely. The differentiation of false labor from true labor is best done by electrical monitoring. The initial evaluation of a woman with possible preterm labor includes urinalysis, complete blood count, and pelvic ultrasonography. If delivery is not imminent, these studies can be performed under monitoring in the ED or obstetrics area. Whenever possible, these patients should be transferred to a perinatal center with an associated intensive care unit.

Management

A viable fetus and healthy mother are indications for medical management directed toward the prolongation of gestation. Preterm labor should not be postponed with medical management in the cases of fetal compromise, major congenital anomalies, intrauterine infection, placental abruption, eclampsia, significant cervical dilation, or PROM.

The treatment of preterm labor involves multiple modalities and is usually performed outside the ED. Tocolytics and fetal maturation therapy combined with bed rest and hydration are used with the hope of prolonging pregnancy (Box 176.3). When tocolytics are indicated, they should be used in coordination with an obstetric consultant. These patients optimally should be transferred to an appropriate center before delivery, whenever possible, because medical management fails in more than 25% of preterm patients for whom it is attempted. The contraindications to tocolytics should be reviewed before initiation of these therapies (Box 176.4). Any patient receiving tocolytics needs to be monitored for signs of fetal distress. Terbutaline has been associated with serious maternal side effects and deleterious behavioral effects in the offspring after in utero exposure. Terbutaline should be limited to short-term inpatient use.

Premature Rupture of Membranes

Clinical Features

PROM is defined as rupture of the amniotic and chorionic membranes before the onset of labor. It affects 3% of all gestations. During pregnancy, the chorionic and amniotic membranes protect the fetus from infection and provide an environment that allows fetal growth and movement. The amniotic fluid is constantly exchanged by fetal swallowing and urination and umbilical cord transfer.

The word *premature* in PROM refers to rupture before labor, not to fetal prematurity. In 8% of PROM cases, the fetus is at or near term, and PROM may result in normal labor. When PROM occurs before 37 weeks, it is called preterm PROM and is associated with significant fetal morbidity and mortality. PROM is the inciting event in one-third of all preterm deliveries.

After the membranes rupture, the period from latency to the onset of labor varies. Longer latent periods are common earlier in pregnancy, and the latency shortens as gestational age increases. At term, labor is a desirable result of PROM, but with fetal immaturity, delivery would result in fetal complications.

Diagnostic Testing

The diagnosis of PROM can be established by the history and physical examination. In most cases, the patient suggests the diagnosis and usually is correct. The patient typically describes a spontaneous gush of watery fluid, followed by a mild persistent seepage. Urinary incontinence or excess vaginal or cervical secretions are occasionally confused with PROM.

Examination of women with potential PROM is performed under sterile conditions to prevent ascending infection. Direct digital examination of the cervix is avoided. The identification of amniotic fluid was previously discussed. Table 176.1 summarizes the bedside testing modalities available to confirm the diagnosis of PROM. Visualization of the cervix for a prolapsed cord or small fetal part is performed during the evaluation for effacement and dilation. Culture specimens for group B streptococci, *Chlamydia trachomatis,* and *Neisseria gonorrhoeae* should be obtained.

BOX 176.3 Commonly Used Tocolytic Agents

Magnesium sulfate
- 4–6 g IV bolus over 20 min
- 1–2 g/hr IV infusion

Terbutaline
- 5–10 mg PO q4–6h
- 0.25 mg SC q20min
- 2.5–5 mcg/min increased every 20 min to max 25 mcg/min

Ritodrine[a]
- 10 mg PO q2–4h
- 10 mg IM q3–8h
- 0.05–0.35 mg/min IV infusion

Isoxsuprine
- 20 mg PO q6h
- 0.2–0.5 mg/min IV infusion

Nifedipine
- 10–30 mg PO q15–20 min for the first hour then 10–20 mg PO q4–8h

[a]Ritodrine and Isoxsuprine have been discontinued in the United States.

BOX 176.4 Contraindications to Tocolysis

Absolute
- Acute vaginal bleeding
- Fetal distress (not tachycardia alone)
- Lethal fetal anomaly
- Chorioamnionitis
- Preeclampsia or eclampsia
- Sepsis
- Disseminated intravascular coagulopathy

Relative
- Chronic hypertension
- Cardiopulmonary disease
- Stable placenta previa
- Cervical dilation > 5 cm
- Placental abruption

TABLE 176.1 Bedside Testing for Premature Rupture of Membranes

Method	Result
Nitrazine	Amniotic fluid (pH > 6.5) will turn Nitrazine paper blue; normal vaginal secretions (pH < 5.5) leave Nitrazine paper yellow
Ferning	Amniotic fluid crystallizes
Smear combustion	Amniotic fluid, when flamed, turns white and crystallizes; vaginal secretions caramelize, turn brown

Management

The management of PROM depends on several factors, including gestational age and fetal maturity, presence of active labor, presence or absence of infection, presence of placental abruption, and degree of fetal well-being or distress. In all cases, fetal heart rate monitoring, obstetric consultation, and admission are indicated. In the immature fetus (24–31 weeks of gestation), the initiation of specific treatment decisions aimed at accelerating fetal maturity should be made in coordination with the receiving obstetrician. This includes the possible administration of corticosteroids to promote pulmonary maturation. Patients with PROM between 31 and 33 weeks' gestation are usually managed expectantly and those at or beyond 34 weeks of gestation are generally delivered.

All patients with PROM should be assessed for intraamniotic infection. Infectious complications should be diagnosed and treated before the mother demonstrates overt clinical signs. We recommend treating preterm PROM with an initial dose of ampicillin (2 g IV) plus azithromycin (1 g PO) followed by ampicillin (2 g IV Q6h × 48h) plus amoxicillin 875 mg PO BID for 5 days.

Chorioamnionitis

Chorioamnionitis occurs when vaginal or cervical bacteria ascend into the uterus, instigating an inflammation of the chorion and amnion layers of the amniotic sac. It occurs in 1% to 10% of all pregnancies; risk factors include prolonged labor, PROM, excessive vaginal examinations, and recent amniocentesis. Box 176.5 summarizes the findings and evaluation of chorioamnionitis. Chorioamnionitis may result in prolonged first- and second-stage labor and decreased responsiveness to oxytocin. Early aggressive treatment, even before evidence of infection occurs, decreases neonatal morbidity and delays delivery, allowing more time for fetal maturation.

BOX 176.5 Chorioamnionitis Evaluation

Fluid in Vaginal Vault
Phosphatidylglycerol

Cervical Cultures
Escherichia coli and other gram-negative bacteria
Neisseria gonorrhoeae

Vaginal Cultures
Chlamydia spp.
Mycoplasma hominis
Group B streptococci
Ureaplasma urealyticum

Amniocentesis Studies
Gram stain (group B streptococci)
Culture
Glucose
Lecithin to sphingomyelin ratio

Maternal Signs and Symptoms
Premature rupture of membranes
Uterine tenderness
Fever
Tachycardia (maternal or fetal)
Malodorous vaginal discharge
Leukocytosis

Fetal Signs and Symptoms
Decreased activity
Abnormal biophysical profile (ultrasonographic examination)
Fetal tachycardia
Decreased variability of fetal heart rate

Vertical Transmission of Human Immunodeficiency Virus

The antiretroviral drug zidovudine (AZT) has long been used to prevent vertical transmission of HIV during labor. With appropriate therapy, the risk of vertical transmission is well under 1%. Current guidelines do not recommend perinatal intravenous AZT for patients with well-controlled disease that are already taking oral antiretroviral medications.[2] If doubt exits as to a patient's HIV progression or medication compliance, AZT (2 mg/kg infused over 1 hour followed by a continuous infusion of 1 mg/kg/hour for 2 additional hours) should be started. Patients with unclear HIV status should be tested on presentation to the ED. Transmission may occur in the antepartum, intrapartum, or postpartum (breast-feeding) period. Because intrapartum transmission accounts for up to 75% of vertically transmitted HIV infections, antiretroviral therapy on presentation, even while labor progresses, can decrease vertical HIV transmission. Risk factors for transmission include high viral loads, prolonged rupture of membranes, maternal drug use, vaginal delivery, and breast-feeding.

Advances in point-of-care testing for HIV have resulted in the ability to make a preliminary diagnosis in a patient with HIV in the ED. Serologic confirmation is recommended, but emergent interventions can proceed on the basis of the bedside result. A positive HIV test result may, in some cases, allow a change in the method of delivery; cesarean section decreases the rate of HIV transmission compared with vaginal delivery methods.

COMPLICATED DELIVERY

Foundations

Deliveries involving dystocia, malpresentation, and multiple gestations are potentially life-threatening emergencies. The emergency clinician cannot solve these obstetric problems with cesarean section and will therefore face the prospect of an extremely high-risk vaginal delivery. As expected, these abnormal deliveries increase the risk of fetal and maternal complications. Aggressive attempts to obtain obstetric, neonatal, and anesthesia support are warranted. If the delivery proceeds in the ED, preparations for maternal and neonatal resuscitation need to be made proactively and rapidly.

Dystocia and Malpresentation

Dystocia, or abnormal labor progression, accounts for one-third of all cesarean sections and half of primary cesarean sections. Because rapid surgical resolution is unavailable to the emergency clinician, intrapartum management skills are required.

Dystocia can be divided into three categories of causative factors. Labor fails to progress when there are problems related to the pelvic architecture (the passage), fetal size or presentation problems (the passenger), and inadequate uterine expulsive forces. Although it is useful to consider these causes independently, dystocia is usually caused by a combination of factors. Presentation problems are particularly important because they become apparent during stage 2 of labor and require immediate action.

In order of increasing incidence, brow, face, shoulder, and breech presentations are the most common malpresentations (Table 176.2). True fetopelvic disproportion is much less common. Cesarean section is indicated when labor arrest or cord prolapse coexists with these presentations.

TABLE 176.2 Relative Incidence of Malpresentations

Malpresentation	Incidence
Breech presentation	1/25 live births
Shoulder dystocia	1/300 live births
Face presentation	1/550 live births
Brow presentation	1/1400 live births

Breech Delivery

Breech is the most common malpresentation, occurring in just less than 4% of all deliveries. Three types of breech presentation exist—frank, incomplete, and complete (Fig. 176.8; Box 176.6).

By convention, the presentation (frank, incomplete, and complete) is followed by the relationship of the fetus to the birth canal, with the fetal sacrum as a reference point. Correlated with this abnormal presentation are several factors, such as prematurity, multiparity, fetal abnormalities, prior breech presentation, polyhydramnios, and uterine abnormalities.

Overall, one-third of breech fetal deaths are believed to be preventable. Asphyxia is often due to umbilical cord prolapse or entrapment of the head. Other complications include labor arrest or brachial plexus injuries, and fetal head and neck trauma can occur if inappropriate delivery techniques are used. Scheduled cesarean section for these patients reduces the potential for an ED presentation. However, emergency clinicians should be prepared for vaginal delivery of breech presentations in the event of premature or unforeseen labor in the absence of immediate surgical services.

The mechanical problem with breech presentations is that the buttocks and legs do not provide a sufficient wedge, hindering cervical accommodation of the relatively larger head. In addition, because the presenting part does not occlude the cervical opening completely, umbilical cord prolapse may occur.

In the successful vaginal delivery of a breech presentation, the legs or buttocks are given time to dilate the cervix. This creates a tenuous appearing scenario where the baby's hips are delivered, but the shoulders and head are still inside the cervical OS. It appears as though the baby can simply be pulled free, but pulling on the hips will bring the shoulders through the OS, trapping the head and obstructing the labor. In fact, the clinician should take care to support, but not pull, the presenting part.

Diagnostic Testing

Before labor, *Leopold maneuvers* (see Fig. 176.3) facilitate the diagnosis of breech presentation. Active labor restricts the use of Leopold maneuvers, and a vaginal examination is required. Bedside ultrasound can help establish position if it is unclear. The differentiation of a vertex presentation from a breech presentation by tactile vaginal exam may be difficult. Whenever a fontanel is not identified on examination, a breech presentation should be suspected. It is helpful to remember that the face and skull have a complete circle of bone, whereas the anus is flanked by bone on only two sides.

If time permits, an ultrasound examination is indicated to distinguish the type of breech presentation, gestational age, fetal weight, and position of the fetal arms and neck. If the fetus has a hyperextended neck, vaginal delivery is associated with a high incidence of spinal cord injuries. If possible, labor should be delayed to allow cesarean section. Similarly, if the arms are over the head, they increase the dystocia when the head enters the birth canal.

Management

Premature infants in the breech position often deliver spontaneously without difficulty. As the infant comes to term, dystocia becomes increasingly common. With commitment to a vaginal delivery, knowledge of breech dystocia mechanics may allow atraumatic delivery. The key goals are to maximize the size of the passage and to minimize the dystocia of the after-coming head. Box 176.7 summarizes the actions associated with successful vaginal breech delivery.

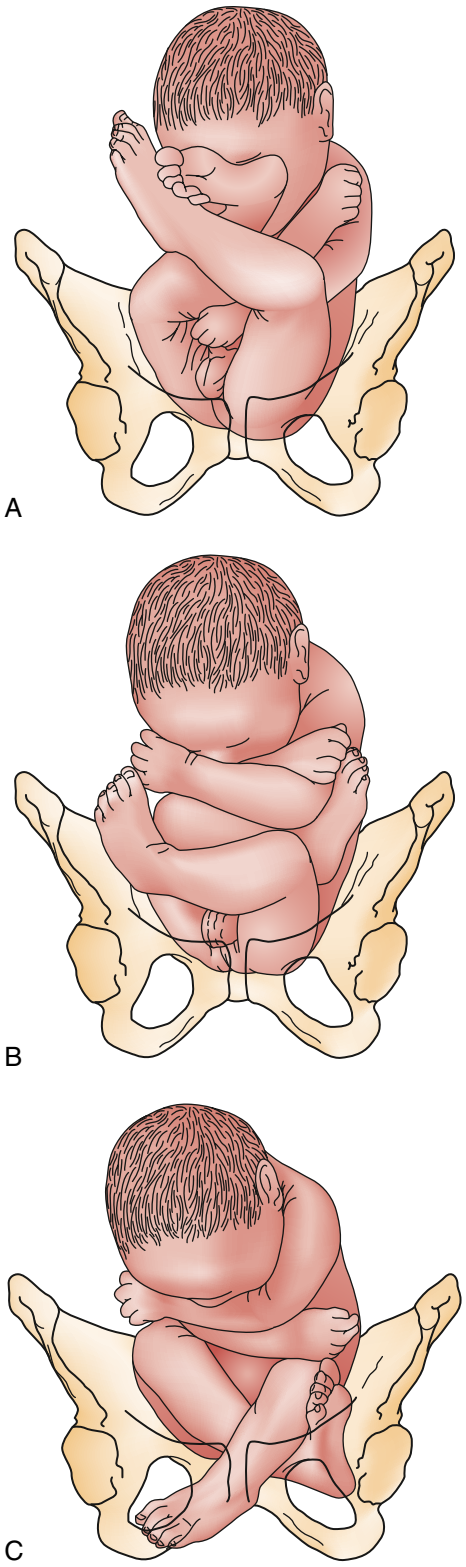

Fig. 176.8 Breech presentations. (A) Frank breech presentation. (B) Complete breech presentation. (C) Incomplete breech presentation. (Adapted from: Cunningham FG, et al. *Williams Obstetrics*, ed 19. Norwalk, CT: Appleton & Lange; 1993.)

The *Mauriceau maneuver* is the use of the fetal mouth to flex the fetal neck and draw in the chin. Because fetal neck extension is associated with cord injuries and worsening dystocia, this maneuver is useful to ensure a successful vaginal delivery. This maneuver should only be attempted once the fetal elbows and chin have entered the pelvic inlet to avoid inducing the Moro reflex, in which fetal head flexion results in the arms being suddenly extended. During this maneuver, the fetal pelvis should be supported to avoid abdominal injuries. A generous episiotomy may be necessary to facilitate the maneuver in a full-term infant. If the after-coming head cannot be delivered quickly, the chances of good fetal outcome are poor.

Shoulder Dystocia

Shoulder dystocia is the second most common malpresentation, occurring in 1.4% of all deliveries. In contrast to a breech presentation, which may be diagnosed in the antepartum period, shoulder dystocia develops in the intrapartum period. Maternal and fetal factors are associated with shoulder dystocia. Maternal factors include diabetes, obesity, and precipitous or protracted labor; fetal factors include macrosomia, postmaturity, and erythroblastosis fetalis. Shoulder dystocia responds well to a variety of intrapartum maneuvers; therefore, the skill involved during delivery is an important determinant of fetal outcome.

The consequences of shoulder dystocia can be devastating. As with a breech presentation, infant complications are more common and severe than maternal complications. Traumatic brachial plexus injuries, clavicular fractures, and hypoxic brain injury are all well-documented complications. Maternal complications are related to traumatic delivery and include vaginal, perineal, and anal sphincter tears, as well as urinary incontinence.

Diagnostic Testing

Shoulder dystocia is diagnosed clinically by the inability to deliver either shoulder. The fetal head may appear to retract toward the maternal perineum, otherwise known as the turtle sign. Traction on the head extends and abducts the shoulders, increasing the bisacromial diameter and worsening the dystocia. Fig. 176.9 shows the normal and abnormal

BOX 176.6 Breech Presentations

Frank Breech
60%–65% of all breech presentations
Hips flexed, knees extended
Buttocks act as good dilating wedge
Incidence of cord prolapse ≈0.5%

Complete Breech
Least common; occurs in ≈5% of all breech presentations
Hips and knees flexed
Buttocks act as good dilating wedge
Incidence of cord prolapse is 5%–6%

Incomplete Breech
25%–35% of all breech presentations
Incomplete hip flexion, single or double footling
Poor wedge
Increased incidence of prolapsed cord (15%–18%)

BOX 176.7 Vaginal Breech Delivery

Actions to Do as Able
Monitor fetal heart rate.
Obtain a focused history.
Diagnose a breech lie.
Determine cervical dilation and station.
Obtain an ultrasound or plain radiographic study.
Evaluate for prolapsed cord if there is spontaneous rupture of membranes.
Perform an episiotomy.
Flex knees and sweep out legs.
Pull out a 10- to 15-cm loop of cord (room to work) after the umbilicus clears the perineum.
Use the bony pelvis as a means of holding the infant.
Keep face and abdomen away from the symphysis and use rotation to deliver the more accessible arm.
Perform the Mauriceau maneuver.

Actions to Avoid
Inappropriate transfer with delivery en route
Misdiagnosis of cervical dilation
Iatrogenic rupture of membranes (cord prolapse)
Moving of patients or leaving them unmonitored
Traction on the fetus during delivery
Grasping of the fetus by the waist, causing abdominal organ injury
Arm entrapment over head
Neck hyperextension

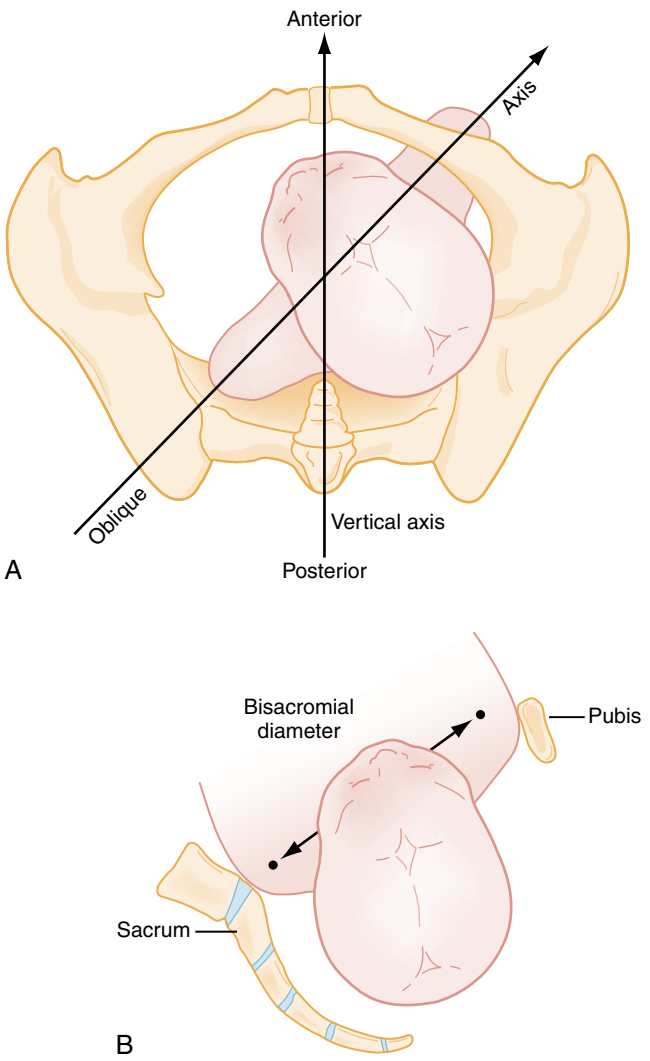

Fig. 176.9 (A) Normal delivery. As the fetal head rotates, the shoulders assume an oblique position and enter the pelvis one at a time. (B) Shoulder dystocia. Both shoulders attempt to clear the pelvis simultaneously, forcing the bisacromial diameter into the opening.

relationship of the shoulders to the birth canal and illustrates why the bisacromial diameter is an important element of fetal biometry.

Normally, the shoulders negotiate the maternal pelvis in sequential fashion, anterior shoulder first. With shoulder dystocia, both shoulders attempt to clear the maternal pelvis simultaneously. In addition to the turtle sign, examination often reveals that the fetal shoulders are on a vertical axis, rather than oblique. These findings, in combination with an arrested delivery, confirm the diagnosis of shoulder dystocia.

Management

When shoulder dystocia becomes evident, knowledge of intrapartum delivery maneuvers can be lifesaving. Successful vaginal delivery is most likely when a directed sequential approach to each maneuver is used. A rapid resolution of shoulder dystocia is important to avoid fetal asphyxia and resultant central nervous system injury. Obstetric and neonatology assistance may improve the outcome, and aggressive attempts to obtain assistance are warranted.

Initial attempts to resolve shoulder dystocia involve increasing the anteroposterior diameter of the passage. An episiotomy may be used for fetal maneuvering by allowing access to the posterior shoulder. Anteriorly, draining the bladder with a Foley catheter can generate room.

The most important first step is to use the *McRoberts maneuver* (Fig. 176.10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder, allowing rapid vaginal delivery to follow. This maneuver "walks" the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus pass through the birth canal, one shoulder at a time. This method, although requiring very little effort, is often successful in alleviating shoulder dystocia.

If the McRoberts maneuver fails to free the anterior shoulder, the application of suprapubic pressure may accomplish this by forcing the anterior shoulder to slip beneath the pubis or posterior shoulder to retreat into the hollow of the sacrum. Digital pressure on the posterior shoulder (through the episiotomy) may help facilitate posterior shoulder retreat. The use of the McRoberts maneuver and suprapubic pressure resolve most cases of shoulder dystocia.

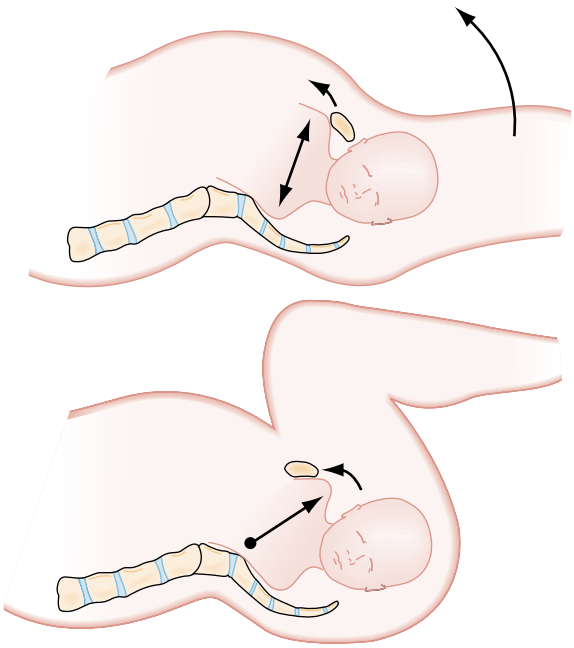

Fig. 176.10 McRoberts maneuver. *Top,* Bisacromial diameter pinned behind pubic symphysis. *Bottom,* Removing the maternal legs from the stirrups and putting the knees up to the chest act as a fulcrum to the pubic symphysis over the impacted anterior shoulder.

If delivery is still impossible, the next step is to attempt the *Rubin maneuver* (Fig. 176.11). The goal of this maneuver is to decrease the bisacromial diameter by pushing the most accessible shoulder toward the fetal chest. Often, both shoulders assume the same attitude, decreasing the bisacromial diameter and allowing delivery. Attempts to manipulate the shoulders for the Rubin maneuver may be transabdominal, through the introitus (anterior shoulder), or through the episiotomy (posterior shoulder).

If the shoulders remain undeliverable, the next step is to use *Wood corkscrew maneuver*. In this process, the impacted shoulders are released through rotation of the fetus 180 degrees. Fetal rotation is achieved by pushing the most accessible shoulder in toward the chest. The fetal axilla can be snared with a digit, or a hand can be slid in along the fetal spine to sweep the hips and generate rotation. Wood corkscrew maneuver is difficult to perform but should be attempted before reaching for an arm.

If the fetus remains trapped and several attempts have failed to yield delivery, consideration of delivery of an arm is appropriate. A hand is introduced along the posterior aspect of the posterior shoulder. The posterior arm is swept across the chest, bringing the fetal hand up to the chin. Attempts to splint the humerus may prevent fractures and brachial plexus injuries. The fetal hand is grasped and pulled out of the birth canal across the face, delivering the posterior shoulder.

The mnemonic HELPER (Box 176.8) is useful to keep these steps organized and facilitate a sequential approach which will successfully deliver almost all cases of shoulder dystocia.

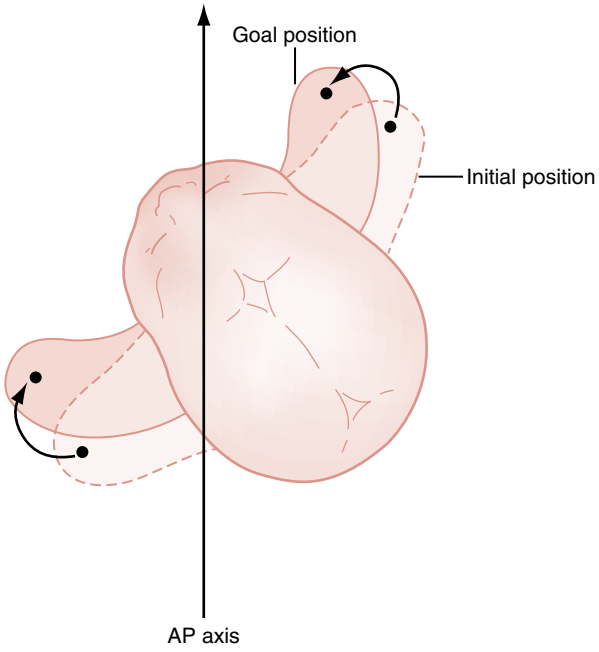

Fig. 176.11 Rubin maneuver decreases the bisacromial diameter. *AP,* Anteroposterior.

BOX 176.8 HELPER Mnemonic for Shoulder Dystocia

Help—obstetrics, neonatology, anesthesia
Epiotomy—generous, possibly even episioproctotomy
Legs flexed—McRobert maneuver
Pressure—suprapubic pressure, shoulder pressure
Enter vagina—Rubin maneuver or Wood maneuver
Remove posterior arm—Splint, sweep, grasp, and pull to extension.

Face, Brow, and Compound Presentations

Face and brow presentations yield a larger engaging aspect of the fetal head and predispose to labor arrest. Although these abnormal presentations can be diagnosed with ultrasonography or Leopold maneuvers, most are discovered during labor by vaginal examination. Approximately 50% are discovered during the second stage of labor.

The engaging diameter of the head in vertex position is approximately 0.8 cm less than a face presentation and 1.5 cm less than a brow presentation. Face presentations are described with the chin as a reference point (e.g., mentum anterior). Face presentation is managed expectantly. The obstetric adage—"if a face presentation is progressing, leave it alone"—is based on the fact that mentum anterior presentations usually deliver vaginally, and mentum transverse presentations frequently rotate to become mentum anterior. Brow presentations, occurring when the fetal head is partially flexed, also spontaneously convert to a vertex or face presentation in more than 50% of cases.

A persistent mentum posterior face and brow presentation cannot be delivered vaginally if the fetus is full term. The resultant labor arrest requires symphysiotomy or cesarean section. Prolongation of the second stage is the most common outcome of both these malpresentations at term. For the emergency clinician, this prolonged second stage may provide a window during which obstetric help may arrive.

Compound presentations are those in which an extremity enters the birth canal with the head or breech. Small and premature fetuses generally proceed to vaginal delivery without incident.

Labor arrest and umbilical cord prolapse are accepted indications for cesarean section in the setting of face, brow, and compound presentations. Manipulation of a compound presentation, including attempts to reduce the hand or arm, increases the rate of cord prolapse. Therefore, manipulation attempts are contraindicated. Cord prolapse rates are 10% to 20%, even without manipulation. Close monitoring and careful examination are indicated.

MULTIPLE GESTATIONS

Due to the increasing use and availability of fertility treatments, the incidence of multiple gestation pregnancies has been increasing. In 2013, twin deliveries accounted for 34/1000 births in the United States. Because multiple gestation deliveries have a higher incidence of preterm labor and low birth weights, maternal and fetal complication rates are correspondingly increased.

Diagnostic Testing

Most women with multiple gestations have the situation identified well before the third trimester. In patients who have had little or no prenatal care, bedside ultrasonography allows for a rapid diagnosis. The stages of labor for twins and other multiple gestations are similar to the stages for a singleton. Of importance to the emergency clinician is a relatively short latent phase of labor, with rapid progression to the active phase. The active phase is usually longer, however, and may allow time for obstetric assistance to arrive.

Vertex twin A and vertex twin B occur in approximately 42% of deliveries. One of the twins presents in a nonvertex position in approximately 35% to 40% of cases.[3]

Management

The presentation of twins is a key determinant for the safety of vaginal delivery. Twins who are vertex-vertex can be delivered vaginally, barring any other obstetric complication. If twin B is nonvertex, many obstetricians recommend cesarean section to prevent delivery-related complications for twin B. External cephalic version and breech extraction are possible maneuvers to facilitate precipitous vaginal delivery. Generally, if twin A is nonvertex, cesarean section is preferred. In such cases, efforts should be made to delay delivery until an operative approach can be used. Proceeding vaginally can result in the interlocking of twins, associated with a high mortality.

The interval between the delivery of twin A and twin B is variable. In most cases, twin B delivers in minutes. When twin B does not follow rapidly, in utero assessment is important to document fetal well-being. If fetal heart tracings are reassuring, the delivery of twin B (especially nonvertex) should not be hastened. Repeated ultrasonographic evaluation may also be used to confirm twin B's presentation and well-being.

After every ED delivery, particularly deliveries that are precipitous or that occur in the out-of-hospital setting, the mother should be examined for the possibility of twins. Ongoing labor may be confused with postpartum cramping, only to have twin B and all the potential complications surprise the emergency clinician. This is particularly relevant for women with inadequate prenatal care and low-birth-weight infants.

UMBILICAL CORD-RELATED EMERGENCIES

Umbilical cord–related complications can occur in normal and abnormal deliveries. Immediate intervention is required to prevent fetal morbidity and mortality. The spectrum of cord-related emergencies includes prolapsed cord, nuchal loops of the umbilical cord, body coils, cord knots, and entangled cords in monoamniotic twins. The cord length is believed to be proportional to fetal activity in utero during the first and second trimesters. Excess cord length increases the potential for umbilical cord complications of all types. Because the umbilical cord supplies the fetus with all its oxygen, interruption of cord circulation before establishment of fetal respiration is a life-threatening emergency. Fetal asphyxia caused by cord circulation compromise is potentially preventable with early recognition and intervention.

Umbilical Cord Prolapse

Clinical Features

Umbilical cord prolapse occurs when the umbilical cord precedes the fetal presenting part or when the presenting part does not fill the birth canal completely. Most cases of cord prolapse are unexpected and develop during the second stage of labor.

Cord prolapse has a variable rate of association with different fetal presentations. Compound, shoulder, and breech presentations yield gaps and a relatively poor dilating wedge. Table 176.3 summarizes the rates of umbilical cord prolapse with various fetal presentations. Malpresentations account for 50% of all cord prolapse cases and the prolapsed cord itself may be the first indication of a malpresentation. The reported incidence of cord prolapse ranges from 1.4 to 6.2/1000 deliveries, and associated perinatal mortality is estimated to be just below 10%.[4]

TABLE 176.3 Conditions Associated With Umbilical Cord Prolapse

Presentation	Incidence (%)
Vertex	0.14
Breech	2.5–3.0
Frank breech	0.4
Complete breech	5
Incomplete breech	10
Shoulder	5–10
Compound	10–20
Face or brow	Rare

Diagnostic Testing

Umbilical cord prolapse may be overt or occult, requiring a pelvic examination to reveal the umbilical cord lying beside the presenting part. The diagnosis may also be made with Doppler ultrasonography. In most cases, the diagnosis is obvious, and the cord is encountered at the perineum or introitus.

Management

When a prolapsed cord occurs with a viable infant, cesarean section is the delivery method of choice. If surgical delivery is available, maneuvers to preserve umbilical circulation should be instituted immediately. The mother is placed in the knee-chest position, with the bed in the Trendelenburg position, and instructed to refrain from pushing to avoid further compression of the cord. The presenting part is then manually elevated off the cord. Elevation is maintained until the baby can be delivered surgically. The time from prolapse to surgical intervention is an important factor in fetal outcome. Perinatal mortality rates are higher for out-of-hospital cases versus those within a monitored setting, and outcomes correlate with time from diagnosis to delivery.

If timely surgical delivery cannot be performed, funic reduction—manual replacement of the cord into the uterus—and rapid vaginal delivery may be necessary. The same maneuvers to decrease cord compression should be used, pushing gently on the cord in a retrograde fashion, above the presenting part. Manipulation and cord trauma should be kept to a minimum because resultant vasospasm can cause fetal hypoxia. After funic reduction, the development of umbilical cord body coils or nuchal loops is common and should be anticipated.

Cord Entanglement

The umbilical cord can also become entangled with itself, spontaneously knotting. Umbilical cord knots are related to intrauterine movements early in pregnancy. Approximately 5% of stillbirths are found to have knots that are believed to have caused fetal demise. Despite this association, cord knots can persist without problems as long as perfusion is maintained.

Loose umbilical cord knots pulled tight at delivery may cause fetal distress. As with cord prolapse, this situation must be resolved quickly to prevent fetal asphyxia. Rapid delivery with avoidance of further cord traction optimizes fetal outcome. No specific interventions have been identified to deal with this problem.

Long umbilical cords are associated with true knots, as well as with entanglements and prolapse. Umbilical cord loops can be single or multiple and can occur around the neck or body. Because the fetal limbs are short and flexed in most presentations, they are rarely involved. Although generally benign, umbilical cord loops may result in fetal complications, such as nonreassuring fetal status and respiratory distress.

During delivery, loose nuchal cords should be reduced at the perineum. Loose body coils usually disentangle spontaneously. The reduction process may be aided by slipping them over the extremities or forward over the head. On occasion, loops are tight enough to impede delivery and cannot be reduced. The solution is to cut the clamped cord and deliver the infant rapidly. The high frequency of nuchal loops (one in five births) means that the emergency clinician should expect to encounter this problem.

MATERNAL COMPLICATIONS OF LABOR AND DELIVERY

Maternal complications of labor and delivery include postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, and infections. Although some are managed medically, severe complications threaten the reproductive future and life of the mother, thereby requiring emergent surgical intervention.

Postpartum Hemorrhage

Clinical Features

Postpartum hemorrhage is the most common complication of labor and delivery. Defined as hemorrhage of more than 500 mL after vaginal delivery, it accounts for up to 11% of obstetric deaths.[5] Postpartum hemorrhage is divided into two categories; the primary category includes blood loss that occurs within the first 24 hours, and the secondary category is hemorrhage 24 hours to 6 weeks after delivery. Because of maternal adaptations during pregnancy, the patient may not show signs of shock until more than 1500 mL of volume has been lost.

Differential Diagnosis and Management

The differential diagnosis of primary postpartum hemorrhage includes uterine atony, genital tract trauma, retained placental tissue, and coagulopathies, or the "four Ts"—***t***one, ***t***rauma, ***t***issue, and ***t***hrombin.

Uterine Atony. Accounting for 75% to 90% of cases, the most common cause of serious immediate postpartum hemorrhage is laxity of the uterus after delivery. Normally, postpartum bleeding from the placental implantation site is limited by contraction of the myometrium, constricting the spiral arteries. If the uterus does not contract, ongoing hemorrhage will occur. Predisposing factors include overdistention of the uterus (e.g., multiple gestations, fetal macrosomia, polyhydramnios), prolonged labor, chorioamnionitis, use of tocolytics, and general anesthesia with halogenated compounds. As a diagnosis of exclusion, a physical examination to rule out obstetric trauma and retained products of conception should be performed before the diagnosis is reached. On examination, the uterus is palpable as a soft boggy mass.

After other causes have been excluded, therapy to augment myometrial contractions is instituted to prevent further hemorrhage. A two-handed uterine massage may stimulate uterine contractions. One hand exerts pressure transabdominally while the other supports the uterus through the introitus. Administration of a uterotonic, such as oxytocin in conjunction with massage usually provides enough stimuli to control bleeding. We recommend 10 units IM following the delivery of the placenta. Intravenous options include oxytocin 5 to 10 units initially followed by an infusion of 10 units/hr to a maximum of 40 units total. Blood is ideally typed, cross-matched, and available for resuscitation should these measures fail, with unmatched O negative blood used in true emergencies

Maternal Birth Trauma. Maternal birth trauma is the second most common cause of postpartum hemorrhage, accounting for up to 20% of cases. Associated factors include uncontrolled delivery, macrosomia, episiotomy, nulliparity, maternal coagulopathy, operative delivery, prolonged second stage of labor, preeclampsia, and malpresentation. Tears and lacerations may involve the perineum, rectum, cervix, vagina, vulva, and urethra. Blood vessels beneath the vulvar or vaginal epithelium can also be injured without frank hemorrhage, resulting in the formation of large contained hematomas. These hematomas may go unrecognized for hours, gradually enlarging and possibly resulting in hemorrhagic shock. Delayed postpartum hemorrhage at these sites can also occur and is often a diagnostic challenge. The physical examination may reveal uterine displacement (lateral or cephalad), and confirmation with ultrasound is helpful in stable patients. Management, decided in conjunction with specialists, may be expectant, involve bedside repair with absorbable suture, or require vascular embolization or surgical intervention, depending on the severity of clinical presentation.

Tears are classified by depth. First-degree tears involve the perineal skin and vaginal mucous membranes only. Second-degree tears extend

through the skin into the fascia and muscles of the perineal body. Third-degree tears extend into the anal sphincter, whereas fourth-degree tears extend through all layers, including the rectal mucosa. Third- and fourth-degree tears should be repaired by an obstetrician in the operating room.

Retained Products of Conception. Approximately 10% of postpartum hemorrhage cases are due to retained placental tissue. Normally, the plane of cleavage between the zona basalis and zona spongiosa results in a clean separation of the placenta from the uterus. When this occurs, the placental tissue delivers as a single unit, without evidence of fragmentation. Any placental defect or evidence of accessory placental tissue may signify a retained cotyledon (part of the embryo). Retained fragments prevent myometrial constriction and result in hemorrhage. Aggressive traction on the placenta during stage 3 of labor can result in retained products of conception, which may cause immediate or delayed postpartum hemorrhage. Ultrasound may reveal an expanded endometrium or solid echogenic mass within the uterus, providing evidence of retention.

Treatment requires removal of the remnant placental tissue. Digital uterine exploration with blunt dissection of the fragments from the myometrium will also facilitate myometrial contractions. Abnormally adherent tissue will not be freed by this maneuver.

The terms *placenta accreta*, *placenta increta*, and *placenta percreta* describe various degrees of abnormal placental attachment to the uterus. In placenta accreta, the placenta adheres to the myometrium without invading the decidua basalis. In placenta increta, the villi extend into the myometrium, and in placenta percreta the placenta penetrates the full thickness of the myometrium.

The current incidence of placenta accreta is approximately 3/1000 deliveries, a relative increase from past decades. Associated risk factors include multiparity, prior cesarean sections, placenta previa, previous curettage, and uterine anomalies.

Coagulopathies. All women with postpartum hemorrhage should receive tranexamic acid (1 g IV) and should also be evaluated for disseminated intravascular coagulation (DIC). DIC can occur as a consequence of placental abruption, eclampsia, amniotic fluid embolism, postpartum infections, and dilution of clotting factors caused by aggressive volume resuscitation. Also, retained products of conception and dead fetal tissue contain excess thromboplastin, which can precipitate DIC. As with DIC from nonobstetric causes, bleeding is associated with hypofibrinogenemia, thrombocytopenia, and elevated levels of fibrin split products and D-dimer.

Appropriate management entails hemodynamic support and correction of coagulopathies. Recent investigations have reported the successful use of recombinant factor VIIa for severe cases of postpartum hemorrhage.

Uterine Exploration and Removal of the Placenta. In the presence of ongoing hemorrhage and retained products of conception, attempts to remove the placenta manually are indicated. The procedure entails risk of infection, perforation, and increased hemorrhage but may be the most expeditious way to control bleeding. Before beginning, the patient is placed on a monitor, vascular access is established, and blood products are secured. Also, a Foley catheter may be placed to reduce bladder distention and monitor urinary output. The umbilical cord is traced through the cervical os to the placenta, allowing the identification of a placental margin. The placental membranes are digitally perforated, and the placenta is gradually divided from the myometrium. After removal of the placenta, the uterus is explored for retained cotyledons. Removal of fragments that are still present may require curettage of the uterine cavity by an obstetrician. Placenta accreta, percreta, and increta may be diagnosed in this way because they are not digitally dissectible.

Once it is emptied, the uterus should be stimulated to contract with uterine massage, oxytocin, and prostaglandins. Prophylactic antibiotic administration at the time of manual placenta extraction has been debated, but is not supported by current evidence.[6]

Pelvic Vessel Embolization. Pelvic bleeding postpartum can be difficult to control. Hysterectomy as a solution results in infertility and brings with it all the complications of general anesthesia and major surgery. Embolization of bleeding vessels by an interventional radiologist is another option with reported success rates of 95% to 100%. The procedure does not require an anesthesiologist, operating room, or obstetrician and may be readily available on an emergent basis. Common sites of bleeding include the uterine artery, pudendal artery, and hypogastric artery. Because only the smallest involved branches are embolized, and recanalization usually occurs, future reproductive capability is generally preserved.

Uterine Packing. When uterine bleeding is severe and uncontrolled, and embolization or hysterectomy are not available, uterine packing may be used to tamponade the bleeding vessels. The procedure has limited morbidity and can be accomplished by inserting sterile gauze or a foley catheter into the uterine cavity.[7]

Opponents of packing point out that an atonic uterus may accommodate a large volume of packing without effective tamponade. Packing may also increase the risk of postpartum infection, even when prophylactic antibiotics are given. As with all uterine manipulation and instrumentation, some risk of perforation also exists. Nevertheless, when pelvic embolization and hysterectomy are not immediately available, uterine packing may be a lifesaving temporizing measure.

Uterotonic Agents. Although they are commonly applied on delivery of the placenta, uterotonic agents also have special application in the case of a postpartum hemorrhage. Uterotonics such as oxytocin and prostaglandins control bleeding by inducing myometrial contractions. Oxytocin, 10 units IM or IV, is recommended.

Hysterectomy. Rarely, hemorrhage continues, despite the interventions outlined. In the case of life-threatening obstetric bleeding, an emergency hysterectomy should be performed.

Uterine Inversion

Foundations

Uterine inversion, a serious complication of delivery that occurs during stage 4 of labor, complicates 1 in 2000 deliveries. The resultant postpartum hemorrhage can be severe and life-threatening, accounting for a maternal mortality rate of up to 15%. Uterine inversion complicates 1 in 2000 deliveries. Risk factors include excessive fundal pressure during delivery, forceful traction on the umbilical cord (especially in conjunction with a fundal placenta), placenta accreta, maternal congenital abnormalities of the uterus, use of magnesium sulfate in the antepartum period, and primiparity.

Clinical Features

The patient will complain of sudden, severe abdominal pain. The abdominal examination reveals tenderness and an absence of the uterine corpus, which is potentially visualized at the cervical os or bulging from the introitus. Profuse bleeding with hemodynamic instability can also occur. Ultrasound may assist in the diagnosis.

Management

Once uterine inversion is identified, the appropriate mobilization of resources should begin simultaneously with efforts to reestablish the correct anatomic position of the uterus. Initial management involves aggressive fluid resuscitation.

The highest likelihood for successful repositioning of the inverted uterus is immediately after inversion occurs. If the placenta is still

adherent, it should not be removed until after repositioning. Removal of the placenta while the uterus is inverted is associated with excessive blood loss. The initial attempt to reposition the uterus should be to push the fundus upward through the introitus. Contraction of the cervical uterine segments can create a muscular ring, preventing repositioning. Therefore, all uterotonic agents should be withheld immediately on diagnosis of uterine inversion.

If initial attempts fail and a cervical ring develops, pharmacologic attempts to relax the uterus with sedation and tocolytics are indicated. Terbutaline (0.25 mg IV or SC) and magnesium sulfate (4–6 g IV over 15–20 min) have been used successfully to relax cervical rings. When the uterus has been repositioned, the muscle relaxants should be halted, and oxytocin and prostaglandin therapy restarted. Firm manual pressure through the introitus should be maintained until the cervical ring contracts. If all these measures fail, and surgical backup becomes available, halogenated anesthetics may be used to induce relaxation of the cervical rings, with or without an attempt at surgical repair. Once uterine inversion has resolved, an assessment must be made to screen for uterine perforation, adherent placenta, and vaginal lacerations.

Uterine Rupture

Foundations

Criticism of the high rate of cesarean delivery in the United States has led to advocacy of vaginal birth after cesarean (VBAC). The high success rate and relative safety of VBAC are countered partly by the risk of uterine rupture, which occurs in approximately 1% of VBAC deliveries following a single cesarean section.[8] The rate of rupture increases in women who have had multiple cesarean sections.

Clinical Features

Uterine rupture occurs late in pregnancy or as stage 1 of labor transitions to the active phase. Defined as a full-thickness uterine wall perforation, the severity of rupture ranges from simple scar dehiscence to complete fetal extrusion. It may be spontaneous but is most often linked to previous uterine surgery. Other risk factors for uterine rupture include multiple gestation, trauma, and prostaglandin administration. Minimal fetal extrusion results in a perinatal mortality rate of less than 1%, whereas complete extrusion results in a 10% to 20% mortality rate. Maternal death is rare, but significant hemorrhage complicates one-third of cases.

Diagnostic Testing

The diagnosis of uterine rupture may be difficult because pain is not always present. In fact, clinical presentation of uterine rupture ranges from abnormal fetal heart rate patterns to frank maternal hemorrhagic shock. Prolonged fetal heart rate deceleration, indicating fetal distress, is the most reliable sign of fetal extrusion. Ultrasound may reveal a protruding amniotic sac, hemoperitoneum, or the myometrial defect; however, good sensitivity data are lacking.

Management

If uterine rupture is suspected, delivery should be hastened to limit fetal hypoxia. Emergency cesarean section is the best method to speed delivery and repair the injury. ACOG guidelines for uterine rupture identify a 30-minute window of opportunity that maximizes fetal outcome. Note that uterotonic agents may exacerbate the rupture and are contraindicated.

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare and catastrophic complication of labor and delivery. The incidence rate is estimated to be between 1 and 12/100,000 maternities. Although the mechanism is not well understood, it is thought to involve the spread of amniotic fluid through the maternal vasculature, activating a complement or anaphylactic cascade. Cesarean delivery, forceps- or vacuum-assisted delivery, uterine rupture, eclampsia, placenta previa, and placental abruption have been found to be associated with amniotic fluid embolism. The diagnosis is clinically evident during labor, during delivery, or within 48 hours of delivery. It is characterized by the sudden onset of hypoxia, coagulopathy or hemorrhage, seizure, fetal compromise, or cardiovascular collapse. DIC occurs in approximately 50% of cases, and maternal and fetal mortality rates are high. Treatment is generally supportive and may include assisted ventilation, central hemodynamic monitoring, vasopressors, and the administration of blood products.[9]

Postpartum Venous Thromboembolism

Pregnancy increases the risk of venous thromboembolism five- to tenfold. The risk increase through pregnancy, but may actually be highest 3 to 6 weeks postpartum.[10] The diagnosis of pulmonary embolism in pregnancy has always been complicated, but recent clinical trials have suggested that an adjusted D-dimer can be used for otherwise low-risk patients.[11] The gold standard remains CT pulmonary angiogram; VQ scans are being performed increasingly less frequently, even in pregnancy. An in-depth discussion of thromboembolism can be found in Chapter 74.

Postpartum Endometritis

Puerperal infections affect 5% of all vaginal deliveries and 10% of all cesarean sections. Predisposing factors include operative delivery, prolonged rupture of membranes, lack of prenatal care, prolonged stage 2 labor, use of intrauterine monitoring, and frequent vaginal examinations. It is estimated that sepsis results in up to 15% of maternal deaths worldwide. Causative organisms for these infections include gram-positive cocci and gram-negative coliforms and, less commonly *Chlamydia* and *Mycoplasma* spp.

Endometritis is the most common puerperal infection, usually developing on the second or third day postpartum. Typically, the lochia has a foul odor, and the white blood cell count is elevated. Fever and abdominal pain indicate greater severity of infection, often warranting inpatient care and intravenous antibiotics. A coexistent surgical wound infection is often present. A search for retained products of conception is indicated, particularly if bleeding is present.

Treatment is empirical and is directed at gram-positive, gram-negative, and anaerobic organisms. We recommend a combination of clindamycin (900 mg IV Q8H) and an aminoglycoside (gentamicin 5 mg/kg Q24H). Most patients with postpartum endometritis require admission.

POSTPARTUM PROBLEMS

Peripartum Cardiomyopathy

For unclear reasons, the peripartum period is associated with the relatively sudden onset of cardiomyopathy in healthy women without evidence of prior cardiac disease. Estimates indicate that peripartum cardiomyopathy (PPCM) occurs in 1 of 2229 pregnancies; reported risk factors include advanced maternal age, preeclampsia, gestational hypertension, multiparity, and being African American. The cause is unknown.

Onset usually occurs days to weeks after delivery; symptoms range from mild fatigue to florid pulmonary edema. PPCM is often unrecognized in its milder form, leading to the consensus that the condition may be more prevalent than reported. Dyspnea on exertion, orthopnea, and fatigue may be easily misinterpreted as normal in the postpartum period, so vigilance in evaluating these symptoms is warranted.

Treatment includes the use of diuretics, vasodilators, and oxygen. Angiotensin-converting enzyme inhibitors are contraindicated if

PPCM occurs during the last month of pregnancy owing to teratogenicity but should be considered a mainstay of treatment postpartum. Hydralazine may be used before delivery to reduce afterload. Bromocriptine and pentoxifylline may also have roles in the treatment of PPCM. Cardiac function returns to normal in up to 30% of patients with PPCM during the following 6 months. Complications result in a mortality rate of approximately 15% worldwide. An in-depth discussion of cardiopathy can be found in Chapter 68.

Postpartum Depression

Considered underdiagnosed, postpartum depression is estimated to affect 10% to 15% of new mothers. Although often self-limited, the condition has important consequences for the mother, infant, and family. Risk factors include previously diagnosed depression, inadequate spousal support, adverse socioeconomic factors, life stressors, and emergency delivery.

Clinical Features

Postpartum depression patients present similarly to those with other major depressive disorders. Symptoms include depressed mood, anhedonia, loss of appetite, insomnia, fatigue, decreased concentration, feelings of guilt and worthlessness, and suicidal ideation. Most women with postpartum depression do not have vegetative signs or symptoms. Symptoms peak at 10 to 12 weeks postpartum, although some cases are diagnosed up to 1 year after delivery. When postpartum depression is unrecognized, these women are at high risk for suicide and may come to the ED with overdoses or other manifestations of a suicidal attempt.

Management

Early identification and referral are the key components of therapy. Dismissal of postpartum fatigue as normal, without consideration of the diagnosis of postpartum depression, can be disastrous. Not only does this condition contribute to marital discord, maternal risk for suicide, and even infanticide, but studies have shown that children of depressed mothers have an increased incidence of delayed cognitive, psychological, neurologic, and motor development. An in-depth discussion of depression can be found in Chapter 97.

CHAPTER 176: QUESTIONS AND ANSWERS

1. After episiotomy, which is the first maneuver that a clinician should attempt when treating shoulder dystocia?
- **a.** McRoberts maneuver
- **b.** Fracture the clavicle
- **c.** Deliver the posterior shoulder
- **d.** Cesarean section

Answer: A. The most important first step is to use McRoberts maneuver (see Fig. 176.10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder. This maneuver "walks" the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus pass through the birth canal, one shoulder at a time.

2. Vaginal delivery of a frank breech is best accomplished by which of the following actions?
- **a.** Pulling hard on the presenting part
- **b.** Pushing the presenting part back through the cervix
- **c.** Supporting the presenting part and giving the cervix time to dilate.
- **d.** Administering oxytocin

Answer: C. The head is the widest part of the fetus. Pulling on the presenting part causes the head to become trapped behind an incompletely dilated cervix.

3. Which of the following medications is effective at reducing postpartum uterine bleeding?
- **a.** Tranexamic acid
- **b.** Terbutaline
- **c.** Magnesium sulfate
- **d.** Gentamycin

Answer: A. Tranexamic acid (1 gr IV) is effective at reducing bleeding. Oxytocin and fundal massage should also be used.

4. Which antibiotic combination provides the best initial coverage for postpartum endometritis?
- **a.** Cephalexin and vancomycin
- **b.** Ciprofloxacin and metronidazole
- **c.** Clindamycin and gentamicin
- **d.** Amoxicillin and nitrofurantoin

Answer: C. Antibiotics should include anaerobic coverage because endometritis is usually caused by genital flora.

5. The first stage of labor ends with which of the following?
- **a.** Delivery
- **b.** Ruptured membranes
- **c.** A fully dilated cervix
- **d.** Placental delivery

Answer: C. The first stage of labor is the cervical stage, ending with a completely dilated, fully effaced cervix.

Trauma in Pregnancy

Valerie A. Dobiesz and Daniel W. Robinson

KEY CONCEPTS

- Female trauma patients of reproductive potential should be screened for pregnancy and assumed to be pregnant until proven otherwise.
- Management of life- and limb-threatening injury in the mother comes first. Saving the mother provides the best chance of saving the baby.
- Even in the stable pregnant trauma patient, the fetus is at increased risk of morbidity and mortality; therefore, the fetus should be monitored by cardiotocography continuously for a minimum of 4 hours after any trauma.
- The fetus is considered viable between 22 to 24 weeks' gestation (>500 grams). This usually corresponds to when the fundus is at or above the umbilicus.
- Alterations in anatomy and physiology that occur during pregnancy alter the pattern of injuries in trauma and the clinical findings related to blood loss, which may mask injuries, making a systematic approach essential.
- Keeping the mother tilted 15 to 30 degrees to the left, or manually displacing the uterus leftward, in any pregnancy of 20 weeks' gestation or greater is recommended to alleviate hypotension due to aortocaval compression in order to improve maternal and fetal perfusion.
- Resuscitative hysterotomy should be initiated for a potentially viable fetus (fundus above the umbilicus) within 4 minutes and completed in 5 minutes after the onset of cardiopulmonary arrest and no return of spontaneous circulation (ROSC) for optimal maternal and fetal benefits.
- The use of ionizing radiation to the pregnant patient, including CT and plain radiography, should be minimized, but imaging should not be withheld if it may provide significant diagnostic information. In certain circumstances ultrasound, MRI, or a period of observation can preclude the need for ionizing radiation.

FOUNDATIONS

Trauma, both intentional and unintentional, occurs in up to 8% of all pregnancies and is the leading nonobstetric cause of maternal death.[1-3] The most common causes of injury in pregnancy are motor vehicle collisions (MVCs), interpersonal violence, and falls. Trauma in pregnancy increases the risk of spontaneous abortion, preterm rupture of membranes, preterm birth, uterine rupture, cesarean delivery, placental abruption, and stillbirth. Because some woman are not aware they are pregnant when they present to a trauma center, all women of reproductive potential should be screened for pregnancy.

Commonly used thresholds of fetal viability are an estimated gestational age between 22 and 24 weeks or an estimated fetal weight of 500 gr. Only viable fetuses are monitored, because no obstetric intervention will alter the outcome with a previable fetus. Counseling on proper seatbelt and alcohol/drug use as well as screening for interpersonal violence may help to reduce the morbidity and mortality rates for pregnant patients.[4] Although the essential principles of trauma management remain unchanged in the pregnant patient, there are special considerations in the management of these patients due to the gravid uterus altering the pattern of injury, and changes in physiology and anatomy that affect multiple organ systems. Although there are two lives involved, maternal life takes priority and fetal outcomes are directly correlated with early and rapid maternal resuscitation.[5]

Anatomic Changes in Pregnancy

The uterus remains an intrapelvic organ until approximately the 12th week of gestation. It reaches the umbilicus by 20 weeks and the costal margins by 34 to 36 weeks. At term, the uterus has often enlarged by 30 cm and has increased fifteen-fold in weight, which alters the normal anatomic location and function of multiple structures. The diaphragm progressively rises in pregnancy with compensatory flaring of the ribs, which may predispose to pneumothorax and a faster progression to tension pneumothorax. A thoracostomy done in the third trimester requires that the chest tube be placed one or two interspaces higher than the usual fifth interspace site to allow for diaphragm elevation.[6]

Abdominal viscera are pushed upward by the enlarging uterus and can alter the location of perceived pain. The gravid uterus itself tends to protect abdominal organs from trauma but substantially increases the likelihood of bowel injury from penetrating trauma to the upper abdomen. Conversely, the upward displacement of the bowel makes it less susceptible to blunt trauma. The stretching of the abdominal wall as pregnancy nears term modifies the normal response to peritoneal irritation (blunting of muscle guarding and rebound), potentially underestimating the extent and severity of maternal trauma despite intra-abdominal bleeding and organ injury.

In the first trimester, the bony pelvis shields the uterus and bladder. After the third month, these structures rise out of the pelvis and become vulnerable to direct injury. Both organs become hyperemic during pregnancy, and injury may lead to a marked increase in blood loss compared with similar injury in a nonpregnant patient. Ureteral dilation secondary to smooth muscle relaxation or from compression by the gravid uterus is often found on imaging studies but is not necessarily pathologic. The ligaments of the symphysis pubis and sacroiliac joints are loosened during pregnancy. As a result, a baseline diastasis of the pubic symphysis may exist that can be mistaken for pelvic disruption on radiographic studies.

Physiologic Changes

Cardiovascular

The normal cardiovascular changes of pregnancy can alter the clinical presentation and may either mimic or mask the recognition of shock or exacerbate the effects of traumatic hemorrhage (Table 177.1). Blood pressure declines in the first trimester, levels out in the second trimester, and then returns to nonpregnant levels during the third trimester. The decline in systole is small, 2 to 4 mm Hg, whereas diastole falls 5 to 15 mm Hg. Heart rate increases in pregnancy but does not rise by more than 10 to 15 beats per minute above baseline (mean of approximately 90 beats/min).

TABLE 177.1 Hemodynamic Changes of Pregnancy (Mean Values)

Parameter	Nonpregnant	Trimester 1	Trimester 2	Trimester 3
Heart rate (beats/min)	70	78	82	85
Systolic blood pressure (mm Hg)	115	112	112	114
Diastolic blood pressure (mm Hg)	70	60	63	70
Cardiac output (L/min)	4.5	4.5	6	6
Central venous pressure (mm Hg)	9.0	7.5	4.0	3.8
Blood volume (mL)	4000	4200	5000	5600
Hematocrit without iron (%)	40	36	33	34
Hematocrit with iron (%)	40	36	34	36
White blood cells (cells/mm^3)	7200	9100	9700	9800

Central venous pressure in supine position during normal pregnancy. Comparative determinations during first, second and third trimesters. *Obstet Gynecol*. 1970;36:769; Letsky E. The haematological system. In: Hytten RF, Chamberlin G, eds. *Clinical Physiology in Obstetrics*. Oxford: Blackwell Scientific Publications; 1980: 43-78; and Cruikshank DP. Anatomic and physiologic alterations of pregnancy that modify the response to trauma. In: Buchsbaum HJ, ed. *Trauma in Pregnancy*. Philadelphia: WB Saunders; 1979: 21-39.

A major contributor to maternal hypotension is the supine hypotensive syndrome. After 20 weeks' gestation, the enlarging uterus has risen to the level of the inferior vena cava, resulting in compression when the mother is supine. Aortocaval obstruction diminishes cardiac preload, which can decrease cardiac output and systolic blood pressure. In late pregnancy, it is common for the inferior vena cava to become completely occluded when the pregnant patient is supine. Hemodynamic improvement occurs when compression is relieved. In determining whether observed hypotension is related to positioning, the pregnant woman can be tilted 15 to 30 degrees onto her left side, or if unable due to injuries, the uterus can be manually displaced to the left by using two hands in order to relieve compression on the inferior vena cava. Elevating the patient's legs will improve venous return. Inferior vena caval compression can also lower central venous pressure (CVP) in the last two trimesters.

Blood volume gradually increases during pregnancy, starting at 6 to 8 weeks' gestation, to as much as 45% above normal, peaking at 32 to 34 weeks' gestation. Blood volumes become increasingly larger for multigravidas and for twin, triplet, and quadruplet gestations. With this increased circulatory reserve, clinical signs of maternal hypotension from acute traumatic bleeding may be delayed. Up to 35% of circulating blood volume may be lost before an injured pregnant patient exhibits signs or symptoms of shock.[5] By the beginning of the second trimester and throughout the remainder of pregnancy, cardiac output is increased 40% to 6 L/min. Blood flow to the uterus increases from 60 mL/min before pregnancy to 600 mL/min at term. This hyperdynamic state is needed to maintain adequate oxygen delivery to the fetus. Because the mother's total circulating blood volume flows through the uterus every 8 to 11 minutes at term, this can be a major source of blood loss in injury.

By the third trimester, there is also marked venous congestion in the pelvis and lower extremities, increasing the potential for hemorrhage from both bony and soft tissue pelvic injuries. Compression of the lower abdominal venous system by the gravid uterus increases peripheral venous pressure and blood volume in the legs, creating the potential for brisk blood loss from leg wounds and can exacerbate bleeding from attempts at central venous catheter placement.

Pulmonary

The pregnant woman at term has a reduced oxygen reserve due to a reduction in functional residual capacity caused by diaphragm elevation and an increase in oxygen consumption related to the growing fetus, uterus, and placenta. Mean arterial oxygen tension drops by 29% in pregnant women at term during 60 seconds of apnea compared with 11% in nonpregnant women. Labor further accelerates this decline. In addition, minute ventilation and tidal volume increase, leading to hypocapnia. Therefore, a partial pressure of carbon dioxide in the arterial blood ($Paco_2$) of 35 to 40 mm Hg may indicate inadequate ventilation and impending respiratory decompensation in the pregnant patient. Maternal hypoxia rapidly leads to fetal hypoxia, distress, and possibly demise. There are no contraindications to rapid sequence intubation during pregnancy. Bag-valve-mask ventilation is more difficult in the pregnant patient due to weight gain and obesity. The incidence of difficult or failed intubations in obstetric anesthesia is four times higher than in surgical nonobstetric patients. Pregnant patients are considered difficult airways with potential for rapid desaturation due to decreased oxygen reserves, increased oxygen demands, upper airway edema, mucosal friability, increased Mallampati scores with increasing gestational age, and increased risk of aspiration. It is recommended that the emergency clinician use a difficult airway algorithm, prepare equipment in advance including rescue devices, call for help early if available, and optimize a ramped, head up, or reverse Trendelenburg position to optimize preoxygenation and apneic oxygenation in all pregnant patients.

Gastrointestinal

Gastroesophageal sphincter tone and gastrointestinal motility are decreased in pregnancy, thus increasing the possibility of aspiration in patients with altered level of consciousness, such as during intubation. Early gastric decompression should be performed in these circumstances.

SPECIFIC DISORDERS

Blunt Trauma

Physical examination is unreliable in predicting adverse outcomes in the pregnant woman with blunt trauma.[7] Risk factors predictive of the onset of contractions or preterm labor include gestational age greater than 35 weeks, assaults, and pedestrian collisions. Fetal mortality can be as high as 40% after maternal trauma, with most likely causes of fetal

death occurring from placental abruption, maternal shock, and maternal death, in order of decreasing incidence. Risk factors significantly predictive of fetal death include ejection, motorcycle and pedestrian collisions, maternal death, maternal tachycardia, abnormal fetal heart rate, lack of restraints, and an injury severity score greater than 9 (see Chapter 32).

Unbelted or improperly restrained pregnant women are twice as likely to experience excessive maternal bleeding and increased maternal death with fetal death being three times more likely to occur. For low- to moderate-severity collisions (constituting 95% of all MVCs), proper restraint use, with or without air bag deployment, generally leads to acceptable fetal outcomes. For high-severity collisions, even proper restraint does not improve fetal outcome.

Pregnant crash-test-dummy trials show that improper placement of the lap belt over the pregnant abdomen causes a threefold to fourfold increase in force transmission through the uterus. The lowest force transmission readings through the uterus occur when a three-point seat belt is used properly. For correct position, the lap belt should be placed under the gravid abdomen, snugly over the thighs, with the shoulder harness off to the side of the uterus, between the breasts and over the midline of the clavicle. Women who receive information on seat belt use during pregnancy from a health care provider are statistically more likely to use seat belts and to use them properly than uninformed controls.

Interpersonal Violence

Women experiencing abuse in the year before or during a pregnancy are 40% to 60% more likely than nonabused women to report high blood pressure, vaginal bleeding, severe nausea, kidney or urinary tract infections, and hospitalization during that pregnancy.[4] Abused pregnant women are more likely to deliver preterm, and children of abused pregnant women are more likely to be born underweight. Children born to abused mothers are more likely than other children to require intensive care at birth. Physicians detect only a minority of interpersonal violence cases in pregnant women, which supports the need for routine screening for interpersonal violence in this population.[4]

Falls

Falls become more prevalent after the 20th week of pregnancy and roughly 25% of pregnant women will fall at least once while pregnant. Protuberance of the abdomen, loosening of pelvic ligaments, strain on the lower back, and fatigability are contributory factors. In a given pregnancy, about 2% of pregnant women sustain repeated direct blows to the abdomen from repetitive falls. Although repeated falls often trigger premature contractions, they seldom result in immediate labor and delivery.

Penetrating Trauma

The gravid uterus affects the injury pattern seen with penetrating trauma to the upper abdomen with the probability of harm to the bowel, liver, or spleen at almost 100%. When the entry site is anterior and below the uterine fundus, visceral injuries are less likely. Although the enlarging uterus can act as a shield against intra-abdominal injuries in the mother, it makes the fetus more susceptible to injury. A high fetal death rate from penetrating trauma to the uterus has been reported and is lower for maternal injuries above the uterus.

Fetal Injury

There is a high risk of fetal loss in the pregnant trauma patient. Poor fetal outcome is predicted by maternal hypotension and acidosis, and a fetal heart rate less than 110 beats/min. When the mother sustains life-threatening injuries, there is a 40% chance of fetal demise, compared with a less than 2% chance in cases of non–life-threatening maternal injuries. Disseminated intravascular coagulation (DIC), which may be caused by placental products entering the maternal circulation, is a significant predictor of fetal mortality. The American College of Obstetrics and Gynecology recommends a minimum of 4 hours of cardiotocographic fetal monitoring after maternal trauma because monitoring is useful in predicting fetal outcome.

Fatal fetal injuries from blunt trauma are usually the result of intracranial hemorrhage and skull fractures secondary to fractured maternal pelvic bones striking the fetal skull as a result of vertex lie.[8] Pelvic and acetabular fractures during pregnancy are associated with a high maternal (9%) and a higher fetal (38%) mortality rate. Both gunshot wounds and stab wounds to the uterus produce substantial morbidity and mortality to the fetus.

Placental Injury

The leading cause of fetal death after blunt trauma is placental abruption.[1] Placental separation results when the inelastic placenta shears away from the elastic uterus during sudden deformation of the uterus. Because deceleration forces can be as damaging to the placenta as direct uterine trauma, abruption can occur with little or no external sign of injury to the abdominal wall. Placental abruption inhibits the flow of oxygen to the fetus and causes in utero carbon dioxide (CO_2) accumulation, resulting in hypoxia and acidosis that leads to fetal distress. Sustained uterine contractions induced by intrauterine hemorrhage also inhibit uterine blood flow, further contributing to fetal hypoxia.

The diagnosis of abruption is made clinically. Classic clinical findings of abruption are vaginal bleeding, abdominal cramps, uterine tenderness, maternal hypovolemia (up to 2 L of blood can accumulate in the gravid uterus), or a change in the fetal heart rate; but many cases of placental abruption after trauma present without vaginal bleeding.

The most sensitive indicator of placental abruption is fetal distress, which can be detected with prompt fetal monitoring. In clinical settings without continuous fetal monitoring capabilities intermittent monitoring of FHR (e.g., every 15 minutes) is recommended, but early transfer should be arranged to a facility with obstetric and neonatal services as the definitive treatment may be surgical. Increased frequency of contractions is associated with abruption. Transabdominal ultrasonography has poor sensitivity for detection of placental abruption (24% sensitivity; 96% specificity).[9] Placental abruption hematomas have a variable appearance on ultrasound including homogenous and heterogenous consistency, and can be either hypo-, hyper-, or isoechoic compared to the placenta depending on the extent and chronicity of bleeding. If the abruption bleeds externally, there may be an insufficient quantity to be detected sonographically. Even with significant intrauterine blood accumulation, accurate ultrasonographic diagnosis may be difficult because of placental position (i.e., posterior) and confounding uterine or placental structural conditions. An ultrasound is useful in clinical practice despite the poor sensitivity because it can help identify other causes of abdominal pain or vaginal bleeding in the setting of trauma.

Placental abruption is associated with an increased risk of stillbirth (after 20 weeks) and preterm delivery (before 37 weeks) even with minor abruption. The extent of placental separation is correlated with the rate of stillbirth. A trial of expectant management with ongoing maternal and fetal monitoring is appropriate when mother and fetus are stable and with partial placental abruptions of less than 25%. This usually applies to fetuses of less than 32 weeks' gestation in which the likelihood of morbidity and mortality associated with prematurity makes delivery management risky. Expectant care in stable patients may allow further fetal maturation and improved outcome. An immediate cesarean section is recommended in cases of fetal distress from

further placental separation. After 32 weeks' gestation, the risk of further placental separation outweighs the benefits of further fetal maturation, so intervention is indicated.

Women with placental abruption are more likely to have coagulopathies than those without abruption. The injured placenta can release thromboplastin into the maternal circulation, resulting in DIC, whereas the damaged uterus can disperse plasminogen activator and trigger fibrinolysis. The precipitation of DIC is directly related to the degree of placental separation. Severe clotting disorders rarely occur unless separation of the placenta is significant enough to result in fetal demise.

Uterine Injury

The most common obstetric complication caused by maternal trauma is uterine contractions. Myometrial and decidual cells, irritated by contusion or placental separation, release prostaglandins that stimulate uterine contractions. Progression to labor depends on the extent of uterine damage, the amount of prostaglandins released, and the gestational age of the pregnancy. The routine use of tocolytics for preterm labor is not recommended because most contractions stop spontaneously. Contractions that are not self-limited are often induced by some pathologic condition, such as underlying placental abruption, which is a contraindication to tocolytic therapy. Some studies describe this risk as relative and have used tocolysis successfully with careful evaluation and intensive monitoring to continue the pregnancy and enhance fetal maturity. The option to use tocolytics ends when cervical dilation reaches 4 cm or greater.

Traumatic uterine rupture is a rare event. It is most often caused by severe vehicular collisions in which pelvic fractures strike directly against the uterus. Uterine rupture may occur from stab wounds and gunshot injuries, but this is rare. Maternal shock, abdominal pain, easily palpable fetal anatomy caused by extrusion into the abdomen, and fetal demise are typical findings on examination. Diagnosing uterine rupture can be difficult. A fractured liver or spleen can produce similar signs and symptoms of peritoneal irritation, hemoperitoneum, and unstable vital signs. Optimal treatment, between suturing the tear or performing a hysterectomy, depends on the extent of uterus and uterine vessel tears and the importance of future childbearing.

DIAGNOSTIC TESTING

All women of childbearing potential presenting with trauma should be assessed for possible pregnancy.

Changes in Laboratory Values with Pregnancy

Increases in plasma volume greater than red blood cells cause a physiologic anemia of pregnancy (hematocrit 32% to 34% by the 32nd to 34th week). Despite the lower hematocrit, there is an overall increase in oxygen-carrying capacity because of an increased total red blood cell mass. Placental progesterone directly stimulates the medullary respiratory center, producing a lower $Paco_2$ (30 mm Hg) from the second trimester until term. The subsequent compensatory lowering of serum bicarbonate slightly reduces blood-buffering capacity during conditions of physiologic stress. A $Paco_2$ of 40 mm Hg in the latter half of pregnancy reflects inadequate ventilation and potential respiratory acidosis that could precipitate fetal distress.

Electrocardiographic changes include a left-axis shift averaging 15 degrees, caused by diaphragm elevation. Consequently, flattened T waves or Q waves in leads III and augmented voltage unipolar left limb lead may be seen (Fig. 177.1)

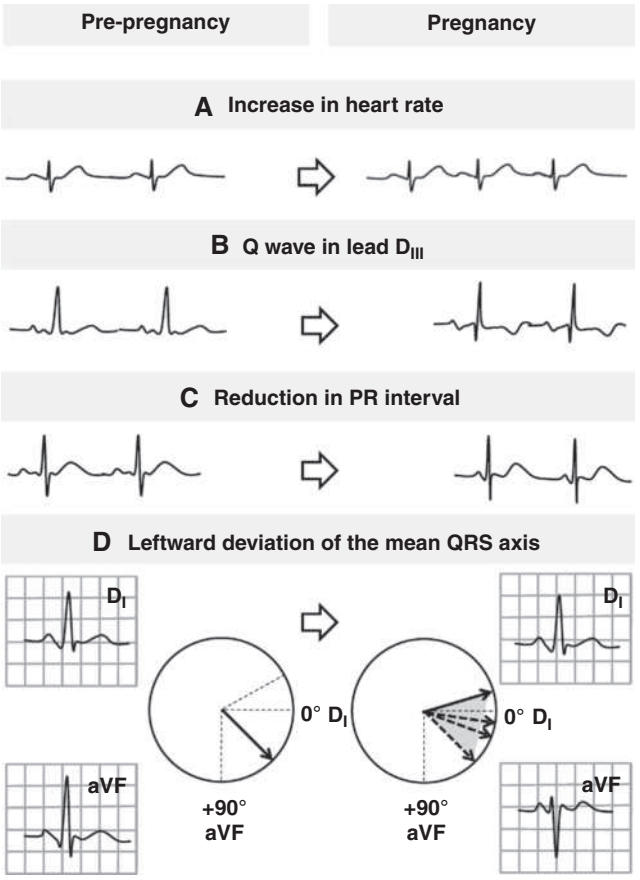

Fig. 177.1 EKG changes in pregnancy. (From: Angeli F, Angeli E, Verdecchia P. *Int J Mol Sci.* 2015;16(8):18454-18473; https://doi.org/10.3390/ijms160818454.)

Laboratory

Laboratory tests for a pregnant patient with trauma should include a complete blood count, basic electrolyte panel, urinalysis, blood type with Rh status, and coagulation studies including fibrinogen.[6] Patients who appear to be stable but have a low serum bicarbonate level may have occult maternal shock. Interpretation of bicarbonate results requires consideration of the physiologic changes that occur in the later stages of pregnancy as a result of respiratory alkalosis (see Chapter 173). Coagulation studies are important in directing management of patients with multisystem trauma or when the diagnosis of placental abruption is considered.

Kleihauer-Betke Test and Fetomaternal Hemorrhage

Fetomaternal hemorrhage (FMH), the transplacental bleeding of fetal blood into the normally separate maternal circulation, is a unique complication of pregnancy. MVCs, anterior placental location, and uterine tenderness are associated with an increased risk of FMH. Massive fetomaternal transplacental hemorrhage causes alloimmunization in Rh incompatibility but also endangers the fetus by causing severe fetal anemia, fetal distress, and possible exsanguination. ABO incompatibility causes less severe disease.

FMH most commonly occurs after 12 weeks' gestation, when the uterus rises above the pelvis and becomes susceptible to direct trauma.

The Kleihauer-Betke test quantifies the amount of FMH. Most laboratories screen for FMH of 5 mL or more, even though the amount of FMH sufficient to sensitize most Rh-negative women is much less than 5 mL. Therefore, it is advisable that all Rh-negative mothers who have a history of abdominal trauma receive one prophylactic dose of Rhesus immune globulin

(RhIG) within 72 hours of injury. Trauma patients at risk for massive FMH will have major injuries or abnormal obstetric findings, such as uterine tenderness, contractions, or vaginal bleeding. Rarely, the amount of FMH will exceed that covered by the maximum RhIG dose (300 μg). Because RhIG can effectively prevent Rh isoimmunization when administered as late as 72 hours after antigenic exposure, the results of the Kleihauer-Betke test are not immediately needed in the emergency department (ED).

Radiography

Adverse effects to the fetus are unlikely if radiation exposure is less than 50 mGy. Less than 1% of trauma patients are exposed to more than 30 mGy. Sensitivity to radiation is greatest during intrauterine development when the embryo undergoes organogenesis in weeks 2 to 15. However, the risk to the fetus of a 10-mGy exposure is thousands of times smaller than the spontaneous risks of malformations, abortions, or genetic disease. Intrauterine exposure to 50 mGy does not appear to cause a significant increase in congenital malformations, intrauterine growth retardation, or miscarriage but is associated with a 0.3% increased risk of childhood cancer and 2% risk of lifetime cancer. Pathologic conditions more readily appear with intrauterine radiation doses of 150 mGy or greater.

Providing information on radiation exposure from diagnostic radiographs is difficult. Fetal dose from computed tomography (CT) scans depends on the type of equipment used, the abdominal girth of the mother, and the fetal distance from the maternal skin. Diagnostic radiographic studies should be performed with regard for fetal protection, but necessary diagnostic studies of the traumatized pregnant patient should not be withheld out of concern for fetal radiation exposure.[10] Fetal irradiation should be minimized by limiting the scope of the examination and using technical means, such as shielding and collimation. Table 177.2 provides estimated radiation doses from various types of examinations.

Ultrasonography

Ultrasonography is the best modality for simultaneous assessment of the mother and fetus. It is useful in detecting major abdominal injury and establishing fetal well-being or demise, gestational age, and placental location. It obviates radiation risks, minimizes diagnostic delays, and provides high sensitivity for injury. The sensitivity of the focused assessment with sonography for trauma (FAST) examination in identifying intra-abdominal bleeding or pericardial bleeding is 61% to 83%, lower than the general population, but it has a specificity and negative predictive value of 99.7%.[11] Ultrasonography has low sensitivity (24%) but high specificity (96%) for placental abruption.[9] Limitations in accuracy include operator experience, patient obesity, the presence of subcutaneous air, and a history of multiple abdominal surgeries.[11]

Computed Tomography and Magnetic Resonance Imaging Scans

CT and, increasingly, magnetic resonance imaging (MRI) studies are used in evaluating abdominal trauma in pregnancy.[6] If ultrasonography is indeterminate and the patient's condition is stable, CT and MRI can identify specific organ damage. They are particularly useful in assessing penetrating wounds of the flank and back. CT can miss diaphragm and bowel injuries. Both of these studies carry the risk of moving the patient from the closely monitored environment of the ED to the radiography suite.

Radiation from CT is a concern in the pregnant trauma patient. However, with shielding, fetal exposure from head and chest CT scans can be kept below an acceptable 1-rad limit. CT of the abdomen can be performed with 4 mGy of exposure to the fetus. Abdomen and pelvic CT produces about 25 mGy of radiation to the fetus, which is well below the 50 mGy level, where a 2% increase in risk of cancer is seen without evidence of malformation to the fetus. Radiation exposure ultimately depends on the patient, scanner, and technique used in performing the study (see Table 177.2).

When available, MRI is preferable to CT because it uses no radiation and has not been associated with significant fetal disease or disability, and it is more sensitive in diagnosing diaphragm and bowel injury.

TABLE 177.2 Estimated Fetal Radiation Dose From Conventional Radiographic and Computed Tomography Examination[21,22]

Imaging Study	Estimated Fetal Dose (mGy)[a]
Radiography	
Cervical spine (AP, lateral)	<0.001
Extremities	<0.001
Chest (PA, lateral)	0.0005–0.01
Thoracic spine	0.003
Abdomen (AP)	0.1–3.0
Lumbar spine (AP, lateral)	1–10
Computed Tomography	
Head or neck	0.001–0.01
Chest (routine)	0.01–0.66
Chest (pulmonary embolism protocol)	0.01–0.66
Abdomen	1.3–35
Pelvis	10–50
Abdomen and pelvis	13–25
CT angiography of the aorta	6.7–56
CT angiography of the coronary arteries	0.1–3
Nuclear Medicine	
Low-dose perfusion scintigraphy	0.1–0.5
V/Q scintigraphy	0.1–0.8
Myocardial perfusion with 99mTc-sestamibi	17
Myocardial perfusion with 99mTc-tetrofosmin	8.45

[a]The naturally occurring background radiation dose during pregnancy is 0.5 to 0.1 mGy.

SPECIAL PROCEDURES

Diagnostic Peritoneal Lavage

In unstable trauma patients with equivocal or negative findings on ultrasonography, diagnostic peritoneal lavage (DPL) may be considered in any trimester. It should be performed in conjunction with a trauma surgeon using an open technique above the uterus following placement of a nasogastric tube and Foley catheter. The gravid uterus, in the later trimesters, makes the procedure riskier and technically challenging.

MANAGEMENT

Management of the patient with multiple trauma is covered in Chapter 32. The following discussion focuses on the aspects of management unique to the pregnant patient.

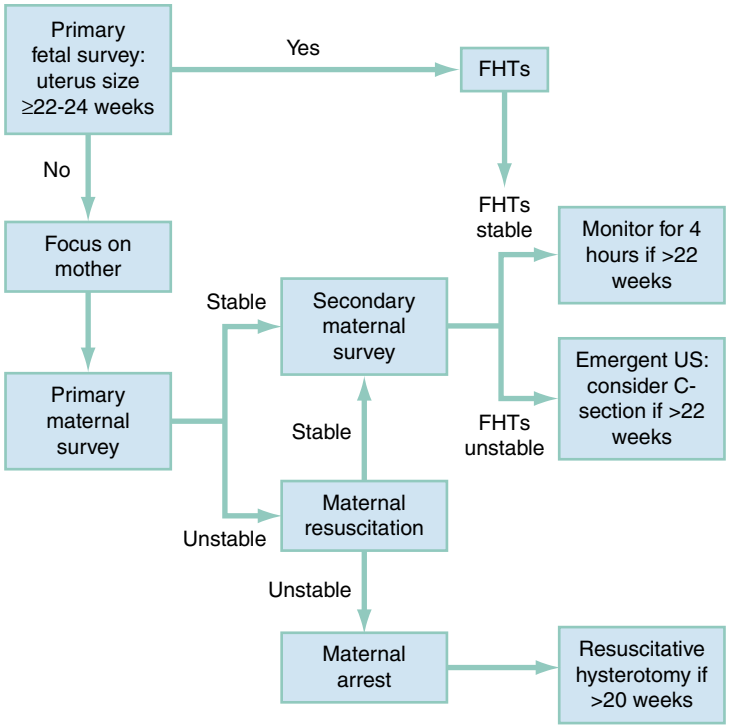

Fig. 177.2 Decision-making algorithm in emergency obstetric care. *C-section,* Cesarean section; *FHT,* fetal heart tone; *US,* ultrasonography.

Depending on the mechanism of trauma, maternal condition, and gestational age, the clinician should consider early notification or consultation with a trauma surgeon, obstetrician, neonatologist, or pediatrician (or all four) for a multidisciplinary approach. A fetal monitor, portable ultrasound, and neonatal resuscitation equipment should be immediately available. Tetanus toxoid and immune globulin have no detrimental effect on the fetus. The World Health Organization (WHO) specifically recommends vaccination during pregnancy. To prevent alloimmunization of a Rh-negative mother, administer one 50-µg dose of RhIG in the first trimester. It is sufficient because total fetal blood volume is only 4.2 mL by 12 weeks' gestation, and a 50 µg-dose covers 5 mL of bleeding. During the second and third trimesters, a 300-µg dose of RhIG is given, which protects against up to 30 mL of FMH. Beyond 16 weeks' gestation, the total fetal blood volume reaches 30 mL or more. Massive FMH likely exceeds the efficacy of one 300-µg dose of RhIG, so the Kleihauer-Betke test can be used to guide effective dosing.

Maternal Resuscitation

Primary Survey

The primary survey focuses on the mother. However, because two patients are present, it is reasonable to gather preliminary information about the age of the fetus at this time (Fig. 177.2).

Airway and Breathing. The general principles of airway management are discussed in Chapter 1. Oxygen therapy should be instituted early in the traumatized pregnant patient because she can quickly become hypoxic due to her reduced oxygen reserve and increased oxygen consumption. The fetus is vulnerable to any reduction in oxygen delivery. Supplemental oxygen is recommended throughout maternal resuscitation and evaluation with oxygenation saturation levels maintained above 95%.[6]

A secure airway enables proper oxygenation and negates the higher risk of aspiration in pregnancy. Rapid sequence intubation after preoxygenation of the pregnant patient is recommended. Data are limited on use of RSI agents during pregnancy but none have been consistently associated with congenital malformations or adverse effects on the fetus. Mechanical ventilation settings need to be adjusted for increased tidal volumes and respiratory alkalosis, which is consistent with the physiologic $Paco_2$ of 30 mm Hg in the last stage of pregnancy. No specific initial ventilation settings are recommended, but settings can be adjusted as clinically indicated and if the patient has ARDS clinicians can use the ARDS network guidelines.[12]

Circulation. Intravenous access with two large-bore catheters above the diaphragm is preferred. Maternal blood pressure and heart rate are not consistently reliable predictors of fetal and maternal hemodynamic stability. Due to an expanded circulating volume, the mother can hemorrhage without showing early signs of hypotension. Uterine blood flow is markedly reduced when maternal circulation is compromised. As a result, after an acute blood loss, uterine blood flow can be substantially decreased while maternal blood pressure remains normal. Consequently, the pregnant woman with borderline hemodynamic stability probably already has a jeopardized fetus. When traditional signs of shock appear, fetal compromise may be far advanced.

Fluid resuscitation with isotonic fluids should occur in all patients with suspected or observed significant blood loss. Type O-negative packed red blood cells are recommended for hemodynamically unstable trauma patients until type-specific blood products are available. Vasopressors are recommended only with refractory hypotension unresponsive to fluid resuscitation because of the adverse effect on uteroplacental perfusion.[6] A massive transfusion protocol should be initiated on all hemodynamically unstable patients in a 1 : 1 : 1 ratio of red blood cells, platelets, and plasma. Tranexamic acid is an antifibrinolytic agent used in trauma to reduce bleeding and mortality and should be administered within 3 hours of injury. Limited data are available on the safety of tranexamic acid in pregnancy but no adverse fetal events have been described. It is unknown if there is a mortality benefit with the use of tranexamic acid in pregnant trauma patients.[1,13]

Beyond 20 weeks' gestation, a left lateral tilt of 15 to 30 degrees or leftward manual displacement of the uterus using two hands is

recommended to reduce compression on the inferior vena cava caused by the gravid uterus. A Foley catheter for measuring urine output provides further information on circulatory volume status.

With trauma in pregnancy, the primary survey is modified to assess uterine size and the presence of fetal heart tones if the patient is severely injured. Otherwise, this assessment belongs in the secondary survey. Uterine size, measured from the symphysis pubis to the fundus, is the quickest means of estimating gestational age. This distance in centimeters equals the gestational age in weeks (e.g., 24 cm = 24 weeks), which allows some early indication of fetal viability if delivery is necessary (Fig. 177.3). Usually, between 22 to 24 weeks is used as the cutoff point for fetal viability (Table 177.3). As a rough guide, the fetus is potentially viable when the dome of the uterus extends beyond the umbilicus. Fetal heart tones can be detected by auscultation at 20 weeks' gestation or by Doppler probe at 10 to 14 weeks. If either the uterus is less than 22 cm in size or fetal heart tones are absent, the pregnancy is probably too early to be viable, and treatment is directed solely at the mother.

Secondary Survey

The secondary survey involves a detailed examination of the patient but is also modified to gather additional information about the maternal abdomen and the fetus. Physical examination of the abdomen, frequently unreliable in the nonpregnant patient, is even more inaccurate with changing organ position, abdominal wall stretching in advancing pregnancy, and uterine contraction pains. Still, valuable information can be gathered about uterine tenderness, contraction frequency, and vaginal bleeding.

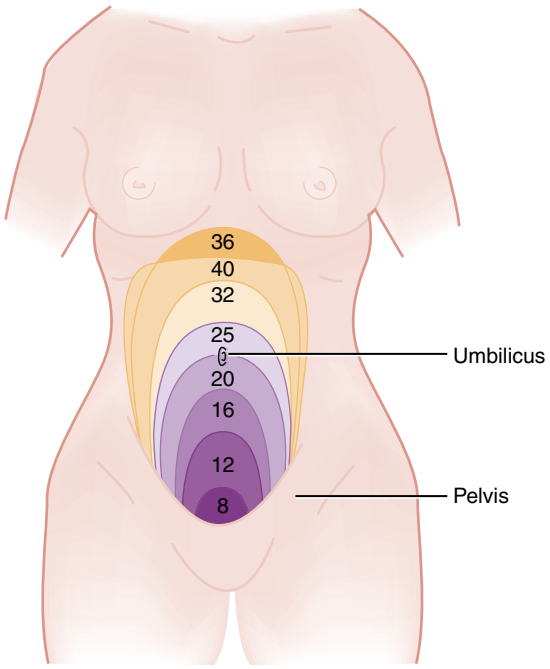

Fig. 177.3 Uterine size at different weeks of gestation. (From: Kravis TC, Warner CG, eds. *Emergency Medicine: A Comprehensive Review*. Rockville, MD: Aspen Publishers; 1979.)

An external perineal examination should be performed. A sterile speculum examination is done in consultation with or by an obstetrician after placental previa has been ruled out by ultrasonography. A bimanual examination is avoided due to the risk of causing prelabor rupture of membranes or bleeding in cases of unidentified placenta previa. Vaginal bleeding suggests placental abruption, and a watery discharge suggests rupture of the membranes. Significant vaginal bleeding from intravaginal injuries can be temporized by packing with sterile moistened gauze. If the mechanism of injury is significant enough and the fetus is judged to be viable, early involvement of an obstetrician may enhance the fetal outcome.

Fetal Evaluation. Fetal evaluation in the secondary survey focuses on the fetal heart rate and detection of fetal movement. When the presence of fetal heart tones has been confirmed, intermittent monitoring of fetal heart rate is sufficient for the previable fetus. If the fetus is viable (i.e., 22 to 24 weeks or more), continuous external monitoring initiated quickly and maintained throughout all diagnostic and therapeutic procedures may be useful in directing management. Such monitoring can also benefit the mother, because fetal hemodynamics are more sensitive to decreases in maternal blood flow and oxygenation than are most measures of the mother. Fetal distress can be a sign of occult maternal distress. However, fetal distress and even demise can occur with seemingly minor maternal trauma. Signs of fetal distress include an abnormal baseline heart rate, decreased variability of heart rate, and fetal decelerations after contractions.

The normal fetal heart rate ranges from 120 to 160 beats/min; rates outside or trending toward these limits are ominous. Heart rate variability has two components. Beat-to-beat variability measures autonomic nervous function, whereas long-term variability indicates fetal activity. Heart rate variability increases with gestational age. The loss of beat-to-beat and long-term variability warns of fetal central nervous system depression and reduced fetal movement caused by fetal distress (Fig. 177.4).

Late decelerations are an indication of fetal hypoxia. These decelerations are relatively small in amplitude and occur after the peak or conclusion of a uterine contraction. By comparison, early decelerations are larger, occur with the contraction, and recover to baseline immediately after the contraction. Early decelerations may be vagally mediated when uterine contractions squeeze the fetal head, stretch the neck, or compress the umbilical cord. Variable decelerations are large, occur at any time, and are possibly caused by umbilical cord compression (Fig. 177.5).

Mother Stable, Fetus Stable

Minor trauma does not exempt the fetus from significant injury. It is estimated that up to 3% of all minor trauma results in fetal loss,

typically from placental abruption. Therefore, once the traumatized mother is stabilized, the focus of care is directed toward the fetus. For the viable fetus (greater than 22 to 24 weeks' gestation), monitoring is the next step. Continuous monitoring maintained throughout all diagnostic and therapeutic actions is advisable. Because direct impact is not necessary for fetoplacental pathology to occur, the traumatized pregnant woman with no obvious abdominal injury still benefits from monitoring.

The recommended 4 hours of cardiotocographic observation of the viable fetus is extended to 24 hours if at any time during the first 4 hours there are more than three uterine contractions per hour, uterine tenderness persists, results on a fetal monitor strip are worrisome, vaginal bleeding occurs, the membranes rupture, or any serious maternal injury is present. Most cases of placental abruption after maternal trauma are detected within the first 4 hours of monitoring.

On discharge from the hospital, the pregnant woman should be instructed to record fetal movements during the next week. If fewer than four movements per monitored hour are noted, the patient should see her obstetrician immediately and a nonstress test is warranted. The occurrence of preterm labor, membrane rupture, vaginal bleeding, or uterine pain also necessitates prompt reevaluation. Serial ultrasound and fetal heart rate tests on viable fetuses a few days after maternal trauma and periodically throughout the remaining portion of the pregnancy are helpful in monitoring fetal well-being.

Mother Stable, Fetus Unstable

Fetal death rates after maternal trauma are three to nine times higher than maternal death rates. If a viable fetus remains in distress despite optimization of maternal physiology, cesarean section should be considered.

Although fetal viability is first reached at 22 to 24 weeks, the ultimate determinant of the age of fetal viability is the level of neonatal care provided by the intensive care nursery unit in each hospital or accessible regional facility. Determining gestational age for fetuses of less than 29 weeks may be difficult. Emergency decisions on fetal viability are therefore made on the basis of the best ultrasonography and gestational age information available.

The presence of fetal heart tones is an important survival marker for fetuses about to undergo emergency cesarean section. The fetal survival rate is zero if there are no fetal heart tones present when emergency cesarean section commences. If fetal heart tones are present and the gestational age is 26 weeks or more, the infant survival rate may be as high as 75%.

Besides fetal distress, other reasons for a cesarean section include uterine rupture, placental rupture with significant vaginal bleeding, fetal malpresentation during preterm labor, and situations in which the uterus mechanically limits maternal repair. Fetal demise without any of the aforementioned conditions is not an indication for cesarean section, because most will pass spontaneously within 1 week.

Mother Unstable, Fetus Unstable

If the mother's condition is critical, primary repair of her wounds is the best course. This may apply even when the fetus is in distress, because a critically ill mother may not be able to withstand an additional operative procedure such as cesarean section, which prolongs laparotomy time and likely substantially increases blood loss. The best initial action on behalf of the fetus is early and rapid restoration of normal maternal physiology. If it is felt that the unstable mother can tolerate an emergency cesarean section, it should be considered for the distressed, viable fetus.

As with nonpregnant patients, operative intervention for blunt trauma and above-the-uterus stab wounds is dictated by clinical findings and diagnostic test results. Above-the-uterus intraperitoneal gunshot wounds require exploration. In situations of severe maternal hemorrhage, massive transfusion protocols should be initiated with fresh frozen plasma, platelets, and red blood cells in a 1:1:1 ratio to lower the rate of coagulopathy and improve survival. There is little evidence to support a definitive management strategy for penetrating trauma to the gravid uterus. In situations of a hemodynamically stable mother, expectant management has been recommended. However, no prospective study has verified this. Damage to the uterus alone can be quite devastating because of its increased circulation. Without exploration, it is impossible to know the occurrence, size, or depth of uterine penetration, and there are no guidelines indicating whether a uterine wound can be left unsutured without incurring an increased risk of infection or delayed uterine rupture. We recommend laparotomy or laparoscopy as the safest means of managing penetrating uterine wounds because missed maternal injuries can quickly compromise the fragile fetus.

Defibrillation

Electrical flow that bypasses the fetus has little effect on the pregnancy. Maternal elective and emergent cardioversion have been performed safely for cardiac dysrhythmias in all three stages of pregnancy. Energies up to 300 Joules on a monophasic defibrillator have been used without affecting the fetus or inducing preterm labor. Although the amount of energy reaching the fetal heart is thought to be small, it is advisable to monitor the fetal heart during maternal cardioversion.

Resuscitative Hysterotomy

Restoration of maternal and thus fetal circulation is the optimal goal with maternal hemodynamic instability. During maternal resuscitation, adequate oxygenation, fluid loading, and a 30-degree left tilting position or manual displacement of the gravid uterus is recommended to improve maternal circulation. If there is no response to advanced cardiac life support, a resuscitative hysterotomy, formerly known as a perimortem cesarean section, should be initiated by 4 minutes and completed by 5 minutes after the onset of maternal cardiac arrest with no return of spontaneous circulation (ROSC).[14-19]

In the event of maternal cardiopulmonary arrest, resuscitative hysterotomy is recommended to rapidly deliver the fetus to relieve aortocaval compression, improve hemodynamics, and optimize maternal and fetal survival.[20] A resuscitative hysterotomy is a rare but potentially lifesaving procedure for both the mother and neonate and is recommended only if uterine size exceeds the umbilicus (20 weeks' gestation or greater). Time since maternal circulation ceased is the critical factor in fetal outcome. Delivery increases venous return and cardiac output by 25% to 30% and leads to higher rates of ROSC and survival benefit for mother. Beyond 20 minutes, there is virtually never survival or favorable neurologic outcome for either mother or fetus.

The most experienced physician available should perform the procedure as cardiopulmonary resuscitation (CPR) is continuing. A midline vertical incision is made from the epigastrium to the symphysis pubis. The uterus is then entered with a midline vertical incision. If necessary, the placenta is incised to reach the fetus; once the fetus has been delivered, the cord is clamped and cut. Maternal revival after delivery of the fetus is reported due to relief of vena caval compression and improved hemodynamics.

DISPOSITION

The emergency clinician should consider the stability of the mother and the viability of the growing fetus when making management and disposition decisions. Any pregnant woman at 22 to 24 or more weeks of gestation who has sustained blunt trauma should undergo at least 4 hours of fetal monitoring, even if she appears well. In general, pregnant women who sustain minor trauma have a favorable pregnancy outcome. Other admission and operative criteria are similar for pregnant and nonpregnant trauma patients.

CHAPTER 177: QUESTIONS AND ANSWERS

1. A 30-year-old female who is 28 weeks' gestation presents to the emergency department after being a restrained passenger in a low-speed MVC. Which of the following is the best indicator of fetal outcome in this scenario?

a. Abdominal tenderness
b. Cardiotocographic monitoring for 4 hours
c. Maternal blood count and arterial blood gas results
d. Maternal vital signs
e. Ultrasonography

Answer: B. For women with mild blunt trauma, fetal outcome is not predicted by maternal vital signs, abdominal tenderness, blood tests, or ultrasound results. Only cardiotocographic monitoring for a minimum of 4 hours is useful to predict fetal outcome. Fetal monitoring can identify fetal distress and the need for further intervention.

2. Which of the following factors is most concerning in the presentation of a pregnant trauma patient?

a. Diastasis of the symphysis pubis
b. Electrocardiogram (ECG) findings of Q waves in III and aV_F
c. Hematocrit 34% in third trimester
d. Hypotension in the third trimester
e. Respiratory alkalosis in the third trimester

Answer: D. Blood pressure declines in the first trimester, levels out in the second trimester, and then returns to nonpregnant levels during the third trimester. In pregnancy, minute ventilation increases, leading to hypocapnia. Therefore, a partial pressure of arterial carbon dioxide ($Paco_2$) of 35 to 40 mm Hg may indicate inadequate ventilation and impending respiratory decompensation. The physiologic anemia of pregnancy, resulting from a 48% to 58% increase in plasma volume and only an 18% increase in red blood cells, results in hematocrits of 32% to 34% by gestational age of 32 to 34 weeks. Electrocardiographic changes include a left-axis shift averaging 15 degrees, caused by diaphragm elevation. Consequently, flattened T waves or Q waves in leads III and aV_F may be seen.

3. A 26-week gravid woman presents to the emergency department (ED) after a moderate-speed motor vehicle collision (MVC). The patient is without complaints, and her vital signs are as follows: blood pressure, 100/60 mm Hg; heart rate, 100 beats per minute; and respiratory rate, 18 breaths per minute. Ultrasound examination shows good fetal movement, with a fetal heart rate of 150 beats per minute. What is the appropriate disposition for this patient?

a. Consult obstetrics for a minimum of 4 hours of cardiotocographic monitoring.
b. Perform a FAST examination and if negative discharge home.
c. Consult trauma and obstetrics for admission and serial examinations.
d. Consult trauma surgery for exploratory laparotomy.
e. Discharge the patient with close follow-up with obstetrics.

Answer: A. Placental abruption results when the inelastic placenta shears away from the elastic uterus during sudden deformation of the uterus. Because deceleration forces can be as damaging to the placenta as direct uterine trauma, abruption can occur with little or no external sign of injury to the abdominal wall. For the viable fetus (more than 22 to 24 weeks' gestation), monitoring is the next step.

CHAPTER 177: QUESTIONS AND ANSWERS—cont'd.

4. A 26-year-old, 30-week gestation woman presents unresponsive with cardiopulmonary resuscitation (CPR) in progress after a high-speed motor vehicle collision (MVC). The patient lost her vital signs 3 minutes before arrival in the emergency department (ED). What is the most appropriate next step in the management of this patient?

a. Transfer to the operating room for emergency cesarean section by obstetrics
b. Resuscitative hysterotomy with vertical midline incision
c. Thoracotomy with cardiac massage
d. Administer epinephrine and continue ACLS guidelines for cardiac arrest
e. Defibrillate immediately at 300 J

Answer: B. In the event of maternal cardiopulmonary arrest, resuscitative hysterotomy is indicated in any pregnancy of greater than 20 weeks' gestation (above the umbilicus) to improve both maternal and fetal survival. It should ideally be performed within 4 minutes of loss of spontaneous circulation and completed by 5 minutes of no ROSC. The most experienced physician available should perform the procedure.

5. A 28-week pregnant patient comes in after a gunshot wound to the epigastrium. Her blood pressure is 95/30 and her heart rate is 125 after receiving 1 liter IV fluids by EMS en route. What is the optimal management for this patient?

a. Explore the wound locally for entrance and exit wounds.
b. Expectant management with serial abdominal examinations.
c. Intraoperative exploratory laparotomy or laparoscopy by a trauma surgeon.
d. Fetal monitoring for a minimum of 4 hours

Answer: C. The gravid uterus affects the injury pattern seen with penetrating trauma to the upper abdomen with the probability of harm to the bowel, liver, or spleen at almost 100%. The gravid uterus tends to protect abdominal organs from trauma but substantially increases the likelihood of bowel injury from penetrating trauma to the upper abdomen. A trauma surgeon/trauma service should be activated or consulted. With persistent hypotension after an initial 1-liter IV fluid bolus, the massive transfusion protocol should be initiated in anticipation of the expected course of action. The patient will need to go to the operating room for an exploratory laparotomy.

178

Care of the Geriatric Patient

Denise Nassisi

KEY CONCEPTS

- The population is aging, with 10,000 Americans turning 65 every day, resulting in an increasing proportion of ED patients that are elderly. Older ED patients have the greatest resource use, longest lengths of stay, and highest admission rates of any age group.
- Delirium, especially hypoactive delirium, is underrecognized by emergency clinicians; the diagnosis of delirium should prompt investigation for life-threatening emergencies, including infection, metabolic abnormalities, and acute coronary syndrome (ACS).
- Nonspecific complaints, such as generalized weakness, are among the top ten presenting complaints for older ED patients, and are often the harbinger of serious underlying illness.
- Atypical presentations of disease result in diagnostic challenges and can lead to misdiagnosis.
- Many older patients with ACS present without chest pain, especially females and those older than 85 years. ACS in older adults is more often complicated by acute heart failure due to age-related decreases in left ventricular compliance. Current recommendations regarding medical and revascularization therapy in those with non-STEMI and STEMI have no age limitations.
- Almost one-third of older ED patients presenting with abdominal pain are ultimately found to have a surgical condition causing the pain; therefore, there should be a low threshold for diagnostic imaging.
- Mortality from sepsis approaches 40% for patients older than 85 years, with respiratory and genitourinary infections being the most common sources. Older adults with infection are less likely to present with fever or leukocytosis and may have SIRS-negative sepsis.

FOUNDATIONS

Emergency department (ED) utilization for patients 65 and over is growing faster than for any other age group. The current growth in the population of older adults is unprecedented in the history of the world. In the United States approximately 10,000 of the "baby boomer" generation turn 65 years old each day, making those aged 65 years and older the fastest-growing segment of the population. By the year 2050, it is anticipated that they will comprise 21% of the population.

Older ED patients are a special population with unique needs and concerns. Altered homeostasis and decrease in physiologic reserve impacts their response to stressors and illness. Body composition changes predispose the older adult to dehydration and hypernatremia. Decreased subcutaneous fat places them at greater risk of hypothermia, and they are more at risk of developing hyperthermia when exposed to high ambient temperatures. The maximal heart rate achievable typically falls with age due to diminished responsiveness of the sympathetic nervous system, while resting heart rate may increase with age. Increases in heart rate may be blunted due to commonly prescribed medications. Reduced cardiac reserve predisposes to postural hypotension. Age-related decreases occur in hearing and vision that can markedly affect communication and functional status. Renal function, with creatinine clearance, declines with age. Changes in body composition and renal function result in pharmacokinetic and pharmacodynamic alterations that predispose older patients to medication adverse events. Polypharmacy is common in older patients, further increasing their risk of adverse drug reactions.

Emergency care should be approached in a holistic multidimensional manner with consideration for important confounding factors. Cognitive dysfunction, decreased functional reserve, frailty, mobility impairment, decreased hearing and decreased visual acuity can impact the ED evaluation and disposition decision making. The evaluation generally needs to be more comprehensive and extensive than those for younger patients. The average ED length of stay is longer for older adults who also have higher utilization of resources and rates of admission. They are more likely to have an emergent condition, higher morbidity and mortality, and are more likely to be misdiagnosed. Clinical presentations may be vague and nonspecific; "classic presentations" of disease are less likely in older patients. The differential diagnoses in the older adult are often expanded to included illnesses, such as mesenteric ischemia, aortic stenosis or giant cell (temporal) arteritis, that are not often seen in younger patients. Confounding chronic comorbidities, such as congestive heart failure, chronic obstructive pulmonary disease, and chronic kidney disease, add to the complexities of evaluation and treatment. Adverse effects of home medications should be considered as a possible cause of their ED visit, especially for presentations of falls or altered mental status.

Cognitive impairment may impact obtaining an accurate history, performing a diagnostic evaluation, and designing a treatment and disposition plan. Corroborating sources of information, especially from caregivers are often needed to obtain a full and accurate history. Cognitive impairment may make sending the patient home potentially more dangerous, particularly if the patient is in the ED unaccompanied. Attention to transitions of care with an evaluation of home and

BOX 178.1 Comprehensive Geriatric Assessment (CGA) Elements Important for ED Assessment

- Comorbidities
- Polypharmacy and medications
- Fall risk
- Home situations and social supports

social supports is often needed. However, hospitalization poses its own risks in that it is associated with increased rates of delirium, nosocomial infections, iatrogenic complications, and adverse drug reactions. It is common for admitted older patients to have a loss of one or more of their basic activities of daily living (ADLs) with a permanent impairment occurring in up to 40% of these patients.

SPECIFIC ISSUES AND DISORDERS

Comprehensive Geriatric Assessment

The common multifactorial issues that affect older adults including chronic medical conditions, polypharmacy, cognitive problems, mobility and functional deficits, as well as psychosocial issues, are referred to as "geriatric syndromes." The Comprehensive Geriatric Assessment (CGA) (Box 178.1) is a multidisciplinary diagnostic and intervention process that identifies and addresses these issues that plague older adults.[1] This approach addresses the complex geriatric syndromes while keeping in mind the patient's goals of care, in an effort to improve the quality of life.

A complete CGA is time-consuming and not practical to be routinely performed for all older ED patients by busy emergency clinicians. However, identification of high-risk older adults may help target further evaluations and interventions and improve disposition planning. Widely disseminated geriatric ED guidelines recommend screening for high-risk patients.[2] CGA in the ED has been linked to reduced need for hospitalization without an increase in mortality, thus reducing exposure of the patient to the hazards of hospitalization. The use of CGA adapted to the ED is an active area of research that will facilitate safe and efficient care for the older adult.[3]

Cognitive Deficits: Delirium and Dementia

Older patients more often have cognitive, functional, and sensory impairments or depression that limit their ability to communicate. These conditions complicate the evaluation and management of older adults and may be underappreciated and underrecognized. Patients with cognitive dysfunction are less able to provide an accurate reason why they are in the ED and less able to comprehend discharge instructions. Patients and caregivers may have difficulties recalling all the details of a long and complex history or multiple medications; therefore, careful review of medical records and medication lists are important adjuncts to the history. Routine performance of a cognitive assessment in older patients is a geriatric quality indicator for EDs.

Delirium

Delirium, an acute confusional state with alterations in cognition and attention, occurs in 10% to 20% of older ED patients. Unfortunately, emergency clinicians miss recognizing delirium up to 75% of the time, especially with the hypoactive subtypes of delirium. There are several brief assessment tools available, including the well-established Confusion Assessment Method. The Delirium Triage Score with brief CAM (DTS and bCAM) is highly recommended for ED use (Fig. 178.1).

Delirium is generally caused by decreased neurologic reserve plus one or more acute precipitants, such as infection, metabolic abnormalities, and acute coronary syndromes. Delirium and dementia are sometimes difficult to distinguish from one another, but the distinction is important because the presence of delirium should lead to concern for a potentially life-threatening medical emergency. Inattention or the inability to sustain focus is a key feature of delirium. Patients with underlying dementia are at high risk for development of delirium and recognition of delirium is even more difficult in patients with dementia. Older ED patients with delirium have higher intensive care unit (ICU) admission, 30-day mortality and 30-day readmission rates.

Dementia

Studies that have universally screened older ED patients found rates of dementia of about 35%, mostly previously undiagnosed. *Dementia* is an umbrella term for chronic disorders causing impairment in two or more cognitive domains (i.e., memory loss, language, motor activity, object recognition, and disturbance of executive function). Although dementia would ideally be diagnosed by primary care physicians, this is not the norm. Detection of dementia by emergency clinicians allows a baseline cognitive status to be documented in the record and prompts patient and family to seek definitive evaluation for prognosis and planning. Most importantly, early recognition prompts additional history seeking from family and other collateral sources. Older adults with dementia are more likely to visit the ED and one recent study found that dementia is a predicator of 30-day ED revisits.[4]

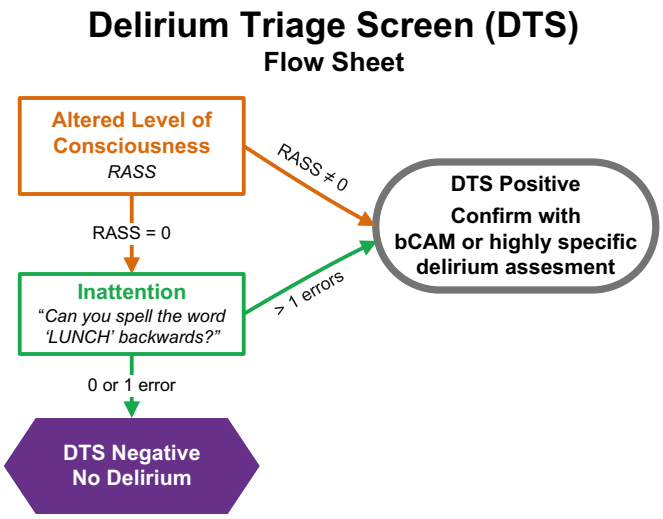
Functional Decline, Vulnerability, and Frailty

Functional status is an important element in the evaluation of older ED patients and predicts short-term, repeat ED visits. Formal functional assessments, including ADLs and instrumental activities of daily living (IADLs), are important (Table 178.1) in that a sudden functional deterioration may be the only manifestation of an acute illness.

Vulnerability screening and risk assessment tools have been developed and utilized to sort out those elderly at highest risk in order to target them for further assessments and/or interventions. The Identification of Seniors at Risk (ISAR), Triage Risk Screening Tool (TRST) and the interRAI are vulnerability screening tools utilized in the ED setting. We recommend using the ISAR tool, which incorporates elements of cognitive impairment and functional decline together to estimate risk (Box 178.2). One study demonstrated that a high/positive ISAR score was associated with an increased risk of 30-day ED re-visits.[5]

Frailty

Older patients are a heterogeneous group and biologic age is not the same as chronologic age. Frailty is a geriatric syndrome or condition in which there is marked decrease in physiologic reserve and resilience. Frail patients have multidimensional failure involving several different organ systems. The stress of illness or injury places them at very high risk for adverse outcomes and mortality. Patients with frailty have higher resource utilization and are more likely to need placement in a skilled nursing facility. Frailty identification is used routinely in geriatric medicine and used for outcomes prediction in surgery and oncology. There is no gold standard for defining frailty, but several tools have been developed for clinical and research purposes.[6] The FRAIL Scale (Table 178.2) is a short 5-item screening instrument that requires no measurements. The Clinical Frailty Scale (Fig. 178.2) is a 9-point scale



RASS, Richmond Agitation-Sedation Scale

Instructions on using the Delirium Triage Screen

The Delirium Triage Screen (DTS) was developed to rapidly rule-out delirium and reduce the need for formal delirium assessments. It takes less than 20 seconds to perform and consists of two components:

1) Level of consciousness as measured by the Richmond Agitation Sedation Scale (RASS).
2) Inattention by spelling the word "LUNCH" backwards.

If the patient has a RASS of 0 (normal level of consciousness) and makes 0 or 1 errors on "LUNCH" backwards spelling test, then the DTS is considered negative. Because the DTS is 98% sensitive, delirium is ruled out in this case and no additional delirium testing is needed. If the patient has a RASS other than 0 (altered level of consciousness) or makes 2 or more errors on the "LUNCH" backwards spelling test, then the DTS is considered positive. Because the DTS is 55% specific, confirmatory testing is needed using the bCAM, 3D-CAM, CAM or 4AT to rule in delirium.

BOX 178.2 Identification of Seniors at Risk (ISAR) Tool

1. Before the illness or injury that brought you to the emergency department, did you need someone to help you on a regular basis? (yes)
2. Since the illness or injury that brought you to the emergency department, have you needed more help than usual to take care of yourself? (yes)
3. Have you been hospitalized for one or more nights during the past 6 months (excluding a stay in the emergency department)? (yes)
4. In general, do you see well? (no)
5. In general, do you have serious problems with your memory? (yes)
6. Do you take more than three different medications every day? (yes)

Each "yes" response ("no" for question 4) counts as 1 point, for a total score ranging from 0 to 6. A patient is considered at high risk when the score is 2 or more.

Adapted from: McCusker J, Bellavance F, Cardin S, et al. Detection of older people at increased risk of adverse health outcomes after an emergency visit: the ISAR screening tool. *J Am Geriatr Soc*. 1999;47:1229-1237.

F	Fatigue ("Have you felt fatigued? Most or all of the time over the past month?") Yes = 1, No = 0
R	Resistance ("Do you have difficulty climbing a flight of stairs?") Yes = 1, No = 0
A	Ambulation ("Do you have difficulty walking one block?") Yes = 1, No = 0
1	Illnesses ("Do you have any of these illnesses: hypertension, diabetes, cancer (other than a minor skin cancer), chronic lung disease, heart attack, congestive heart failure, angina, asthma, arthritis, stroke, and kidney disease?") Five or greater = 1, fewer than 5 = 0
L	Loss of weight ("Have you lost more than 5 percent of your weight in the past year?") Yes = 1, No = 0
	Frail scale scores range from 0 to 5 (0 = best, 5 = worst) and represent frail (3 to 5), pre-frail (1 to 2), and robust (0) health status.

Data from: Morley JE, Malmstrom TK, Miller DK. A simple frailty questionnaire (FRAIL) predicts outcomes in middle aged African Americans. *J Nutr Health Aging.* 2012;16:601; and Woo J, Yu R, Wong M, et al. Frailty screening in the community using the FRAIL Scale. *J Am Med Dir Assoc.* 2015;16:412.

with scoring assigned based on clinical judgement. Both scales have been successfully used in the EDs, however further studies are needed to determine impact.

Goals of Care, Transitions of Care, and Palliative Care

Transitions in Care

Older patients undergo more transitions of care than younger patients. These transitions include home to ED, nursing home to ED, ED to inpatient, ED to nursing home, and ED to home. Transitions of care can be a risky period for patient safety; frail older patients are particularly vulnerable due to the complexity of their medical conditions and needs. Poor communication during transitions of care may result in adverse outcomes as a result of medication errors, adverse drug events, unnecessary treatments and hospitalizations, and lack of timely coordination of follow-up care. A number of groups, including the American College of Emergency Physicians, have identified management of transitions in care as a quality gap in emergency medicine and have advocated for greater vigilance around these transitions.

Depending on local resources, social work and/or case managers can help facilitate safe care transitions. They can identify psychosocial and financial needs, provide home safety assessments, transportation assistance, assistance in obtaining durable medical equipment, referrals for home care services, and access to community resources such as senior centers and meal delivery programs. Many transitional

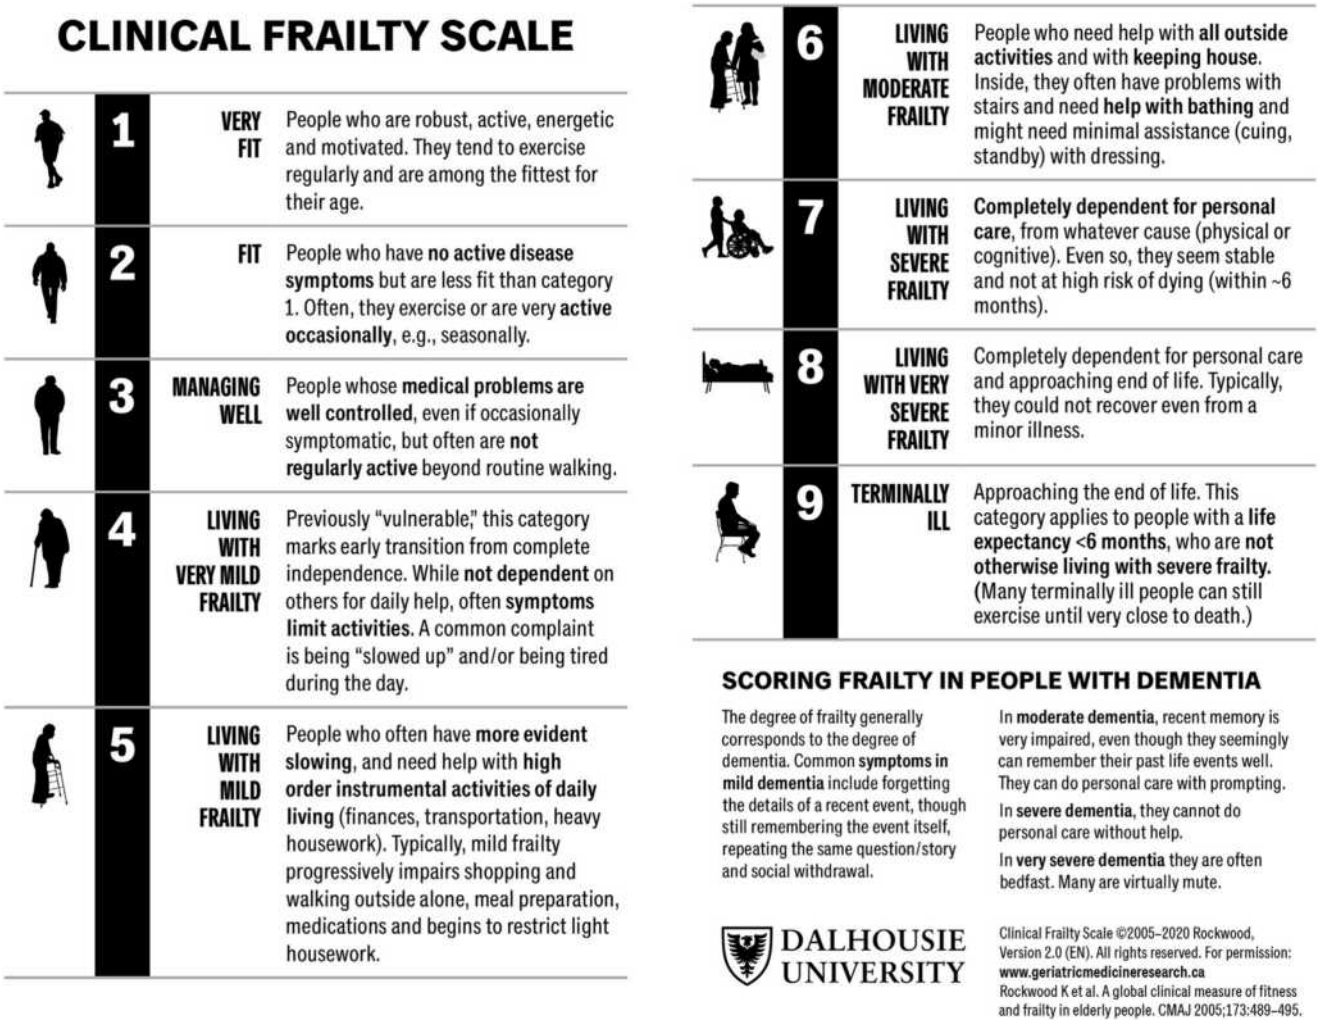

Figure 178.2 The Clinical Frailty Scale. © 2007–2009. Version 1.2. All rights reserved. Geriatric Medicine Research, Dalhousie University, Halifax, Canada.

care models include rapid telephone follow-up post-ED discharge to reinforce adherence to instructions, identify needs, and assist with follow-up referrals. The use of a dedicated transitional care nurse was studied and found to be effective to reduce risk of inpatient admission and 30-day readmission.[7]

Goals of Care and Palliative Care

Older patients with advanced and end-stage disease frequently present to the ED with repeat visits. A patient-centered approach utilizing shared decision making to determine goals of care is especially important for older patients, with a balanced discussion on the benefits and harms of care.[8] Quality of life versus length of life preferences will vary by individual and also by the specifics of a particular situation.

For patients with advanced life-limiting disease, the role of the emergency clinician is a combination of curative care, such as infection management, and palliative care, with a focus on quality of life and symptom management. End-of-life frequent complaints include pain, dyspnea, anxiety, agitation and delirium, constipation, pruritus, excessive oral secretions, stomatitis and nausea, vomiting, and diarrhea. Prognostication in the ED setting is challenging, as is communication with patients and families regarding goals of care in an inherently fast-paced ED environment. However, these interventions are nonetheless necessary and the benefits of palliative care include improved patient satisfaction, reduced length of stay, cost savings, and improved outcomes.[9]

Nonspecific Complaints and Atypical Presentations

Unfortunately, the classic model of medical diagnosis, in which signs and symptoms are evaluated, tabulated, and formulated into a specific diagnosis, is not sufficient for older patients. Nonspecific complaints and atypical presentations are common in older patients, which makes arriving at a diagnosis challenging. Chief complaints such as generalized weakness, fatigue, or dizziness are consistently among the top presenting complaints for older ED patients. Sometimes patients complain that they "just don't feel well" and family or caregivers may complain that the patient "just isn't their normal self." Compounding the challenge is the fact that many patients who present with nonspecific complaints develop a serious condition within 30 days (e.g., infections, metabolic abnormalities, and malignancies.) One-third to one-half of older patients in the ED have atypical presentations of illness.[10]

Acute Coronary Syndrome

Cardiovascular heart disease is the leading cause of death in men and women older than 65 years. Older patients with acute coronary syndrome (ACS) have higher associated morbidity and mortality, and older age is an independent risk factor for mortality after both ST elevation myocardial infarction (STEMI) and non-STEMI. An accurate clinical assessment for older patients is needed, as well as an optimal therapeutic strategy, taking into consideration the patient's quality of life and goals of care.

The incidence of the "classic" symptoms of ACS diminishes with increasing age. Chest pain at presentation with STEMI occurs in only about 50% of patients who are 85 years or older. Atypical presentations of ACS occur more often in older patients who are more likely to present with dyspnea, syncope, diaphoresis, shoulder or back pain, abdominal pain, weakness, fatigue, and/or delirium. One-third of women older than 65 years with acute myocardial infarction present with abdominal pain alone. As a result, the diagnosis of ACS may be delayed, and older patients may present instead with delayed complications, such as acute congestive heart failure. Consideration should also be made to other conditions that are more prevalent in the elderly, including severe aortic stenosis, aortic dissection, and pulmonary embolism.

Acute heart failure at presentation occurs in nearly 50% of STEMI patients 85 years or older compared to only 1.7% of STEMI patients younger than 65 years. Myocardial ischemia impairs left ventricular relaxation, which leads to an increase in left ventricular end-diastolic pressure (LVEDP). This increased LVEDP, superimposed on age-related decreases in left ventricular compliance, frequently results in elevated pulmonary capillary wedge pressure and heart failure.

Current evidence supports an early invasive approach over conservative treatment for both non-STEMI and STEMI. American Heart Association (AHA) guidelines recommend no absolute age restrictions for revascularization therapy for non-STEMIs and STEMIs. However, older patients often do not receive as aggressive treatment, including early referral for cardiac catheterization, as their younger counterparts and are less likely to receive ACS care according to recommended guidelines.[11] The evidence to inform optimal care for elderly patients is limited. Despite the high prevalence of ACS and its higher morbidity and mortality in older patients, they were excluded and underrepresented in earlier randomized controlled trials of ACS. The After Eighty Study specifically targeted patients over 80 years of age with non-STEMI and unstable angina. The results demonstrated superior outcomes for an early invasive approach compared with conservative strategy for clinically stable octogenarians but were inconclusive for patients over 90 years of age.[12]

Syncope

Patients 65 and over with syncope are more likely to have a serious etiology than younger patients, with almost half of these patients ultimately being diagnosed with a cardiac condition, including dysrhythmias, valvular heart disease, acute coronary syndrome, and aortic dissection. Medication effect and results of polypharmacy (i.e., multiple drug interaction) is yet another concern.

In older patients, syncope should be considered as a possible etiology of any unexplained fall, and the elderly are more susceptible to serious injury. Amnesia may confound the evaluation. Vasovagal syncope in the elderly is less likely to have a prodrome. Orthostatic hypotension is more common in older patients due to reductions in baroreflex responsiveness, cardiac compliance, and attenuation of the vestibulosympathetic reflex.

Abdominal Pain

Older ED patients with acute abdominal pain are at increased risk of having a surgical condition and of dying. Presentations may be deceptively subtle, including the lack of rebound tenderness or guarding on abdominal palpation, despite serious intra-abdominal pathology. Etiologies of abdominal pain that are not intra-abdominal processes should also be considered in the differential diagnosis (e.g., myocardial ischemia or infarction, pneumonia, and herpes zoster).

Several factors in older patients that can complicate the ability to make a diagnosis based on the history and physical examination alone, include altered pain perception, aging effects on the immune system, medications that limit tachycardic response to stress, and decreased ability to mount a febrile response to infection. Additionally, sometimes older patients may present only with nonspecific generalized symptoms such as delirium, malaise, or dizziness when the cause is an acute abdominal condition. Laboratory values are frequently normal, despite the presence of surgical disease. There should be a low threshold for imaging, particularly computed tomography (CT).

Vascular disease increases with age and vascular emergencies remain some of the most time-sensitive and highly morbid causes of abdominal pain in the older patient. Abrupt onset symptoms are a red flag. Although the diagnosis of a ruptured abdominal aortic aneurysm

(AAA) may be fairly straightforward in the older patient who has abdominal pain, hypovolemic shock, and a pulsatile abdominal mass, most patients lack this triad at presentation. AAA is commonly misdiagnosed as acute renal colic, and any older patient presenting with symptoms of new-onset nephrolithiasis should have imaging to evaluate the aorta for AAA. Acute mesenteric ischemia is a disease of older adults and an important consideration in the differential diagnosis of abdominal pain. It is a more common etiology than appendicitis or AAA complications in patients over age 75.[13] Superior mesenteric artery occlusion is the most common cause of acute mesenteric ischemia. Risk factors for mesenteric ischemia include cardiac arrhythmias, atherosclerosis, and prothrombotic conditions such as infection.

Biliary tract disorders are the most common cause of abdominal pain in the older adult, with the incidence of gallstones increasing with age. Cholecystitis is the most common indication for abdominal surgery in the older patient. About one-third of older patients with cholecystitis have no fever or leukocytosis. Additionally, about one-third of older adults with acute cholecystitis will present with minimal abdominal pain and an absence of peritoneal signs. Due to the poor vascularity of the gallbladder, older patients are at increased risk of complications such as perforation and emphysematous cholecystitis. Additional complications seen more often in the elderly include bile stone ileus, pancreatitis and choledocholithiasis.

Appendicitis is the third most common indication for abdominal surgery in the older patient population. Older patients have a higher incidence of perforation and mortality due to much higher rates of delayed diagnoses and/or presentations. Appendicitis historically has been misdiagnosed half of the time in older adults because many patients lack fever, anorexia, or leukocytosis. One-quarter of older patients have no right lower quadrant pain at all.

Peptic ulcer disease (PUD) is more prevalent in older adults due to increased use of nonsteroidal antiinflammatory drugs and to increased *Helicobacter pylori* infections. Abdominal pain is lacking in approximately 30% of elderly patients with PUD. Complications of bleeding and perforation result in higher mortality rates in older patients. Diverticulitis and bowel obstructions are also more prevalent in older adults. Tumors are a cause of large bowel obstructions in older patients. Hernias should be considered in older patients with possible bowel obstruction, and they should be examined for hernias, especially those with significant cognitive deficits who may not realize or neglect to mention their presence.

Infections

As with other conditions, infections in the elderly often present atypically. Older patients with infection are less likely to have vital sign abnormalities of fever or tachycardia. Although fever of 38.0°C or higher is strongly associated with bacterial infection, the sensitivity is low with fever present in 12% to 25% with pneumonia and 20% with urinary tract infection (UTI).[14] Elevation in white blood cell count is similarly not a sensitive marker of infection with 20% to 45% of patients subsequently found to have bacteremia lacking leukocytosis. Older patients with pneumonia or UTI are less likely to have localizing symptoms. Further confounding the difficulty of diagnosing an infection is that asymptomatic bacteriuria is common in older patients. Distinguishing asymptomatic bacteriuria from UTI is challenging especially in older cognitively impaired adults.

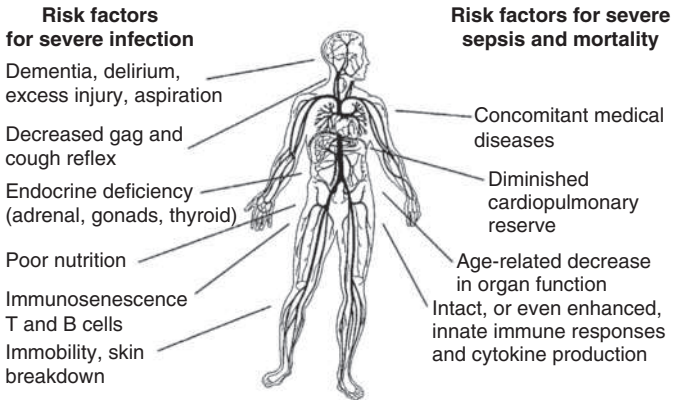

Fig. 178.3 Predisposing factors for sepsis in older individuals. (From: Girard TD, Opal SM, Ely EW. Insights into sepsis in older patients: from epidemiology to evidence-based management. *Clin Infect Dis*. 2005;40:719-727.)

Older patients experience an increased incidence of severe infection and severe sepsis with advanced age. Mortality from sepsis approaches 40% for patients older than 85 years. Aging effects on immunity include a decline in cell-mediated immunity and antibody production. Older patients may also have multiple risk factors for sepsis (Fig. 178.3) including comorbid diseases, exposure to instrumentation, malnutrition, and institutionalization.

With aging, the ability to generate a fever in response to pyrogens is decreased. Because of this blunted fever response, and because medication use or cardiac disease may limit tachycardic response to infection, older patients may have systemic inflammatory response syndrome (SIRS)–negative sepsis. Abnormal triage vital signs in adults 75 years and older have poor sensitivity (73%) and specificity (50%) for predicting death or ICU admission. Emergency clinicians must look more broadly than just the typical SIRS criteria to suspect and diagnose sepsis accurately.

Management of suspected sepsis in older patients is similar to that for younger patients, with an emphasis on early identification of sepsis, fluid resuscitation, and early and appropriate antibiotics. Just as with younger adults, older patients with sepsis have improved mortality with comprehensive sepsis treatment. Older patients are more dependent on having an adequate preload to increase cardiac output in response to sepsis because the ability to raise the heart rate is blunted. However, aging-associated diastolic dysfunction is common, and fluid resuscitation goals may need adjustment if patients develop hypoxia or hypervolemia. In regard to the choice of empirical antibiotics, sepsis in older patients compared to younger patients is more likely to be due to respiratory or genitourinary infections, with pneumonia as the single most common cause of sepsis.

CHAPTER 178–QUESTIONS AND ANSWERS

1. An 80-year-old female with history of COPD and arthritis comes to the ED following an episode of loss of consciousness while seated at the table after eating lunch. The patient and her husband, who witnessed the event, deny any symptoms prior to the event and deny any recent illness or symptoms. Her vitals are normal, and her physical exam is unremarkable. Which of the following is the most likely etiology of the syncopal episode?

a. Cardiac event
b. Cerebrovascular accident
c. Infectious process
d. Hypoglycemic reaction

Answer: A. Syncope is more likely to have a serious etiology in older adults, with 40% ultimately found to have a cardiac etiology. Hypoglycemia is highly unlikely because she does not have diabetes and just ate lunch. Cerebrovascular accident and infection are potential causes of syncope but are much less likely given that she has been well, asymptomatic, and her examination is normal.

2. Which of the following is a key feature of delirium that helps differentiate it from dementia?

a. Use of inappropriate language with swearing
b. Inability to correctly name the current date
c. Physical agitation with combativeness
d. Inability to focus or maintain attention

Answer D. Delirium and dementia can be difficult to diagnose and can exist together, with dementia being a predisposing factor to the development of delirium. A key feature of delirium is inattention with the inability to maintain focus. Confusion with the inability to name the current date, agitated behavior with combativeness, and the use of inappropriate language with swearing can all be seen in both dementia and delirium and therefore do not help with differentiation.

3. The presentation of infection in older patients differs from the presentation in younger patients. Older patients are more likely to have which of the following?

a. Elevated inflammatory markers, such as erythrocyte sedimentation rate and C-reactive protein
b. Fever
c. Left shift of the white blood cells
d. Normal white blood cell count

Answer: D. Older patients are more likely to have a normal white blood cell count, as well as a normal differential. They are less likely to have fever and signs or symptoms from the infection process. They are more likely to have complications and suffer long-term morbidity or mortality.

4. Which of the following statements is true regarding acute myocardial infarction (AMI) in older adults?

a. Atypical presentations portend a more benign course.
b. Atypical presentations increase with age.
c. Painless AMIs occur more commonly in men.
d. The absence of chest pain is rare.

Answer: B. Atypical presentations of AMI increase with age and are of equal severity as typical cases. Women have painless presentations more than men, and present with abdominal pain almost one-third of the time. The absence of chest pain is not uncommon.

5. A 74-year-old man with a history of hypertension and hyperlipidemia presents to the ED with acute onset of severe, nontraumatic, left flank pain. His vital signs include a heart rate of 72 beats/min and blood pressure of 120/70 mm Hg. Which approach to his care would be most appropriate?

a. Arrange for him to be in the observation unit overnight for serial abdominal examinations to help clarify his diagnosis.
b. Consider abdominal aortic aneurysm only after the patient's urinalysis and renal ultrasound are negative for nephrolithiasis.
c. Diagnose him with nephrolithiasis without any further testing.
d. Evaluate for a possible abdominal aortic aneurysm.

Answer: D. Vascular disease prevalence increases with age. Vascular emergencies remain some of the most time-sensitive and highly morbid causes of abdominal pain in the older patient and should always be considered first, particularly for abrupt-onset symptoms.

Geriatric Trauma

Lauren T. Southerland and John J. Fath

KEY CONCEPTS

- Do not let a low-impact mechanism, patient cognitive impairment, or vital signs within the range of normal reduce your pretest probability of significant injury in an older patient.
- Age-specific trauma alert criteria improve the care of injured older adults.
- Vital signs, including tachycardia and hypotension, are unreliable to detect hemodynamic instability in older adults. Ultrasound is a helpful tool to assess volume status in the older trauma patient.
- Older patients are at high risk of hypothermia and develop pressure ulcers more rapidly than younger patients. Unnecessary spinal immobilization (cervical collars and backboards) causes pressure ulcers, respiratory distress, and delirium in this population.
- Clinical decision tools for radiographic imaging have generally excluded older patients. A low threshold for imaging should be used for older adults with trauma, and computed tomography (CT) should be used as the primary modality, except for extremity imaging.
- Falls are the leading cause of injury-related death in older adults, and ground-level falls can result in major injuries. Assessing the patient's future fall risk, home safety, and home resources is important prior to leaving the ED or hospital.
- Rib fractures and pulmonary contusions are associated with poor outcomes in older patients. ICU care should be considered for those with two or more rib fractures or pulmonary contusions.
- Older adults with hip fractures have improved survival on a dedicated orthogeriatric service. Consider transfer of patients to hospitals where these services are available.
- Routinely screen for elder abuse. A valid screening question is: "Has anyone close to you tried to hurt you or harm you recently?" Another query is: "Does anyone at home scare you or threaten you?"
- All older adults with fractures should be assessed for osteoporosis/osteopenia, and malnutrition as leaving this untreated reduces healing and increases morbidity and mortality.

FOUNDATIONS

Older adults make up a growing proportion of trauma patients in emergency departments (EDs). Although the general principles of trauma care for younger adults apply to older adults, there are special considerations for the older trauma patient from the initial decision to activate the trauma team through injury management and disposition.

Background and Importance

There is no standard definition of the term *geriatric trauma* in the literature; studies vary in their age criteria. In this chapter, unless noted, we are referring to patients 65 years and older. In 2016, older adults accounted for almost 13% of all injury-related ED visits in the United States, and this percentage is expected to increase with the aging of the population. Currently, unintentional injury is the sixth leading cause of death among older adults, and falls are the most common cause. Given the same mechanism of injury, older adults sustain more severe injuries than younger adults. Even low-energy mechanisms can cause morbidity and mortality. Managing these patients appropriately requires a holistic, multidisciplinary approach as recommended by the American College of Surgeons' Geriatric Trauma Management Guidelines, the Eastern Association for the Surgery of Trauma Practice Management Guidelines for Geriatric Trauma, and the Geriatric ED Guidelines. These guidelines incorporate geriatric principles into the care of the injured older adult from the trauma alert through the initial Advanced Trauma Life Support (ATLS) assessment, imaging decisions, and injury management.

SPECIFIC ISSUES

Age as a Trauma Triage Criterion

Trauma activation and/or transfer to a trauma center improves outcomes for older adults. Treatment at a trauma center reduces mortality in the first 7 days after injury (hazard ratio 0.62).[1] However, injured older adults are less likely to be transported to a trauma center either by emergency medical services (EMS) or by a referring hospital.[2] Traditional trauma triage criteria are less sensitive to the presenting signs and symptoms of older adults. For example, confusion could represent a baseline mental status or be a sign of acute traumatic brain injury (TBI). Medication effects such as anticoagulation must also be considered. Trauma triage criteria specific for older adults have been developed with age limits for triage criteria ranging from 55 years to 77 years. The most researched age-specific trauma criteria at this time is the Ohio Prehospital Geriatric Trauma Triage Criteria, which incorporates an age limit of 70 years old or older with additional mechanisms of fall and pedestrian struck by motor vehicle.[3] Pedestrians older than 50 years old who are struck by a motor vehicle have a mean Injury Severity Score 9 points higher than younger adults, which is why this mechanism is part of geriatric trauma triage criteria. These criteria increase sensitivity from 61% to 93%, reducing the under-triage of older adults.

Mechanisms of Injury

Falls are the leading mechanism of injury and the leading cause of injury-related death in older adults. Most falls are from standing and occur at the place of residence; 12% of community-dwelling older adults fall each year. Traditional trauma criteria include a fall from a significant height or down a full flight of stairs, but for older adults a fall from standing or even out of a chair has an associated risk for injury. Mortality from a ground-level fall is only 0.1% for younger adults, but 4% to 5% for older adults.[4] The next most common injury mechanism is motor vehicle collisions. A detailed crash history is important, and single-vehicle crashes should raise the suspicion that a medical problem

Fig. 179.1 Pressure damage to the skin occurs most frequently over bony prominences. This image shows pressure damage to the knee and thigh of an older man after being on the floor for several hours after a fall

caused the crash (e.g., syncope, myocardial infarction, stroke). An evaluation for coincident events leading to trauma should be undertaken during the ATLS trauma evaluation.

Thermal injuries, elder abuse/neglect, and self-injury are less common but are also important injury mechanisms. Burns can require significant wound care and recovery time which may be difficult for older adults to manage. In one multicenter study of older adults with a burned body surface area of 10% or greater, inpatient mortality was 25% and of the survivors, 15% required inpatient rehabilitation and 18% to 50% needed skilled nursing facility placement at discharge.[5] Burns, head and neck injuries, and delayed injury presentation are also all suspicious for elder abuse. Elder abuse is a complex problem (see Chapter 181). The secondary exam should include a full skin and genital exam and thorough documentation of any injuries. The Geri-IDT (Geriatric Injury Documentation Tool) can be helpful in guiding this assessment.[6]

A final concerning mechanism in geriatric trauma is self-injury. Older adults have a higher likelihood of completing suicide attempts than any other age group. Risk factors include recent bereavement, decreasing functional status, and increasing burden of disease. They are less likely to present with a chief complaint of depression/suicidality and less likely to receive mental health care in the ED.

Pathophysiology of Aging Affects Both the Injuries Sustained and the Recovery

Although older adults in a good state of health have sufficient reserves to accomplish activities of daily living, when they are stressed by acute trauma and the subsequent response to injury, the decrease in physiologic reserve can lead to rapid progression of tissue hypoperfusion and organ failure. In a trauma registry study out of Germany, 30% of older trauma patients experienced sepsis, 20% had multiple organ failure, and 45% had cardiovascular failure.[7] Renal function also decreases with age and can be misrepresented by assessing creatinine clearance. Serum creatinine is a muscle breakdown product; in an older adult creatinine clearance can appear artificially normal due to decreased overall muscle mass.

Skin changes predispose to skin tears, poor wound healing, and pressure ulcers (Fig. 179.1). Backboards and cervical collars placed during a trauma activation can lead to skin injury. In one study, trauma patients had a median time in a cervical collar of 117 minutes, 78% developed pressure damage to the skin, and 28% developed severe indentations.[8] A final area of concern in older adults is age-related changes in the inflammatory and pain responses. Older adults have higher pain thresholds and reduced sensitivity to some types of painful stimuli. Decreases in the functionality of their white blood cells result in muted inflammatory responses and a lack of peritoneal abdominal signs on exam. In the older trauma patient, any abdominal tenderness is concerning for significant intra-abdominal injury.

Comorbidities

Older adults with polytrauma and a single comorbidity have 5.5 times higher risk of death than those without preexisting conditions. Comorbidities also increase the risk of injury by contributing to falls and impaired driving. Comorbidities complicate the evaluation process by impeding the ability to obtain an accurate history and interpret the physical exam. A patient with a blood pressure of 120/80 may be severely volume depleted if their normal systolic blood pressure is 150 due to hypertension. Table 179.1 provides examples of the effects various comorbidities can have on the evaluation and treatment of older adults following trauma.

Medications

A patient's daily medication regimen can increase the risk of a trauma and risk of death from an injury, obfuscate the clinical exam, and require changes in management and treatment of injuries. Medications also alter the response to resuscitative measures. A full medication review is essential for injured older adults with attention to specific drug classes (Table 179.2). Among older adults in a Canadian trauma registry, 30-day mortality increased by 24% for each medication a patient was taking. If the medication was potentially inappropriate based on the American Geriatrics Society Beers Criteria, the risk of death doubled.[9] Medication reconciliation in the setting of trauma is thus a matter of life and death. The most time-critical issue is the use of anticoagulation. Trauma patients on preexisting anticoagulation, regardless of type, have higher rates of complications and higher transfusion needs.[10] An "anticoagulation alert" system for older adult trauma activations may reduce mortality from injuries.

ATLS Assessment

A systematic trauma assessment per ATLS guidelines should be conducted in older adults (see Chapter 32). One change to the airway, breathing, circulation, disability mnemonic is to consider circulation alongside airway. Post intubation hypotension is more likely in older patients and 30% of these patients will die. Consideration should be given to resuscitation to restore perfusion prior to or concomitant with securing the airway.

Airway

Because older patients are likely to have multiple risk factors for a difficult airway, emergency clinicians should perform a systematic airway assessment. Early intubation is indicated for unstable patients, as defined by signs of shock, altered mental status, and significant chest trauma. However, this population is more likely to have advanced directives or other care planning documentation that should be consulted prior to intubation. Bilevel positive airway pressure (BIPAP) or high-flow oxygen may be used as temporizing measures while the goals of care are discussed.

If intubation is required, video laryngoscopy is recommended. Up to 30% of older trauma patients will require multiple intubation attempts. Consider sedation with ketamine to maintain the respiratory response and blood pressure (see Chapter 1). Etomidate is a second choice, as it is also not associated with significant hypotension, unlike propofol which may cause hypotension. We recommend rocuronium

TABLE 179.1 Comorbidities Common in Older Adults and Their Effects on the Evaluation and Management of the Patient After a Traumatic Injury

Comorbidity	Effect (*Contributing to Trauma, –Complicating the Trauma Exam, +Complicating Injury Management)
Cardiovascular disease	*Acute coronary syndrome may cause a fall or motor vehicle accident. –Higher risk of dissection with blunt chest trauma –Decreased peripheral perfusion from peripheral vascular disease +Risk of acute coronary syndrome from the catecholamine surge of trauma +Predisposed to pulmonary edema with large IV fluid boluses
Chronic kidney disease	+Need to decrease opioid and antibiotic doses and monitor for toxicity +More susceptible to volume depletion due to inability to concentrate the urine to conserve fluids +More susceptible to shock-induced acute on chronic kidney injury
Chronic lung disease	–Decreased pulmonary functional capacity can lead to significant respiratory compromise from cervical collars or lying flat. +Decreased tolerance of lung or chest wall injuries +Decreased ability to clear secretions from the lungs +Risk of encephalopathy from decreased ventilation and respiratory acidosis
Dementia	–Decreased ability to give a complete history –Agitation or behavioral disturbances from advanced dementia may complicate exam. +Increased risk of developing delirium from trauma or hospitalization +Decreased ability to express pain or request as needed (PRN) medications
Diabetes	–Results in peripheral neuropathy which can obscure injuries –Altered mental status with hyper- or hypoglycemia +Increased risk of wound infection and poor wound healing
Frailty	–Higher levels of mortality from even "minor" injuries +Higher risk of delirium +Need screening for nutritional deficits, home safety, and mobility issues. Consider early initiation of therapy (physical, occupational, speech) and geriatric consultations. +More likely to require skilled nursing facility placement, consider early case management and social work consultations
Joint replacements	–Periprosthetic or juxtahardware fractures may present with minimal deformity.
Neurovascular disease	*Neurologic deficits increase the risk of falls and injury. –Prior cerebrovascular accidents (CVA) or neurotrauma can obfuscate the neurologic exam. –Risk of recrudescence or another CVA with acute hypotension
Ophthalmologic	–Medications and prior surgeries (such as cataract repair) may change pupil exam for reactivity or symmetry.
Osteoporosis or Osteopenia	–Increased risk of fractures with minimal trauma –Prior atraumatic vertebral compression fractures complicating the evaluation of new injuries –X-rays have decreased sensitivity for detection of fractures. –Older adults will often still be able to ambulate despite pelvic or hip fractures; the ability to range a joint or ambulate cannot definitively rule out a fracture. +Osteopenia on CT scan is associated with a hazard ratio for death at 1 year of 12 times more than patients without osteopenia.
Rheumatoid Arthritis	*Associated cervical spine disease leads to fractures. –Joint deformities can be mistaken for acute fractures. Additional imaging may be needed to distinguish rheumatic disease from acute fracture.
Spinal diseases	*Degenerative disk disease of the spine increases the risk of endplate fractures. *Spinal stenosis can be associated with SCIWORET (Spinal Cord Injury without Radiographic Evidence of Trauma).

if a paralytic is required for an older trauma patient. Succinylcholine paralysis is contraindicated in the patient at risk for hyperkalemia from prolonged time on the floor after a fall. Limited mobility of the cervical spine and the temporal mandibular joint complicate visualization, making induction and paralysis key to successful airway management in the older adult. Dental changes such as bridges or lack of teeth can interfere with grip during scissoring and jaw thrust maneuvers. If dentures are securely in place, they do not need removal as they can improve the seal for bag mask ventilation.

Age is not a contraindication to performing a cricothyroidotomy, though this procedure can be more difficult in older patients. Flexion from cervical spine kyphosis compresses the anterior cervical anatomy which shortens and deepens the operative field, leading to a higher risk of failure of the procedure or injury to larger vessels.

Breathing

Older adults have more difficulty clearing secretions in the mouth and lungs and may require frequent suctioning. Lung disease and spinal kyphosis decrease functional lung volumes. A 45-degree incline can assist with oxygenation and ventilation. If there is concern for spinal injury, it is acceptable to ramp the entire bed (reverse Trendelenburg) to keep the head and chest elevated while the back is straight. Capnography

TABLE 179.2 Examples of Common Classes of Medications Taken by Older Adults and the Effects to Consider During Trauma Evaluation and Management of Injuries

Medication Class [Examples]	Medication Effects (*Contributing to Trauma –Complicating the Trauma Exam and Care)
Anticholinergics [Diphenhydramine, Meclizine, Promethazine, Hydroxyzine]	*Increase risk of falls, confusion, and delirium –Decrease urine output and cause constipation
Antihypertensives and Diuretics [Metoprolol, Carvedilol, Cardizem, Lisinopril, Furosemide]	*Increase risk of orthostatic hypotension and falls –AV nodal agents blunt the ability to mount a tachycardia response despite level of blood loss. –Baseline blood pressure may be hypertensive, so normotensive can signal relative blood loss.
Anticoagulants and Antiplatelets [Warfarin, Clopidogrel, direct oral anticoagulants (Apixaban, Rivaroxaban), aspirin, dabigatran, prasugrel, tigacrelor]	*Increase risk of spontaneous bleeding such as intracranial hemorrhage –Increase bleeding, bruising, and bleeding time –Increase mortality from intracranial hemorrhages
Corticosteroids [Prednisone, Dexamethasone]	*Chronic use increases risk of fractures. –Decrease wound healing –Decrease inflammatory response and may decrease sensitivity of exam for pain –Increase risk of wound infections –Increase risk of refractory hypotension
Hypoglycemic Agents [Metformin, Insulins, Sulfonylureas, Pioglitazone]	*Hypoglycemia can lead to falls or motor vehicle accidents. –Trauma patients are often placed on NPO (no oral intake) status causing iatrogenic hypoglycemia.
Opioids [Hydrocodone, Oxycodone, Codeine, illicit opioids]	*Sedative effects can lead to falls or motor vehicle collisions. –Blunt the pain response, increasing the risk of missed injury –Withdrawal may present with abdominal pain and tachycardia.
Sedatives [Benzodiazepines, Alcohol abuse, antipsychotic sedatives Mirtazapine and Trazodone]	*Increase risk of falls and motor vehicle accidents. –May affect Glasgow Coma Scale and cognitive assessments –Risk of respiratory sedation –Withdrawal may present as tachycardia and confusion.

is highly recommended if there is any concern for underlying lung disease, acute thoracic injury, or if analgesia or sedatives are given.

Circulation

As previously noted, older adults are particularly vulnerable to shock due to limited physiologic reserve. Adaptive responses to hypovolemia such as tachycardia and hypotension are reduced by physiologic changes and medications (see Tables 179.1 and 179.2). *Normal* initial vital signs are not reassuring, but *baseline* vital signs are helpful. Trends are more informative than specific cutoffs.

During resuscitation, the therapeutic window for cardiac preload is narrow, and inadequate monitoring of fluid status may lead to over- or under-resuscitation. Evaluation of the collapsibility of the inferior vena cava by ultrasound is recommended to assess overall fluid status and guide resuscitation. In patients in whom there is no obvious source of blood loss, incremental boluses (e.g., 500 mL) of warmed isotonic crystalloid can be used for resuscitation. Patients in shock with injuries that have a high likelihood of acute blood loss should be given blood early and empirically. The indicators for need of massive transfusion, such as the Assessment of Blood Consumption and the Trauma Associated Severe Hemorrhage scores, are not as sensitive in older adults. We recommend to start transfusing 1 unit packed red blood cells while obtaining imaging if there is any suspicion of significant blood loss. Frequent (every 30 minutes) reassessment of the hemodynamic status will avoid iatrogenic pulmonary edema and respiratory failure. Thoracic ultrasound is fast, available in most trauma bays, and with skilled operators is more sensitive for signs of pulmonary edema (B lines) than chest x-ray. Thoracic ultrasound for pulmonary edema or abdominal ultrasound of the inferior vena cava can be helpful in directing fluid resuscitation for the trauma patient.

Anticoagulation reversal is another method of improving circulation by reversing life-threatening bleeding. Considerations for reversing coagulation abnormalities in older trauma patients are the severity of injury, the volume of reversal agents required, the urgency for the reversal, the availability of various reversal agents and the corresponding risk of fluid overload (see Chapter 180).

Disability

Evaluation of older adults for disability includes examination for TBI, spinal cord trauma, vertebral fractures, and extremity injuries. In contrast to younger adults, older adults can have intracranial hemorrhages and yet maintain a Glasgow Coma Score (GCS) of 15. Any GCS less than 15 is concerning for TBI, and a GCS score below 8 is predictive of a poor outcome. Subtle changes in mental status such as confusion or decreased alertness or symptoms such as headache may be the only signs of TBI. Confirming baseline mental status with family or caregivers is essential. Ultimately, no combination of historical features and physical findings has been shown to reliably predict the absence of intracranial injuries in the older trauma population. Brain computed tomography (CT) is indicated for all older adults with head trauma, multisystem trauma, or symptoms or signs of TBI, because no clinical decision rule has been validated in older trauma patients.

The evaluation of the patient's cognitive status is critical to detecting delirium. A patient who is cognitively impaired or acutely delirious may not express pain or answer questions and therefore their physical examination may not be accurate. Delirium can be the cause of traumatic injury, such as falls, or can be the result of traumatic injuries. The Brief Delirium Triage Screen has high sensitivity in emergency department patients and is more rapid than the full CAM-ICU. Brief cognitive screening tests such as the Mini Cog or the 4AT Delirium Assessment

tool are also helpful when probing for cognitive impairment. Delirium is common among all trauma patients, especially those in the ICU or intermediate care units, and is associated with worse outcomes. A quarter of older trauma patients with rib fractures will develop delirium. Missing delirium on the initial evaluation in the ED is associated with prolonged length of stay in the hospital and increased morbidity.

Exposure

Older trauma patients often have a combination of chronic, acute, and iatrogenic skin injuries. Because even minor wounds can cause serious complications in older patients, a thorough skin exam should be performed. Once exposed, older trauma patients are at risk of developing hypothermia because normal thermoregulatory mechanisms may no longer be intact, or are disrupted from the stress of trauma. Hypothermia on arrival should raise suspicion of infection leading to the fall and injury, or prolonged exposure or immobilization after the fall.

Secondary Assessment

A complete history should be obtained from the patient or a care provider, with particular emphasis on corroborating the accident history, past medical history, medications, allergies, and social history, including baseline functional status and living arrangements. Code status and confirmation of any advanced care planning documentation is essential. Baseline functional status includes the patient's ability to walk and any need for assistive devices prior to the injury. In addition to the basic history, a history of falls should be obtained and fall risk factors identified. Patients should be screened for alcohol abuse, substance abuse, and elder abuse. Home living situation, caregivers and caregiver availability, and home safety concerns need to be understood to ensure a safe discharge. Social workers often assist with this evaluation and early assistance from these teams can greatly speed care and disposition of the older trauma patient.

Laboratory Testing

In addition to the recommended trauma labs (see Chapter 32), we recommend a urine culture and a cardiac evaluation (ECG, troponin, and cardiac monitoring). A creatinine kinase level should be considered in every patient who has been immobilized by fall or injury. Electrocardiography (ECG) and cardiac monitoring are advised because of the risk of cardiac causes or complications of their traumatic event.

COMMON INJURIES IN OLDER ADULTS

Traumatic Brain Injury (TBI)

TBI can occur with minimal head trauma in older adults and can be initially asymptomatic. Physiologic changes of aging and the frequent use of anticoagulant medications increase the likelihood and severity of TBI in older adults. With aging, the size of the brain decreases by 10% on average, resulting in increased intracranial free space, stretching of bridging veins to the dura, and increased brain mobility within the calvarium. With this increased freedom of movement even minor trauma can lead to shearing of blood vessels and intracranial hemorrhage. These injuries can be devastating; a fifth of older adults admitted for TBI will die or enter a vegetative state.[11]

Clinical variables alone are insufficient to identify all cases of intracranial injury reliably in older patients; the New Orleans Criteria, NEXUS II CT Head Rule, and Canadian Head CT Rule all exclude older adults. Newer research into biomarkers of glial injury have shown some promise, but as of yet are not validated in older adults. A noncontrast head CT is the imaging of choice to diagnosis hemorrhagic TBI. The TBI spectrum in older adults also includes concussions, which as in sports related injury, may result in headaches, nausea, short-term memory deficits, and sleep disruption. We recommend the Center for Disease Control's Acute Concussion Evaluation.

Treatment of moderate to severe TBI includes supportive care, rapid reversal of anticoagulation, and early neurosurgical consultation (see Chapter 33). Patients with mild TBI (GCS 13 to 15) may be safe for monitoring and anticoagulation reversal (if required) on a regular hospital floor or observation unit. Physical therapy and occupational therapy consultations are recommended both to assess for subtle deficits and to address any home safety, safe mobility, or care needs. Older patients with head trauma who are not anticoagulated and have a normal head CT are generally safe for discharge if they have a safe environment, responsible care provider, and reliable follow-up. In patients on therapeutic anticoagulation, if the initial head CT does not show any injury, the risk of subsequent development of an intracranial hemorrhage is less than 2%.[12] Although this risk is low, we recommend that any patient with neurologic deficits, confusion, or who is without reliable monitoring at home should be observed for 12 to 24 hours to assess for concussion or evolving intracranial injury.

Vertebral Fractures and Spinal Cord Injuries

Changes in bone mineral density (BMD) and spinal kyphosis with aging contribute to several distinct fracture types in older adults: C1 to C2 cervical fractures and vertebral compression fractures. In contrast to younger patients, in older adults the most common cervical spine fractures are at the level of C1 and C2, with more than 50% of cervical fractures occurring at the level of C2. These fractures are usually the result of a fall with impact to the head, resulting in anterior or posterior displacement of the odontoid process. Mortality from these fractures is high (16% in the first month, up to 32% in the first year for nonoperatively treated C2 fractures).[13] Vertebral compression fractures are also common and can be asymptomatic other than the slight loss of height. In one series of hospitalized women, the prevalence of incidental thoracic vertebral fractures on chest x-ray was 2.4% in women aged 50 to 59 years, 8.9% in women aged 60 to 69 years, and 21.9% in women aged 70 years or older.[14] A lack of initial symptoms unfortunately does not mean that these fractures lack long-term morbidity.

Establishing a diagnosis of cervical spine fracture in older patients is complicated because 20% of adults older than 55 years with a cervical spinal fracture do not report neck pain. The Canadian C-Spine Rule classifies all patients 65 years or older as inherently high risk. The National Emergency X-Ray Utilization Study (NEXUS) criteria include all ages, but validation studies of NEXUS have shown lower sensitivity in older adults. In any blunt trauma to the older neck, lack of spinal tenderness or lack of pain on range of motion does not completely rule out spinal injury. We recommend CT imaging for any older adult with trauma and neurologic symptoms or cognitive impairment.

Older adults are also at increased risk of thoracic, lumbar, and sacral vertebral fractures. Per trauma guidelines, CT imaging should be used liberally for older adult trauma patients. Consider imaging the entire spine for those with altered mentation or dementia. Clinical exam can only rule out thoracolumbar injury in the awake, alert, older adult without cognitive impairment or other comorbidities/medications that limit the sensation or expression of pain.

Up to 20% of women over 70 years of age have suffered a vertebral compression fracture; magnetic resonance imaging (MRI) is helpful in determining acuity. Finally, if one acute spinal fracture is found, the rest of the spine should be imaged. In blunt trauma patients with a cervical fracture, 20% to 26% will have a noncontiguous thoracolumbar fracture. In the past, flexion/extension x-rays were used to evaluate for ligamentous injury, but this is controversial and no longer general practice.

Consultation with a spine surgeon is essential for all spinal injuries. Kyphoplasty or vertebroplasty can help control pain. Braces or collars can assist with pain and recovery, but these also limit an older adult's abilities to perform activities of daily living. Spinous process and other stable cervical fractures are sometimes managed without immobilization because of the respiratory effects and discomfort from cervical collars.

Thoracic Trauma

Older adults are at increased risk of rib and sternal fractures, pulmonary contusions, and their complications with low-force injuries. In-hospital mortality from thoracic trauma ranges from 3% to 15%.

Obtaining a chest x-ray combined with extended FAST exam has a sensitivity of only 64% for detecting clinically significant thoracic injuries; therefore, chest CT is recommended for the potentially multiply injured patient.

Management of the older adult with thoracic trauma is similar to management of younger adults, but a lower threshold for ICU monitoring is suggested. Although these patients may appear stable by vitals, admission to the ICU for older adults with multiple rib fractures significantly decreased complications, hospital length of stay, and need for discharge to a skilled nursing facility in one single-center study.[15] Alternatives to opioid analgesia such as epidural analgesia, paravertebral analgesia, and/or topical lidocaine can be considered for pain management.

Fragility Fractures

Fractures are common injuries in older adults with decreased BMD. Even nonoperative, distal extremity fractures can affect mobility and the ability to live independently. The most common upper extremity fractures sustained by older adults, in order of frequency, are distal radius fractures, proximal humerus fractures, and elbow fractures. The most common lower extremity fractures in older adults are ankle fractures, hip and pelvic fractures, and tibial plateau fractures. Pelvic fractures can occur with relatively little force in older adults and often patients continue to ambulate on a fractured pelvis. Although the majority of pelvic fractures are stable, these fractures can be associated with hemorrhage. In-hospital pelvic fracture mortality is 2.8%, and up to 21% in older patients with open pelvic fractures. The initial in-hospital mortality from hip fractures (intratrochanteric) is low, but due to debility the longer-term mortality in this population is high (45% at 1 year), with men twice as likely to die as women.

Hip fractures can be seen on plain x-ray films but occult fractures are a well-described phenomenon in older adults. Patients with the inability to ambulate or who have persistent pain after trauma require further evaluation; MRI is useful to delineate the pathology.

Older adults with hip fractures have better outcomes with early surgery (<72 hours) and care in a distinct orthogeriatric service. Emergency clinicians should consider transferring older adults with hip fractures to hospitals with such services. For pain management, consider ultrasound-guided blocks such as the fascia iliaca. For other fractures, management is similar to that of younger adults except that the emergency physician is uniquely poised to discuss the treatment and diagnosis of two common syndromes: low BMD and malnutrition.

A fragility fracture should be suspected in all women older than 50 years and men older than 70 years old presenting with a fracture. The classic fragility fractures are distal radius, hip, and spine, but in the setting of trauma low BMD can contribute to fractures anywhere. If osteopenia is seen on the trauma CTs, then low BMD can be presumed. Treatment includes testing calcium and vitamin D levels and starting the patient on supplementation (if needed) pending full evaluation by their primary care doctor, orthopedist, or endocrinologist. The major contraindications to starting vitamin D and calcium supplementation from the ED include: end-stage renal disease, parathyroid disease, coronary atherosclerosis (currently debated), and renal stones.

Nutritional status also directly affects perioperative mortality and long-term healing from injuries. Malnutrition assessment in the older injured patient is endorsed by trauma guidelines. A study of older adults with hip fractures found that malnourishment was associated with increased in-hospital (27% versus 7%) and 1-year mortality (46% versus 17%).[16] Calcium levels, vitamin D levels, body mass index, and pre-albumin/albumin levels can all suggest malnourishment.

BOX 179.1 Suggestions to Limit the Side Effects and Complications of Analgesics for Injured Older Adults

- Limit NSAID (nonsteroidal antiinflammatory drug) use to 1 week or less to avoid renal and gastric injury. NSAIDs increase bleeding risk if patient is taking aspirin.
- Discuss total daily acetaminophen consumption limits and if any medications are combination pills with acetaminophen to avoid accidental overuse.
- Skeletal muscle relaxers such as cyclobenzaprine, methocarbamol, and benzodiazepines are discouraged for use by the American Geriatrics Society Beers Criteria.
- Tramadol lowers the seizure threshold, is renally metabolized, and can cause SIADH/hyponatremia and hypoglycemia in addition to the regular side effects of opioid medications. Use with caution.
- Tramadol, codeine, and morphine are not recommended for patients with renal insufficiency (GFR <30 mL/min).
- Discuss a bowel regimen that includes a promotility agent such as senna, docusate, bisacodyl, or prune juice.
- Consider topical agents such as lidocaine and topical NSAIDs.
- Consider early referral to physical therapy to assess mobility and pain, and reduce functional decline from injury.

Compiled from the American Geriatrics Society 2019 Beers Criteria and the American Geriatrics Society Geriatrics at Your Fingertips.

DISPOSITION, END-OF-LIFE CONSIDERATIONS, AND RECOVERY

Although age alone is not an indication to withhold aggressive treatment, comfort measures may be more appropriate than transferring patients to a trauma center in select cases (e.g., grave prognosis or when the patient's goals of care are known). Early referrals to palliative medicine and hospice from the ED help with pain and end-of-life care (see Chapter e5). The majority of older adults will recover from their injuries, but many will require additional help during recovery. Even minor decreases in range of motion of a joint can have a large impact on older adults' ability to care for themselves at home; additional help, equipment, or acute rehabilitation facility placement may be needed. An observation unit can be used to coordinate physical and occupational therapy consultations and home equipment prior to discharge from the ED. Lastly, prior to discharging an older adult to home, a safe and effective strategy for pain control is required (Box 179.1).

CHAPTER 179: QUESTIONS AND ANSWERS

1. A 76-year-old man is brought to the emergency department (ED) after a fall at home. The paramedics tell you that he slipped in the shower and struck his head on a tile floor. The patient is awake and alert. He is unsure if he lost consciousness and complains of headache. When you obtain a computed tomography (CT) scan of his head, it reveals evidence of a subdural hematoma. The paramedic tells you that he has a history of severe congestive heart failure (CHF) and takes warfarin and furosemide daily. When he returns from CT, he seems slightly confused. Laboratory tests are pending. What is the best initial treatment?

a. Administer prothrombin complex concentrate (PCC)
b. Administer tranexamic acid
c. Administer protamine sulfate
d. Transfuse 2 units fresh frozen plasma

Answer: A. Prompt reversal of anticoagulation is important. Specific considerations for reversing coagulation abnormalities in older trauma patients are the volume of reversal agents required and corresponding risk of fluid overload. PCCs require minimal volume compared with fresh-frozen plasma (FFP) but are costly. To reverse anticoagulation fully, 1 to 2 L of FFP may be required, presenting a limitation to rapid reversal in older patients at risk of fluid overload. Platelets, tranexamic acid, and DDAVP will not reverse the elevated international normalized ratio caused by warfarin.

2. Which of the following is the most common cervical spine fracture in geriatric trauma patients?

a. Compression fracture
b. Jefferson fracture
c. Spinous process fracture
d. Type 2 odontoid fracture

Answer: D. Because of the relative immobility of the cervical spine related to degenerative joint disease, the most common level of cervical spine injury in older adults is C1 to C3, a higher level than in younger patients. Among these upper cervical spine fractures, the most common is a type 2 odontoid fracture.

3. An 80-year-old woman presents after a motor vehicle accident. Her vital signs on arrival are: heart rate of 112 beats/min, blood pressure of 88/65 mm Hg, respiratory rate of 18 breaths/min, and oxygen saturation measured by pulse oximetry (Spo_2) of 98%. The paramedic tells you that she has a history of CHF and takes furosemide daily. FAST does not reveal a source of bleeding. There are no obvious external injuries or bleeding. The IVC collapses more than 50% with inspiration. Which of the following treatments is most appropriate to address the patient's tachycardia and hypotension while searching for its cause?

a. Give a bolus of 500 mL warmed normal saline.
b. Give 2 units of non–crossmatched type O blood.
c. Run an infusion of warm normal saline wide open.
d. Start norepinephrine at a low dose.

Answer: A. If the patient has an obvious source of hemorrhage, use of non–crossmatched type O blood would be appropriate as a first step, starting with 1 unit. However, this patient has no signs of bleeding on FAST or external exam. The most prudent approach in this hypotensive older trauma patient is controlled boluses of warmed isotonic fluids, with frequent assessment of physical examination, vital signs, pulse oximetry, lactate, and IVC status. Resuscitation with crystalloid may correct the patient's hypotension, obviating the need for transfusion. Hypotension should be immediately addressed, and treatment should not be delayed for type-specific blood. Given her history of CHF, a wide open infusion of normal saline without an endpoint should not be administered. Vasopressors such as norepinephrine should not be given to any trauma patient, except in extreme circumstances of persistent hypotension despite adequate volume resuscitation.

4. A 76-year-old man presents after slipping and falling down several stairs at home. He notes his doctor just started him on a medication

CHAPTER 179: QUESTIONS AND ANSWERS—cont'd.

for dizziness (meclizine). The patient is awake and alert and denies loss of consciousness after the fall. He complains of chest pain and has left chest wall tenderness on examination. When you obtain a CT scan of his chest, it reveals three contiguous lateral rib fractures. The patient's pain is only moderately relieved by 0.15 mg/kg of morphine sulfate IV. What is the most appropriate disposition for this patient?

a. Admission for pain control with IV opioids
b. Admission with anesthesia consultation for pain management
c. Continued observation in the ED for 6 additional hours of IV opioid management, followed by reassessment
d. Discharge home after a bupivacaine rib block for pain.

Answer: B. Geriatric trauma patients with severe pain from rib fractures often require hospitalization to allow adequate and safe pain management, and those with flail segments or larger numbers of rib fractures may require intensive care unit admission. Pain control is of particular importance because rib fractures will lead to splinting and atelectasis and increase the risk of pneumonia. Analgesia can be administered with IV opioids via patient-controlled analgesia or via rib block with anesthetics. An anesthesia consultation is appropriate for the older rib fracture patient without pain relief from parenteral opioids.

5. Late in the evening, an 82-year-old woman is transferred to your ED for a burn to the hand. Your ED is the local burn center. Her vital signs on arrival are as follows: heart rate of 94 beats/min, blood pressure of 110/70 mm Hg, respiratory rate of 12 breaths/min, and oxygen saturation measured by pulse oximetry (Spo_2) of 97%. You note circumferential first and second degree burns to the entire left hand with some sparing over the flexor areas of the 2-5th digits. She has no respiratory distress and there are no other injuries on exam. The adult grandson who cares for her says she was cooking and stuck her hand into boiling soup to grab a spoon. He also notes her dementia is worsening and it has been harder to care for her. She has no known history of neuropathy or self-injury. In addition to local wound care, what is the next step in the management of this patient?

a. Pain control prescription, and discharge to home with family.
b. Pain control prescription, and discharge to home with family. Put in a call to Adult Protective Services to follow up on the patient.
c. Analgesics, IV fluid resuscitation per the Parkland formula, and admission.
d. Analgesics, and admission for further investigation of elder abuse vs caregiver fatigue.

Answer: D. Older adults are at risk for inadvertent burns while cooking, but a circumferential burn with signs of a clenched fist (sparing over the flexor areas of the fingers) suggests the hand was forced into the liquid. This woman is not safe for discharge both due to her injuries (circumferential hand burn) and her safety risk. The patient should be admitted for continued medical care and a full social work assessment and collaboration with Adult Protective Services. Most police agencies prefer to be notified at the time of injury as well if there is concern for criminal abuse, just as you would for a younger victim of interpersonal violence. As isolated hand burns are less than 10% BSA, there is no indication to start Parkland formula resuscitation. The main intervention is keeping her safe from possible abuse.

6. A 67-year-old construction manager is the restrained driver in a head on collision with a roadside barrier at 45mph. Airbags deployed and he complains of right knee pain, chest pain, and back and neck pain. Vital signs are heart rate of 85 beats/min, blood pressure of 130/67 mm Hg, respiratory rate of 12 breaths/min, and oxygen saturation measured by pulse oximetry (Spo_2) of 97%. He is oriented to self, time, and place but does not remember everything about the accident or how he veered off the road. He has a history of diabetes, hypertension, and cirrhosis and takes a daily aspirin, lisinopril, hydrochlorothiazide, metformin, and glipizide. Which laboratory tests should be ordered in addition to the basic trauma evaluation (coagulation studies, a type and cross, alcohol and drug testing, a complete blood count and a basic metabolic panel)?

a. Erythrocyte sedimentation rate
b. Troponin, hepatic function panel, ammonia, and urinalysis
c. Creatinine kinase.
d. Venous blood gas.

Answer: **B.** This patient was in a high speed MVA without a clear inciting cause. He requires both a trauma evaluation for any injuries but also an evaluation for the cause of the collision. The initial workup therefore includes a bedside glucose (he is on two oral antihyperglycemic medications), a troponin to assist in evaluating whether his chest pain is from a cardiac cause or chest trauma, an ammonia and hepatic function level to evaluate for cognitive difficulties from cirrhosis, and a urinalysis to check for infection, volume depletion, and other causes. An erythrocyte sedimentation rate is not be specific for injury. A venous blood gas is likely unnecessary as he is oxygenating well and has no history of pulmonary disease. A creatinine kinase to evaluate for rhabdomyolysis is unnecessary as the patient was not immobilized and so is not at risk for this.

7. A 72-year-old woman who runs a dance instruction studio presents for 3 days of L hip pain. She slipped and fell on the hip and initially required assistance to get up, but has been ambulating since the injury. She presents to your ED because the pain is not improving with acetaminophen and time. On exam, there is no angulation, bruising, deformity or limb length discrepancy. She tolerates passive range of motion of the L hip but is tender over the greater trochanter and with pelvic compression. The initial x ray demonstrates osteoporosis but no fractures. An MRI shows a stable pelvic ring fracture that does not require operative management. What is the best recommendation for pain management?

a. Prescribe two weeks of ibuprofen 600mg tabs to use every 6-8 hours.
b. Prescribe tramadol and a strong muscle relaxer such as Valium to prevent spasms.
c. Prescribe a walker to decrease her weight bearing on that limb, a referral to early physical therapy, and topical nonsteroidal anti inflammatory cream.
d. Prescribe two weeks of oxycodone 5mg tablets to use every four hours.

Answer: **C**. A multimodal approach that also assists with ambulation and healing is appropriate. Non-steroidal anti-inflammatories can cause renal injury or peptic ulcer disease if used at high doses or for a longer time period. Try to limit use to lower doses (200-400mg) and under a week at a time. Tramadol and skeletal muscle relaxers are not indicated for use in older adults, and this combination is especially concerning for increasing the patient's risk of another fall and injury. Oxycodone may be needed if her pain is severe, but should not be prescribed without a bowel regimen.

Geriatric Drug Therapy

Christopher J. Edwards and Arthur B. Sanders

KEY CONCEPTS

- Those with a chronologic age of 65 years or older are commonly referred to as older adults (or the elderly), but physiologic age is more indicative of a drug's therapeutic or toxicologic effect. Besides age, overall patient assessment should include organ function, comorbidity, and functional status to guide drug dosing.
- Pharmacokinetic and pharmacodynamic changes that occur with age need to be considered to optimize drug dosing and minimize toxicity in older adults. In most cases, a "start low, go slow" approach is recommended. Multiple or repeated dosing is more likely to lead to drug accumulation compared to single doses in the emergency department (ED).
- Polypharmacy is common in older adults, predisposing them to adverse drug effects, drug interactions, and functional and cognitive impairment. Some of these medications do not have legitimate indications or may be inappropriate.
- Published lists of potentially inappropriate medications, such as the Beers list and the STOPP and START criteria, can help to identify potentially problematic medications; however, there are limited studies to enable extrapolation to the ED setting.
- Anticoagulation-related hemorrhagic complications are common in elderly patients, particularly if drug accumulation occurs in patients taking renally eliminated direct-acting oral anticoagulants.
- Older adults often present to the ED with altered mental status. Drug-related causes such as anticholinergic medication burden should be considered in the differential diagnosis.
- Geriatric patients with pain-related complaints are less likely to receive analgesics in the ED compared to younger adults, placing them at risk for poor pain control. Dosing of opioids should be cautious, with frequent monitoring and titration. Given the availability of alternative opioids, the use of meperidine should be avoided.
- A growing number of institutions have pharmacists practicing in the ED. In geriatric EDs, there is a great opportunity to integrate and consult with pharmacists, given the myriad drug therapy issues that can lead to suboptimal care.

FOUNDATIONS

There are approximately 23 million visits to United States (US) emergency departments (EDs) by adults over the age of 65 annually.[1] As the US population ages, the number of ED visits by older adults is expected to increase disproportionately compared to the general population based on estimates from the US census.[2] Drug therapy issues are particularly challenging in older adults because of altered pharmacokinetics and pharmacodynamics compared to younger adults. In addition, older patients take more medications, have more comorbidities, and are at increased risk for adverse drug effects because of the physiologic changes that occur with aging. Medication selection and dosing must be age-adapted for optimal patient outcomes. Also, given that advanced age is a commonly applied exclusion criterion in clinical trials, there is less high-quality evidence for many drug therapy interventions in older adults compared to younger adults. This can make extrapolating from studies and evaluating risks versus benefits for pharmacologic options more challenging, particularly for patients who are 80 years of age or older.

Most developed countries have adopted the chronologic age of 65 years to define the geriatric or older population.[3] The World Health Organization does not have a standard definition, but generally uses the age of 60 years or older to refer to older persons.[3] This categorization may be overly simplistic, and stratification, such as young old (60–69 years), middle old (70–79 years), and very old (≥80 years), is more suitable and medically useful. From a drug therapy perspective, physiologic age is more indicative of the anticipated therapeutic or toxicologic effect; however, there are no physiologic markers that define the aging process or that can be routinely used in clinical practice.[4] Most studies evaluating medication use in older adults have used a cutoff value of 65 years, and this serves as the basis for recommendations from the American Geriatrics Society.[5]

In this chapter, we refer to older adults as those with a chronologic age of 65 years or older; however, from the emergency clinicians' perspective, this is an arbitrary value for making drug therapy decisions. In addition to chronologic age alone, an overall assessment that incorporates organ function, comorbidity, functional status, and lifestyle is a better determinant of drug therapy selection and dosing. This should also be considered when interpreting recommendations for older adults, such as what is considered to be an inappropriate medication. This chapter reviews select aspects of pharmacology for older adults and the clinical implications in emergency medicine.

Pharmacokinetics

The time course of drug exposure is determined by pharmacokinetic parameters including absorption, distribution, metabolism, and elimination. The drug effect is primarily determined by this exposure, which can be quantified by serum drug concentrations over time. It is assumed that increased exposure is more likely to result in toxic medication effects. Thus, an understanding of pharmacokinetic changes in older adults is useful for determining risks of adverse drug reactions and can help guide medication selection and dosing.

The effect of physiologic changes on drug absorption is an important consideration for orally ingested medications. Changes in gastric pH, gastric emptying, splanchnic blood flow, bowel motility, and absorptive capacity all impact drug availability. For example, the increase in gastric pH seen in older adults can decrease the dissolution of medications that are weak bases, reducing absorption and resulting in lower serum drug levels. Conversely, decreased bowel motility can increase transit

time, allowing more opportunity for absorption to occur, leading to increased serum drug levels. Clearly, age-related changes in the gastrointestinal system can have a varied effect on drug absorption, leading to unpredictable effects on serum drug concentrations. As an example, decreased absorptive capacity coupled with decreased bowel motility can increase transit time, leading to a net neutral effect on drug exposure. Gastrointestinal and other comorbidities can have a greater effect on absorption than age alone. Given these considerations, it would be prudent in the ED to use the intravenous route for acute conditions, when rapid drug absorption is needed to achieve a therapeutic concentration.

Age-related changes in body composition have an effect on the distribution of drugs. There is an increase in total body fat and a decrease in relative skeletal muscle mass in older adults compared to young adults. This change in body composition accelerates between 60 to 75 years and then may start to decline. Lipophilic medications have a greater volume of distribution with increasing adiposity, whereas the opposite is true for hydrophilic medications. Opioid analgesics such as fentanyl and most sedatives (e.g., benzodiazepines, propofol) are very lipophilic, so there is distribution and accumulation of the drug within adipose tissue, and its metabolites are renally eliminated. With prolonged use, this can lead to an increased duration of effect due to redistribution of drug from tissue to serum and central nervous system. Conversely, hydrophilic medications such as digoxin would require lower loading doses in older adults to achieve similar serum concentrations due to a smaller volume of distribution. This has the potential for drug toxicity if not dosed appropriately for age.

Most drugs require biotransformation into polar metabolites before final elimination. This primarily occurs in the liver via phase 1 metabolism by cytochrome P450 enzymes (oxidation) or phase 2 (conjugation, acetylation, sulfation) reactions. With advanced age, hepatic mass and blood flow may decrease by up to 40%, which reduces the delivery of medications to the liver and their subsequent metabolism. This decrease in first-pass metabolism improves drug bioavailability resulting in increased serum levels and potentially increasing the risk of drug toxicity for certain agents. Drugs with a high hepatic extraction ratio are more dependent on hepatic blood flow for drug metabolism, and the slowing of hepatic metabolism seen with age has mainly been related to changes in phase 1 pathways. For example, morphine is a high–extraction ratio drug and would lead to greater drug exposure as hepatic blood flow is reduced. Commonly used benzodiazepines in the ED also vary in their metabolic pathways. Midazolam undergoes phase 1 metabolism, and hepatic impairment would lead to drug accumulation, especially with repeated or prolonged use. Conversely, lorazepam undergoes phase 2 conjugation and is preferred in patients with hepatic impairment because this metabolic pathway is less dependent on hepatic blood flow. The effect of aging on phase 1 metabolism via CYP3A4 is controversial. This enzyme represents the metabolic pathway for most medications, and studies have shown no significant differences between younger and older populations.

Renal blood blow, renal mass, and the number of nephrons decrease with age, leading to a decrease in renal function. In a longitudinal study, renal function decreased by approximately 10% for each decade between 30 and 80 years of age. This decrease was independent of comorbid conditions and was attributed to aging alone. Although this decline is likely to occur in most patients, up to one-third may have no decline, and some may have an increase in renal function. Kidney function is expressed as the glomerular filtration rate (GFR) and is routinely estimated by the Cockcroft-Gault equation. However, this equation may not accurately estimate the GFR, so the modification of diet and renal disease (MDRD) equation has been suggested as a more accurate estimation.[6] Common equations used to calculate creatinine clearance and estimate GFR are in Box 180.1. Discordance in drug doses selected may occur 10% to 40% of the time when comparing the two equations, and there has been considerable debate regarding the most appropriate equation to use in practice.[7,8]

BOX 180.1 Equations to Estimate Glomerular Filtration Rate (GFR, in mL/min)

Cockcroft-Gault Equation

Creatinine clearance (mL/min) = (140 − age)
× (weight in kg) /72 × serum creatinine × (0.85 if female)

Use ideal body weight (IBW). If patient is obese, use adjusted body weight.

IBW (male) = 50 + [2.3× (height in inches − 60)]

IBW (female) = 45.5 + [2.3× (height in inches − 60)]

Adjusted body weight = IBW + [0.3 × (actual weight − IBM)]

Modification of Diet and Renal Disease Equation

$GFR = 175 \times \text{serum creatinine}^{-154} \times \text{age}^{-0.203}$
(× 1.212 if patient is black; × 0.742 if patient is female)

Typically, drug dosing in manufacturers' labeling per the US Food and Drug Administration is based on creatinine clearance determined by the Cockcroft-Gault equation and, as such, most pharmacists continue to use this equation for drug dosing. The Cockcroft-Gault equation is also easier to calculate compared to the MDRD. While many electronic health records and laboratories use MDRD to calculate and report GFR, there is no universal industry standard approach, and it is important to know which equation is used to calculate the GFR reported in the medical record. Although cumbersome, one approach is to calculate estimated GFR based on both equations and evaluate if there is a discrepancy in dosing recommendations. This approach is useful if the initial estimate is close to a cut-off value that would alter the dosing regimen. If a discrepancy exists, the decision to use a more or less conservative dosing strategy will depend on the clinical scenario. In general, a low-dose approach should be used for medications with a narrow therapeutic index, particularly when the risk of toxicity is high and serum concentration monitoring is not available. In general, medication dosing should be higher in the ED when the implications for therapeutic failure warrant such an approach, assuming the medication has a broad safety margin. An example would be erring on the side of more aggressive dosing when using antibiotics in a patient with sepsis or febrile neutropenia. Thus, clinical circumstances may override drug dosing recommendations, especially when there is discordance between equations, and professional judgment is always required. These equations use the serum creatinine level to estimate creatinine clearance, which is affected by muscle mass. Therefore, although serum creatinine values may be normal, they may not accurately estimate renal function in some older adults, especially those with less musculature. For all older patients, some providers routinely round serum creatinine values less than 1 mg/dL up to 1 mg/dL to account for reduced muscle mass; however, this practice should be avoided because it has been shown to underestimate clearance.

Given the limited number of repeat doses typically administered in the ED, even in patients with hepatic or renal impairment, drug accumulation is unlikely to be clinically meaningful. If, however, several doses of a medication are administered in the ED, especially when patients are boarded, drug toxicity or prolonged effects may become

TABLE 180.1 Pharmacokinetic Changes in Older Adults

Parameter	Change	Comments
Absorption		
Gastric pH	↑	Net absorption may be increased or decreased.
Gastric emptying	↓	Peak effect will likely be delayed.
Splanchnic blood flow	↓	The intravenous route is preferred in the ED for rapid and predictable effect
Bowel motility	↓	
Absorptive capacity		
Distribution		
Adipose tissue	↑	Lipophilic medications will accumulate with repeated dosing, which increases duration of effect.
Total body water	↓	Hydrophilic medications will have a lower volume of distribution, requiring lower loading doses.
Metabolism		
Phase 1 metabolism	↓	Medications with phase 1 metabolism are more likely to accumulate than those metabolized via phase 2 pathways.
Phase 2 metabolism	↓	
Liver blood flow	↓	
Elimination		
Glomerular filtration rate	↓	This is the most important consideration for drug dosing. Calculate creatinine clearance using the equations in Box 180.1 and adjust dosing. First doses of antibiotics and most one-time doses do not require adjustment.

clinically relevant. In general, a "start low and go slow" approach is prudent in older patients. When this strategy is used, it is critical to reevaluate the patient after the anticipated onset of the administered medication to determine if additional doses are necessary because failure to do so could lead to undertreatment. The risks versus benefits of drug therapies generally increase with age, suggesting that a more conservative approach is warranted, particularly when using drugs with a narrow therapeutic index. Pharmacokinetic changes in older adults are listed in Table 180.1.

Pharmacodynamics

Even at similar plasma concentrations, drugs may have altered effects in older adults, perhaps because of changes in the number and sensitivity of receptors, signal transduction, and reduction in homeostatic processes that help maintain equilibrium. Thus, physiologic mechanisms that help restore function are attenuated, leading to an exaggerated or relatively unopposed pharmacologic effect. Pharmacodynamic changes in older adults that are most relevant to consider in the ED include those that pertain to the cardiovascular, central nervous, and coagulation systems. For example, there is a decreased response to both β-adrenergic receptor agonists and antagonists. Conversely, there is no age-related change in α_1-adrenergic receptor sensitivity. Calcium channel blockers cause a greater drop in blood pressure and heart rate in older adults compared to younger adults, so the risk for postural hypotension is higher in older adults. The diminished inotropic response to catecholamines contributes to this risk. In the ED, non-dihydropyridine calcium channel antagonists such as diltiazem or verapamil are commonly used for patients with supraventricular tachycardias. Lower doses are appropriate in older adults, especially when the patient has tenuous blood pressure.

There is increased sensitivity to benzodiazepines in older adults, and lower doses are needed to obtain similar sedative-hypnotic effects. This is because of changes in the structure, composition, and function of the γ-aminobutyric acid (GABA) receptor complex. Similarly, in one investigation, older patients required less propofol for the induction and maintenance of sedation during procedures in the ED.[9] The dose required for induction was 0.5 mg/kg less than in the cohort of young adults. In older adults, it is more suitable to start propofol with a 0.5-mg/kg rather than the 1-mg/kg bolus that is typically recommended. Some studies have shown that older patients have increased sensitivity to opioids. Pharmacodynamic effects in these studies were measured in terms of electroencephalographic readings, which do not reliably indicate the presence of pain. However, the risk of adverse effects and interactions due to the use of concurrent medications is likely increased in older adults, suggesting that a cautious approach is appropriate when dosing opioids.

There is an age-related decrease in dopamine content in the central nervous system, which predisposes patients who are given neuroleptics and other dopamine antagonists to extrapyramidal symptoms. Similarly, there is a decrease in acetylcholine synthesis in older adults, which increases the risk for anticholinergic neurotoxicity with commonly used antihistamines, antispasmodics, and antiparkinsonian agents.

Bleeding is a potentially life-threatening consequence of anticoagulants. Historically, warfarin has been the most commonly used oral anticoagulant, although, more recently, newer oral agents such as direct thrombin and factor Xa inhibitors have become available. At similar warfarin plasma concentrations, there is greater vitamin K inhibition in older adults. Thus, it is recommended that warfarin should be initiated at a daily dose of 5 mg or less for older adults, when indicated. In the ED, this may occur for patients discharged after a venous thromboembolism in conjunction with low-molecular-weight heparin as bridge therapy. There is emerging evidence supporting the early use of direct-acting oral anticoagulants for certain patients presenting with a venous thromboembolism (VTE). While data regarding the use of direct-acting oral anticoagulants in older patients being discharged from the ED with VTE are sparse, when used, careful attention must be paid when selecting an agent and formulating a dosing regimen. Certain agents, such as dabigatran, should be avoided in advanced age (greater than 80 years of age), while others, such as apixaban, require an adjustment when renal dysfunction is present in patients above a certain age threshold (Table 180.2).[10,11] Dosing regimens and recommendations for adjustment also differ based on indication. In addition, therapeutic

TABLE 180.2 Harmful Drug Interactions From Studies in Older Patients

Object Drug	Adverse Event	Comments
ACE inhibitor or ARB	Hyperkalemia	Avoid potassium sparing diuretics or TMP-SMX Apixaban Subtherapeutic, increased VTE risk Interacts with carbamazepine
Benzodiazepines and sedative-hypnotics	Fractures, falls	Interacts with macrolides and has additive effect with other CNS depressants
Calcium channel blockers	Hypotension	Interacts with macrolides
Digoxin	Toxicity	Interacts with macrolides Haloperidol Toxicity Interacts with Parkinson's treatments
Lithium	Toxicity	Interacts with diuretics, ACE inhibitors, and NSAIDs
Phenytoin	Toxicity	Interacts with TMP-SMX
Sulfonylureas	Hypoglycemia	Interacts with TMP-SMX, fluconazole, macrolides, and fluoroquinolones
Theophylline	Toxicity	Interacts with ciprofloxacin
Warfarin	Bleeding	Interacts with most antibiotics and antifungal agents. Increased risk with NSAIDs

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CNS,* central nervous system; *NSAID,* nonsteroidal antiinflammatory drug; *TMP-SMX,* trimethoprim-sulfamethoxazole.

drug monitoring is not routinely available for these agents, making it difficult to assess the degree of anticoagulation, further enhancing the need for nuance and attention to detail to ensure they are being used appropriately. The other primary anticoagulant used in the ED is intravenous heparin for acute coronary syndrome or venous thromboembolism. Patient age does not correlate with heparin dose requirements, so heparin dose adjustments are not required.

SPECIFIC DISORDERS

Polypharmacy and Drug Interactions

The term *polypharmacy* is used to describe the use of multiple medications. There is no standard definition or consensus regarding the number of medications that serves as a cut point for this term; however, the American College of Emergency Physician's Geriatric Emergency Department Guidelines and other experts consider five or more medications to constitute polypharmacy.[12] Older patients are particularly prone to polypharmacy because they have a greater number of comorbidities and conditions requiring treatment for medications. In one national estimate of community-residing older adults, close to one-third of the population took five or more medications, and approximately half also took over-the-counter medications and dietary supplements. Polypharmacy may result in adverse drug effects, drug interactions, and functional and cognitive impairment, and can lead to falls, resulting in injury.[13,14] An estimated 10% of ED visits by older adults may be attributed to an adverse drug-related event.

An important consequence of polypharmacy is drug interactions, which occur more commonly in older adults. A drug interaction occurs when there is an alteration in the effect of a drug due to the coadministration of another. The alteration could be the increase in effect, leading to toxicity, or a decrease in effect, resulting in therapeutic failure. The mechanism of interaction could be pharmacokinetic, which is primarily due to the inhibition or induction of drug-metabolizing enzymes such as the cytochrome P450 system or alterations in drug transporter activity. Alternatively, the interaction could be pharmacodynamic, in which the change in effect is unrelated to pharmacokinetic mechanisms. This primarily occurs due to the pharmacologic effects of drugs, which may be additive or antagonistic. For example, the use of a benzodiazepine with an antibiotic that inhibits its metabolism leading to an increased or prolonged effect would be a pharmacokinetic interaction, whereas the use of a benzodiazepine with an opioid, leading to additive central nervous system depression, would be a pharmacodynamic interaction.

There are thousands of possible drug-drug interactions, which increase exponentially with the number of medications that a patient is taking. The use of ED pharmacists may help to identify clinically relevant drug-drug interactions, particularly in patients with complex medication regimens. Clinical decision support systems integrated with electronic medical records may also provide a useful mechanism to reduce this risk; however, there are several challenges that need to be overcome in the ED setting so that providers can make the best possible decisions. The identification of an interaction is dependent on an accurate medication history, which is often difficult to obtain. Clinical decision support systems identify many drug interactions that are not clinically meaningful, leading to alert fatigue. It is estimated that providers override more than 96% of alerts, even when the interactions are significant.[15] Furthermore, most interactions are based on preclinical studies during drug development, have a theoretical basis, and often lack high-level evidence. This leads to discrepancies in major drug information systems, and there is no standard classification to guide decisions.

A prudent approach is to focus on the most common drug interactions that have been known to result in patient harm and that may be most applicable to the emergency clinician. Single doses of drugs administered within the monitored setting of the ED are less likely to lead to harm than those prescribed on discharge and used for several days. Adverse events can be narrowed down to several interactions that resulted in hospitalization from hyperkalemia, hypotension, fractures, hypoglycemia, bleeding, and specific drug toxicities. The object drugs involved in these interactions should serve as important flags to alert prescribers when giving a new medication (Table 180.3). Most of these adverse events are seen to occur when new antibiotics are prescribed. Thus, antibiotics prescribed to patients need to be considered carefully for potential interactions, especially when patients are taking a medication such as one mentioned earlier. However, there are many other high-risk medications, such as antidepressants, neuroleptics, and antiepileptics, that are also known to have several drug-drug interactions. Ideally, consultation with a pharmacist is helpful in identifying and determining the risk of potential drug interactions and modifying the therapeutic plan, if necessary.

Potentially Inappropriate Medications

Beers Criteria

In 1991, Beers and colleagues developed explicit criteria defining inappropriate medication use in older adults. They are now known as the Beers criteria and are periodically updated by the American Geriatrics Society.[5] At that time, it was observed that residents of skilled nursing

TABLE 180.3 Dose Adjustments for Direct Oral Anticoagulants (DOACs)

Drug	Indication	Adult Regimen	Recommended Dose Adjustments
Apixaban	Venous Thromboembolism or Pulmonary Embolism	10 mg bid × 7 days followed by 5 mg bid	None
	Non-Valvular Atrial Fibrillation	5 mg bid	2.5 mg bid if 2 of the following: age > 80 y, weight ≤ 60 kg, sCr > 1.5 mg/dL
Dabigatran	Venous Thromboembolism or Pulmonary Embolism	150 mg bid after at least 5 days of parenteral therapy	Patients ≥ 75 y: Use extreme caution and consider other options[a] Patients > 65 y: Use with caution CrCl 30–50 mL/min and P-glycoprotein inhibitor use: 75 mg bid CrCl avoid use
	Non-Valvular Atrial Fibrillation	150 mg bid	Patients ≥ 75 y: Use extreme caution and consider other options[a] CrCl 50–80 mL/min: Use caution due to increased drug exposure CrCl 30–50 mL/min: Adjust if significant drug interactions, use with caution in advanced age CrCl ≤30 mL/min: Avoid use
Edoxaban	Venous Thromboembolism or Pulmonary Embolism	After at least 5 days of parenteral therapy and CrCl < 95 mL/min : 60 mg daily	CrCl 15–50 mL/min OR age >65 AND weight <60 kg OR use of concomitant P-glycoprotein inhibitors: 30 mg daily CrCl < 15 mL/min: Avoid use
	Non-Valvular Atrial Fibrillation	CrCl < 95 mL/min: 60 mg daily	CrCl 15–50 mL/min: 30 mg daily CrCl < 15 mL/min: Avoid use
Rivaroxaban	Venous Thromboembolism or Pulmonary Embolism	15 mg bid with food × 21 days followed by 20 mg daily with food	CrCl <30 mL/min: Avoid use
	Non-Valvular Atrial Fibrillation	20 mg daily with food	CrCl 15–50 mL/min: 15 mg once daily CrCl < 15 mL/min: Avoid use

[a]Dabigatran has shown an increased risk of excessive anticoagulation leading to hemorrhagic complications, including fatalities, with increased age. DOACs should be avoided in all patients with moderate to severe hepatic impairment and nursing mothers.

facilities were prescribed eight medications on average; more than 50% of them received a psychoactive medication. The Beers criteria were applied to the older residents in nursing homes, representing the frailest of the population. Inappropriate medications were defined by an expert panel as those that should be avoided, except under unusual clinical circumstances. This was because of the lack of effectiveness, risks outweighing the benefits, or safer alternatives that were available. The criteria were developed so that they could be assessed from easily identifiable pharmacy records using minimal clinical data. This made it feasible for use for the quality improvement initiatives in skilled nursing facilities. The Beers criteria were subsequently updated so that they could be applied to all older patients, regardless of the place of residence. The most recent version from the American Geriatrics Society was developed by a 13-member panel with expertise in geriatric medicine, nursing, pharmacy, research, and quality measures.[5] Each criterion for medication or class includes a quality of evidence rating and strength of recommendation, serving as a valuable resource for clinicians involved in the care of older adults.

However, important questions remain regarding the applicability of the Beers criteria to practice in the ED. For example, promethazine is considered to be an inappropriate medication for older adults because of its anticholinergic and central nervous system effects, and avoiding this agent was given a strong recommendation based on high-quality evidence by the expert panel. Although the chronic effects of promethazine, such as drug-related falls, constipation, and dry mouth, are not of particular concern in the ED, promethazine-induced confusion or sedation may be problematic in patients presenting with altered mental status. A safer alternative for nausea or vomiting in this latter circumstance would be a 5-HT_3 receptor antagonist, such as ondansetron. However, ondansetron has been associated with QTc interval prolongation, which could be concerning in older patients who are already taking QTc-prolonging medications, leading to a potentially severe drug interaction. These nuanced therapeutic decisions require emergency clinicians to consider patient-specific parameters and realize that a "one size fits all" approach may not be appropriate.

Medications provided on discharge create another challenge. Although benzodiazepines appear on the Beers list, a single dose of a short-acting benzodiazepine used for procedural sedation in a controlled environment with monitoring and observation until the patient has returned to baseline is unlikely to cause long-term issues; however, medications prescribed on discharge must be more cautiously considered. Medications given to older patients on discharge should be prescribed for a limited duration until outpatient follow-up can be provided. In this setting, the Beers criteria may provide important guidance. For example, the Beers criteria expert panel has recommended that benzodiazepines should be avoided for the treatment of insomnia in older adults. This is because of the increased risk for cognitive impairment, delirium, falls, fractures, and motor vehicle collisions. Even short-term use of benzodiazepines after ED discharge could be associated with these adverse effects. In one randomized controlled trial, the use of a clinical decision support system in the ED was able to reduce the prescribing of potentially inappropriate medications in

TABLE 180.4 Most Common Beers List Medications Prescribed to Patients Discharged from the Emergency Department

Rank	Inappropriate Medication[a]
1	Promethazine
2	Diphenhydramine
3	Diazepam
4	Hydroxyzine
5	Amitriptyline
6	Cyclobenzaprine
7	Clonidine
8	Indomethacin

[a]Propoxyphene is not included because it is no longer available.

TABLE 180.5 Top 10 STOPP Criteria

Rank	Criteria
1	Long-term use of benzodiazepines
2	Duplicate prescriptions from the same drug class
3	Proton pump inhibitor for peptic ulcer disease at full dose for >8 wk
4	NSAIDs in patients with moderate to severe hypertension
5	Long-term use of opioids—first-line treatment for mild to moderate pain
6	Aspirin without adequate cardiovascular risk
7	Warfarin and NSAID used together
8	Beta blocker in patients with chronic obstructive pulmonary disease
9	Prolonged use of first-generation antihistamines
10	NSAID use in patients with chronic renal failure

NSAID, Nonsteroidal antiinflammatory drug; STOPP (Screening Tool of Older People's Potentially Inappropriate Prescriptions).

patients being discharged from the ED. Interestingly, the study targeted only a few medications, which accounted for 80% of the inappropriate medications prescribed on discharge. These medications, listed from the most to least commonly used, are in Table 180.4. Each institution should periodically evaluate trends in medications being prescribed and assessed for appropriateness because this can vary by center.

STOPP and START Criteria

In 2008, the STOPP (***S***creening ***T***ool of ***O***lder ***P***eople's Potentially Inappropriate ***P***rescriptions) and START (***S***creening ***T***ool to ***A***lert doctors to ***R***ight ***T***reatment) tools were developed and validated to build upon the Beers criteria and overcome some of their limitations. The Beers criteria account for only a small subset of medications that are prescribed inappropriately to older adults. In addition, many of the medications in the Beers criteria may not be available in European countries or are seldom prescribed. In the ED setting, these tools can be used to identify drug-related presentations, to determine if medications are suitable to be used in the ED during acute illness, and to guide medication prescribing on discharge. Even if a presentation is not drug-related, assessment in the ED is an opportunity to identify medications that may be problematic and lead to future admissions. In this regard, the STOPP screening tool was able to identify more elderly ED patients with potentially inappropriate medications than the Beers criteria (35% versus 25%). The STOPP-related medications also contributed to twice the number of admissions (12% versus 6%). The most recent version includes 80 STOPP and 34 START criteria.[16] The top 10 criteria that identified the most patients with inappropriate medications are listed in Table 180.5.

Anticoagulation and Bleeding

Oral anticoagulation use is common for age-related conditions such as atrial fibrillation. Warfarin has been used for several decades but is less than ideal because it has a narrow therapeutic range, routine laboratory monitoring is required, and numerous drug and food interactions lead to an unpredictable response, often resulting in hemorrhagic complications.

More recently, newer direct acting oral anticoagulants have become available that do not require routine laboratory monitoring and have fewer drug interactions and are not affected by diet. These include a direct thrombin inhibitor, dabigatran, and the factor Xa inhibitors rivaroxaban, apixaban, and edoxaban. High-quality randomized clinical trials of these direct oral anticoagulants (DOACs) have shown them to be equivalent or superior to warfarin with regard to stroke prevention and bleeding occurrence for patients in atrial fibrillation. A recent meta-analysis of these agents found that when used for atrial fibrillation in elderly patients, DOACs were associated with a lower risk thromboembolic events when compared to warfarin.[17] This analysis also found no difference in the rate of major bleeding events, a decreased risk of intracranial bleeding, hemorrhagic stroke, and fatal bleeding compared to warfarin, but were associated with a higher risk of gastrointestinal bleeding compared to warfarin. Current prescribing trends indicate that warfarin use is declining and the use of DOACs is on the rise both in the general population and specifically in older adults.[18,19]

One drawback of these agents is that they undergo renal elimination, and patients with severe renal impairment were excluded from major trials. Although several of these agents provide recommendations for dosing adjustments based on creatinine clearance, the fluctuating course of renal function in older adults during an acute illness may contribute to accumulation and bleeding. Furthermore, routine laboratory testing does not quantify the level of anticoagulation. For warfarin-induced bleeding, reversal is achieved when the international normalized ratio (INR) is less than 1.5. The new oral anticoagulants increase prothrombin time (PT), activated partial thromboplastin time (aPTT), and thrombin time, but these measures do not reliably estimate the level of anticoagulation and thus have limited ability to guide therapy. Laboratory parameters such as ecarin clotting time, diluted thrombin time, and chromogenic antifactor Xa assay may be useful; however, these tests are not widely available.

The most common major hemorrhagic complication resulting from anticoagulation is intracranial hemorrhage (ICH) following traumatic brain injury. While high-quality prospective research is lacking, recent studies suggest that patients receiving DOACs have worse outcomes and increased risk for delayed ICH following TBI.[20,21] Prompt reversal of anticoagulation is recommended in the setting of a life-threatening hemorrhage after careful evaluation of the thromboembolic risk of reversal in relation to the anticipated benefit of achieving hemorrhage control. There is limited evidence to guide anticoagulation reversal specifically in elderly patients; however, in general, reversal strategies used in younger adults are reasonable to use in elderly patients.

Neurologic Conditions

Altered mental status and delirium are common chief complaints among older patients presenting to the ED. Although there are many factors that can influence mental status, medication-related adverse effects are a common cause of altered mental status and delirium. Evaluation of a

patient presenting with altered mental status or delirium should include a thorough medication history, including prescription and nonprescription medications as well as over-the-counter nutritional supplements. Many of the medications are included on the Beers list are included due to their propensity for causing adverse neurologic effects. Medications with anticholinergic properties, benzodiazepines, sedatives, hypnotics, and opioids are commonly associated with delirium. Avoidance of anticholinergic agents in elderly patients was given a strong recommendation based on moderate- to high-quality evidence by the American Geriatrics Society.[5] There are numerous medications with anticholinergic effects, and toxicity is often due to a cumulative anticholinergic burden. Treatment begins with supportive care and nonpharmacologic measures, including discontinuation of the offending medications.

When nonpharmacologic measures have been unsuccessful and the patient is presenting a danger to themselves or others, pharmacologic management should be considered. Antipsychotic agents such as haloperidol or an atypical antipsychotic may be used. When used in older adults, lower starting doses are typically recommended (e.g., haloperidol doses of ≤5 mg IM [intramuscular] or IV) to reduce the risk of extrapyramidal symptoms.[22] Large doses of haloperidol given via the IV route have been associated with QTc interval prolongation, so monitoring of the electrocardiogram (ECG) is important, if feasible, especially if repeated doses are needed. Avoid haloperidol use in patients with Parkinson's due to increased risk of mortality. Use an intramuscular/intravenous atypical antipsychotic instead such as olanzapine or ziprasidone if one is needed.

There are certain, specific situations where short-term use of low-dose benzodiazepines may be considered for agitated delirium, including suspicion that the patient is withdrawing from alcohol or benzodiazepines or if the patient has comorbid conditions, such as Parkinson disease or QTc prolongation, that would preclude the use of an antipsychotic agent; however, there is weak to moderate-quality evidence that benzodiazepines may contribute to delirium, and they should generally be avoided in the elderly.[22]

There are also differences in the pharmacologic management of some key neurologic emergencies in older adults. In patients with community-acquired bacterial meningitis, the Infectious Disease Society of America has additional recommendations for older adults compared to young adults. In older adults, ampicillin is recommended in addition to the standard empirical regimen for coverage of *Listeria monocytogenes*. Thus, older patients should receive a triple regimen of vancomycin, ceftriaxone, and ampicillin. However, the cutoff value for age is 50 years rather than the traditional age definition. Similarly, there are differences in the eligibility criteria for thrombolytic therapy for ischemic stroke based on age. The American Heart Association guidelines on the management of ischemic stroke allow for extending the time window for the provision of thrombolysis from 3 to 4.5 hours after onset of symptoms in select patients.[23] This recommendation incorporates the exclusion criteria utilized in the primary trial showing benefit from this approach. The ECASS-3 trial excluded patients older than 80 years, and as a result, while extending the time window to 4.5 hours in patients over 80 years old is still recommended, it is given a lower level recommendation compared to younger patients.

Analgesia

In a national survey of US EDs, geriatric patients with pain-related complaints were less likely to receive any analgesics than young adults.[24] The risk for poor pain management in older adults is multifactorial and increases with logistic constraints, such as ED crowding. Pain perception and susceptibility to adverse drug effects of analgesics is also different in older patients. Dosing of opioids should be cautious and monitoring for respiratory depression needs to be vigilant. It is difficult to anticipate how much opioid would be required for pain control in the ED. Instead of large single doses, a lower dose with titration consistent with pharmacokinetic and pharmacodynamic characteristics of the opioid is ideal. For example, morphine and hydromorphone have their peak analgesic effect at approximately 15 minutes. Thus, redosing every 1 to 2 hours is an unnecessarily long time and leads to suboptimal pain control. One strategy that has been successfully used in older patients for severe pain in the ED is a two-step hydromorphone protocol.[25] Patients are given 0.5 mg IV hydromorphone, which is repeated in 15 minutes if the patient desires another dose when asked, "Do you want more pain medication?" However, previous opioid exposure needs to be considered to determine appropriate dosing. For example, in some older cancer patients with chronic opioid consumption, doses will likely need to be escalated for pain control.

Meperidine use should be avoided in older patients. It has a neurotoxic metabolite that accumulates with renal impairment common in these patients. Given the availability of alternative opioids, there is little reason to use this medication in the ED, and it is also listed on the Beers criteria.

Regional anesthetics, such as fascia iliaca compartment blocks in patients with hip fractures, have been shown to reduce opioid requirements and should be considered, particularly in older patients, when feasible.[26] Other strategies, such as hematoma blocks and intra-articular steroid injections, should be considered to minimize systemic analgesics when appropriate.

Ketorolac is a valuable alternative to opioids in the ED, and single doses have been shown to be as effective as opioids for pain related to certain indications, such as renal or gallbladder stones. However, it is a potent nonsteroidal antiinflammatory drug (NSAID) with the possibility of causing renal failure or gastrointestinal hemorrhage. This is less likely to occur with isolated doses in the ED setting. Nonetheless, studies have demonstrated similar analgesic effects from ketorolac doses of 10 mg, 15 mg, and 30 mg, indicating a ceiling effect.[27] To minimize the possibility of adverse effects, doses over 10 mg are not recommended, particularly in older adults. Despite lacking antiinflammatory effects, IV acetaminophen has been shown to provide similar pain control compared to IV ketorolac in a heterogenous prehospital population that included older patients.[28] Acetaminophen is a reasonable alternative to NSAIDs in select patients; however, in most health systems, only oral and rectal acetaminophen are readily available. Studies in the perioperative and postoperative settings have failed to show a significant difference in pain reduction or opioid sparing effects between IV and oral acetaminophen leading many health systems to restrict the use of IV acetaminophen given the relatively high cost of the parenteral dosage form.[29]

Clinical Pharmacy Services

There are a growing number of institutions that have pharmacists who practice in the ED. The American College of Emergency Physicians (ACEP) has a policy statement advocating for dedicated pharmacy services to be provided to the ED to promote safe, efficient, and effective medication use in the emergency department.[30] In geriatric EDs, there is a great opportunity to integrate pharmacists, given the myriad drug therapy issues that can lead to suboptimal care.[12] Older adults have more medications prescribed, which increases the risk for medication errors.[31] Pharmacists are able to intercept these errors, preventing patient harm. Given the possibility of drug-induced admissions, pharmacy services can be used to identify medications that may have contributed to an ED presentation. However, resource constraints make it difficult for pharmacists to evaluate each geriatric patient, especially in EDs with large bed capacities.

Obtaining an accurate medication list is necessary for determining the cause of an adverse effect, but this often requires phone calls to

multiple pharmacies and physicians' offices. One option is the use of pharmacy technicians who are also able to perform this function with similar accuracy.[32] Patients can also be referred to the pharmacist based on variables that have been associated with adverse drug events.[33] One clinical decision rule was able to identify 91.3% of patients with adverse drug events by limiting referral of less than half of patients to a pharmacist so that a full review could be conducted. This decision rule is shown in Fig. 180.1.

Even if the presentation is unrelated to an adverse drug event, clinical pharmacists can be used to identify potentially inappropriate therapies that the patient is taking to minimize the possibility for readmissions. For example, it is possible that a patient may be taking two medications from the same drug class prescribed by two different physicians. Applying the Beers, START, and STOPP criteria, the anticholinergic burden and other opportunities for drug therapy optimization can be assessed. Finally, pharmacists serve as an important safety net for drug therapy prescribed by ED clinicians, both within the ED and on discharge. Setting up a system whereby the pharmacist can be consulted and is available to review these medication orders for potential harm is a risk mitigation strategy that may help reduce readmissions by older adults.

CHAPTER 180: QUESTIONS AND ANSWERS

1. Which of the following pharmacokinetic change in older adults is associated with increased plasma concentration of drug?

- **a.** Decrease in absorptive capacity in an orally administered medication
- **b.** Decreased glomerular filtration rate in a renally eliminated medication
- **c.** Increase in gastric pH in a medication that is a weak base
- **d.** Increased liver blood flow in a high–extraction ratio medication
- **e.** Increased total body water in hydrophilic medications

Answer: B. Decrease in glomerular filtration rate is common with age. This leads to decreased elimination and increased plasma concentration of a drug. All other options listed would lead to decreased plasma drug concentrations. Liver blood flow, glomerular filtration rate, total body water, and absorptive capacity decrease with age. However, gastric pH increases.

2. Which of the following is the most appropriate strategy for analgesic provision in an older patient with renal insufficiency and severe abdominal pain in the emergency department?

- **a.** Hydromorphone 0.5 mg IV, followed by the same dose in 15 minutes, if needed
- **b.** Ketorolac, 30 mg IV qid
- **c.** Meperidine, 50 μg IV every 2 hours
- **d.** Morphine, 4 mg IV every 2 hours
- **e.** Oxycodone/acetaminophen, 5/235 mg orally every 2–4 hours

CHAPTER 180: QUESTIONS AND ANSWERS—cont'd

Answer: A. One strategy that has been used successfully in older adults is a two-step hydromorphone protocol. Patients are given 0.5 mg IV hydromorphone, which is repeated in 15 minutes if the patient desires another dose when asked, "Do you want more pain medication?" Hydromorphone does not have active metabolites that would accumulate with renal insufficiency, so it would be an appropriate option for severe pain. Ketorolac should be avoided in older adults with renal insufficiency because the inhibition of prostaglandins can decrease renal blood flow. Meperidine use is no longer recommended because of a neurotoxic metabolite and accumulation in renal insufficiency. Morphine has an active metabolite that also accumulates in renal insufficiency. Oxycodone-acetaminophen given orally is not appropriate for severe acute pain due to delayed onset of effect. Bioavailability of oral medications may further be delayed in older adults.

3. Which of the following agents should be avoided for outpatient use in an older patient being discharged from the emergency department?
   - **a.** Diphenhydramine
   - **b.** Loratadine
   - **c.** Acetaminophen
   - **d.** Clindamycin
   - **e.** Metronidazole

Answer: A. Diphenhydramine and other first-generation antihistamines should be avoided in older patients given the potential for anticholinergic toxicity. The use of diphenhydramine in the emergency department for severe allergic reactions is appropriate; however, longer term outpatient use is not recommended. This effect is much less common with second-generation antihistamines such as loratadine. Acetaminophen is generally considered safe in older patients. Antibiotics such as clindamycin and metronidazole have the potential to cause drug-drug interactions with other home medications; however, by themselves they are not typically problematic.

4. Which of the following medications prescribed on discharge is most likely to interact in an older patient taking warfarin?
   - **a.** Albuterol inhaler for asthma
   - **b.** Ciprofloxacin for urinary tract infection
   - **c.** Insulin NPH for hyperglycemia
   - **d.** Oxycodone for fracture pain
   - **e.** Promethazine for nausea

Answer: B. Studies of harmful drug interactions in older adults have shown that the initiation of antibiotics in patients taking warfarin can lead to bleeding. Ciprofloxacin can lead to an elevation in the international normalized ratio (INR) due to disruption of vitamin K synthesis in patients taking warfarin. Thus, more frequent monitoring is required when ciprofloxacin is initiated. The other options listed do not interact with warfarin. However, oxycodone and promethazine can be harmful because of central nervous system effects, potentially leading to falls.

5. Which of the following statements is true regarding neurologic emergencies in older adults?
   - **a.** Ampicillin is added for the treatment of bacterial meningitis for additional coverage against *Enterococcus faecalis.*
   - **b.** Anticholinergic medication use is not associated with delirium.
   - **c.** Haloperidol, 10 mg IV, is recommended for acute agitation due to underlying psychiatric illness.
   - **d.** In patients with ischemic stroke who are older than 80 years, alteplase should not be administered if the patient presents 4 hours after the onset of symptoms, according to guidelines.
   - **e.** Large doses of haloperidol given via the IV route have been associated with QTc interval prolongation

Answer: E. There is a US Food and Drug Administration (FDA) black box warning regarding the use of haloperidol and QTc interval prolongation. This risk is increased with large doses given intravenously. Polypharmacy in older adults also puts them at risk for drug interactions due to concomitant QTc-prolonging agents. Doses of haloperidol should be less than 5 mg in most older adults. Ampicillin is added for bacterial meningitis to cover *Listeria monocytogenes.* Although recent evidence has extended the 3-hour time window to 4.5 hours for receiving alteplase after the onset of stroke in a small subset of patients, those older than 80 years are not eligible, according to guidelines. Anticholinergic medications are known to be associated with delirium and sedation.

Geriatric Abuse and Neglect

Tony Rosen

KEY CONCEPTS

- Elder mistreatment, which includes physical abuse, sexual abuse, neglect, emotional/psychological abuse, abandonment, financial/material exploitation, and self-neglect, is common and may have serious medical and social consequences.
- Elder mistreatment is under-recognized by emergency clinicians and under-reported to the authorities.
- Signs suggestive of potential elder abuse and neglect that should be recognized by emergency clinicians may exist in the medical history, physical examination, and medical/laboratory markers.
- Emergency clinicians should be vigilant in assessing for the possibility of elder abuse or neglect and routinely ask elderly patients about mistreatment, even in the absence of signs and symptoms. Screening protocols may be helpful.
- Using a team-based approach including social workers and other emergency department (ED)-based professionals may improve elder abuse detection, and Emergency Medical Services can play a critical role.
- ED management of elder abuse should include the following: treating acute medical and psychological issues, ensuring patient safety, and proper reporting to the authorities. Trauma-informed care should be provided.
- Emergency clinicians should hospitalize elderly patients who are in immediate danger or implement a care plan that prevents them from having any contact with the suspected abuser(s) but must respect the wishes of an older adult with decision-making capacity who refuses interventions and desires to return to an abusive situation. Trauma-informed care should be provided.
- Emergency clinicians should document completely and accurately the history and all physical findings in cases of suspected elder abuse or neglect, as this documentation may be critical to ensure justice for the victim.

FOUNDATIONS

Background

An ED encounter offers an important opportunity to identify and initiate intervention for elder abuse and neglect, a common but under-recognized phenomenon that may have serious medical and social consequences. Elder abuse and neglect includes: any actions or negligence that may cause harm or risk of harm committed by someone in a relationship of trust or when the victim is targeted due to age or disability, Table 181.1. Many victims may suffer concurrently from multiple types of abuse.

Epidemiology and Scope of the Problem

As many as 10% of older adults living in the community and more than 20% of nursing home residents experience some form of abuse, neglect, or exploitation each year. Psychological/emotional abuse, financial mistreatment, and neglect are most commonly reported, while physical and sexual abuse are less common. Elder abuse is strongly associated with adverse health outcomes, including depression, exacerbations of chronic illness, and dramatically increased mortality. Older adults suffering abuse are more likely to present to the ED, be hospitalized, and be placed in a nursing home. The direct medical costs of elder abuse and neglect, though challenging to quantify, are estimated to be many billions of dollars annually and growing as the geriatric population continues to increase.

Despite its frequency and potential for harm, elder abuse and neglect is under-recognized and under-reported, with many sufferers enduring it for years before discovery. Studies suggest that as few as 1 in 24 cases of elder abuse is reported to the authorities, and much of the associated morbidity and mortality is likely due to delay in identification and intervention.

Many factors contribute to elder abuse and neglect (Table 181.2), and researchers have attempted to identify risk factors for becoming a victim or perpetrator. Findings have been inconsistent and difficult to interpret, partly due to methodological limitations, and to the heterogeneity of elder mistreatment cases. Potential risk factors for becoming a victim or perpetrator based on existing evidence are described in Box 181.1. Cognitively impaired older adults are more likely to be victimized. Sub-populations including military veterans and lesbian/gay/bisexual/transgender older adults may be at particularly high risk. Many cases of elder mistreatment occur in the absence of risk factors, however, and the phenomenon crosses ethnic and socioeconomic boundaries.

Identifying Elder Abuse and Neglect in the Emergency Department

The ED visit provides an opportunity to identify elder abuse or neglect. For many older adults, assessment by health care providers is their only contact outside the family. Limited research suggests that elder abuse and neglect victims are less likely to see a primary care provider but receive ED care more frequently than other older adults,[1] often for management of acute illnesses or injuries. A recent study found that 7% of cognitively intact older ED patients reported a history of physical or psychological mistreatment during the previous year.[2] The actual prevalence is likely much higher, as abuse is more common among cognitively impaired older adults, and because neglect and financial exploitation were not included.

TABLE 181.1 Types of Elder Abuse and Neglect

Type	Definition	Examples
Physical abuse	Intentional use of physical force that may result in bodily injury, physical pain, or impairment	• Slapping, hitting, kicking, pushing, pulling hair • Use of physical restraints, force-feeding • Burning, use of household objects as weapons, use of firearms and knives
Sexual abuse	Any type of sexual contact with an elderly person that is non-consensual or sexual contact with any person incapable of giving consent	• Sexual assault or battery, such as rape, sodomy, coerced nudity, and sexually explicit photographing • Unwanted touching, verbal sexual advances • Indecent exposure
Neglect	Refusal or failure to fulfill any part of a person's obligations or duties to an elder, which may result in harm—may be intentional or unintentional	• Withholding of food, water, clothing, shelter, medications • Failure to ensure elder's personal hygiene or to provide physical aids, including walker, cane, glasses, hearing aids, dentures • Failure to ensure elder's personal safety and/or appropriate medical follow-up
Emotional/ psychological abuse	Intentional infliction of anguish, pain, or distress through verbal or nonverbal acts	• Verbal berating, harassment, or intimidation • Threats of punishment or deprivation • Treating the older person like an infant • Isolating the older person from others
Abandonment	Desertion of an elderly person by an individual who has assumed responsibility for providing care for an elder or by a person with physical custody	
Financial/material exploitation	Illegal or improper use of an older adult's money, property, or assets	• Stealing money or belongings • Cashing an older adult's checks without permission and/or forging his or her signature • Coercing an older adult into signing contracts, changing a will, or assigning durable power of attorney against his or her wishes or when the older adult does not possess the mental capacity to do so
Self-neglect	Behavior of an older adult that threatens his/her own health or safety—excluding when an older adult who understands the consequences of his or her actions makes a conscious and voluntary decision to engage in acts that threaten his/her health or safety	• Refusal or failure of an older adult to provide himself or herself with basic necessities such as food, water, shelter, medications, and appropriate personal hygiene • Disregard for maintenance of safe home environment and/or hoarding

Adapted from National Center on Elder Abuse: Types of abuse. Available at https://ncea.acl.gov/Suspect-Abuse/Abuse-Types.aspx.

TABLE 181.2 Selected Theories of the Underlying Causes of Elder Abuse and Neglect

Theory	Description
Transgenerational violence	Family violence is a learned behavior, and abused children grow up to potentially abuse not only their own children but also perhaps parents
Psychopathology of the abuser	Mental health issues of the abuser, including personality disorders, poorly treated mood disorders or schizophrenia, alcoholism, and other substance abuse problems, lead to abusive behavior
Dependency	Increasing frailty, including functional and cognitive disability, result in overwhelming care needs that leave an older adult vulnerable to abuse by an overburdened caregiver
Stressed caregiver	A caregiver who has become increasingly stressed (from caregiving or other causes) may be more likely to be abusive
Isolation	Greater social isolation due to disability, illness, and age increases an older adult's vulnerability to abuse or neglect

Adapted from: Jones JS, Holstege C, Holstege H. Elder abuse and neglect: understanding the causes and potential risk factors. *Am J Emerg Med*. 1997;15:579-583.

Additionally, the nature of an ED encounter increases the potential for detection, as an older adult is typically assessed over several hours by multiple providers.

Despite the opportunity, emergency clinicians seldom identify and report elder abuse and neglect. Several reasons exist for this missed opportunity, including inadequate training, difficulty distinguishing between intentional and unintentional injuries, lack of time to conduct a thorough evaluation for abuse, concern about involvement in the legal system, a victim's unwillingness to report, and a victim's inability to report due to cognitive impairment. For the health of our patients, it is critical that all emergency care providers embrace the challenge of identifying and initiating care for victims of elder abuse and neglect.

CLINICAL FEATURES

Observation and Medical History

When initially assessing an older adult with a caregiver present, carefully observe their interaction, identifying any clues of a strained relationship. Observations that increase suspicion for elder abuse or neglect are listed in Box 181.2.

History should be taken from the patient in as private a setting as possible, without caregivers or family present. The patient should be assured of privacy and confidentiality since victims may be reluctant to

BOX 181.1 Potential Risk Factors for Elder Abuse

For Becoming a Victim

Functional dependence or disability
Poor physical health
Cognitive impairment/dementia
Poor mental health
Low income/socioeconomic status
Social isolation/low social support
Previous history of family violence
Previous traumatic event exposure
Substance abuse

For Becoming a Perpetrator

Mental illness
Substance abuse
Caregiver stress
Previous history of family violence
Financial dependence on older adult

BOX 181.2 Observations from Interaction Between Older Adult and Caregiver That Should Raise Concern for Elder Abuse or Neglect

Older adult and caregiver provide conflicting accounts of events
Caregiver interrupts/answers for the older adult
Older adult seems fearful of or hostile towards caregiver
Caregiver appears unengaged/inattentive in caring for the older adult
Caregiver appear frustrated, tired, angry, or burdened by the older adult
Caregiver appears overwhelmed by the older adult
Caregiver appears to lack knowledge of the patient's care needs
Evidence that the caregiver and/or older adult may be abusing alcohol or illicit drugs

disclose due to a desire to protect the abuser (often a spouse or child), dependency on the caregiver, shame, cultural or ethnic beliefs, or a fear of reprisal or institutionalization. If a translator is needed, a professional translator or telephone/virtual translation service should be provided. A family member or the caregiver should not be used as an interpreter even if they are not suspected to be an abuser.

The assessment for elder mistreatment should be incorporated into the routine evaluation. Potential historical indicators of elder mistreatment are listed in Box 181.3. The emergency clinician may ask in detail about the reason for the visit and then inquire about the patient's health in general, focusing on the safety of the home environment, functional status, cognition, need for support or assistance, and any feelings of isolation and depression. Box 181.4 suggests potential questions to assess for abuse. If the older adult is presenting with an injury, the

BOX 181.3 Indicators from the Medical History of Possible Elder Mistreatment

Poor living conditions according to paramedics or others
Unexplained injuries
Past history of frequent injuries
Delay between onset of medical illness or injury and seeking of medical attention
Recurrent visits to the ED for similar injuries
Using multiple physicians and EDs for care rather than one primary care physician ("doctor hopping or shopping")
Noncompliance with medications, appointments, or physician directions
Patient or caregiver reluctant to answer questions
Strained patient/caregiver interaction
Inconsistent history of injury mechanism between the patient and caregiver
Elderly patient referred to as "accident prone"
Caregiver not able to give details of the patient's medical history or routine medications
Caregiver answers the questions regarding the patient
Abandonment of the patient in the ED by the caregiver

ED, Emergency department.

patient should be questioned about how the injury occurred, including directed questions regarding whether anyone has hit, punched, pushed, tripped, or kicked the patient. The evaluation should also include an assessment for behavioral signs and symptoms suggestive of potential elder mistreatment, including fear, anxiety, poor eye contact, low self-esteem, and helplessness.

Unfortunately, obtaining a reliable history from victims of elder abuse and neglect is often difficult. Many older adults have cognitive impairment that prevents them from providing an accurate medical history. Even in these cases, an attempt should be made to interview the patient, in that recent research suggests that older adults with cognitive impairment can reliably report abuse.[3] Whenever an older adult is unable to provide a history, information should be sought from others besides the caregiver such as other family members, the primary care physician, neighbors, or visiting nurses.

A separate interview of the caregiver or suspected abuser is often useful. It may reveal discrepancies from the patient's history. In addition, a caregiver who is unfamiliar with an older adult's routine medications and necessary medical care may be neglecting them. The interview should be conducted in a nonthreatening and nonjudgmental manner. Verbal expressions of sympathy, explicit recognition of the challenges, and demonstrations of support can be beneficial for the caregiver and also promote information sharing. Questions should also explore whether any important changes or recent stresses have occurred in the household, whether the caregiver feels that the patient is a burden, the caregiver's other dependents and responsibilities, and whether any respite services or other home help services have been made available.

Physical Examination

Physical examination should include a thorough exam for signs of injury and abuse, including identification of bruising peritoneal injury. Additional attention should be given to the skin and intra-oral exam. Geriatric patients with multiple suspicious physical findings may be more likely to be victims of elder abuse or neglect than those with isolated findings.

When an older adult presents with an acute injury (such as a fall), consider whether the reported mechanism is consistent with the injuries suffered. Research has begun to systematically explore

BOX 181.4 Questions for Use in Asking Patients About Elder Abuse

Please explore any positive responses in more detail.
In the last 6 months:

Physical Abuse	Has anyone tried to harm you? Have you been hit, slapped, pushed, grabbed, strangled, or kicked? Are there guns or other weapons in your home? Does anyone close to you have access to guns or other weapons?
Sexual Abuse	Has anyone touched you in ways or places you did not want to be touched?
Neglect/Functional Status	Have you relied on people for any of the following: bathing, dressing, shopping, banking, or meals? a. If yes, have you had someone who helps you with this? b. If yes, how often do you receive help? Is this help enough? c. Have they done a good job? Are they reliable? d. What happens if no one is available to help? Has anyone prevented you from getting food, clothes, medication, glasses, hearing aids, medical care, or anything else you need to stay healthy?
Psychological Abuse	Has anyone close to you called you names, put you down, or yelled at you? Has anyone close to you ever threatened to punish you or put you in an institution? Have you felt sad or lonely at home? Have you felt afraid of anyone close to you? Do you distrust anyone close to you? Does anyone close to you drink or use drugs?
Financial Exploitation	Has anyone tried to force you to sign papers against your will, or that you did not understand? a. Has anyone pressured you to give them money or property? Has anyone taken money or things that belong to you without asking? Does anyone close to you rely on you for housing and/or financial support?

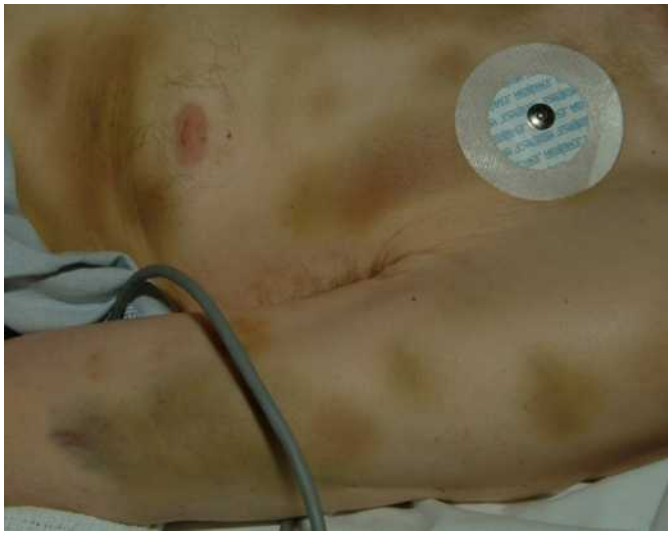

Fig. 181.1 Atypical bruising of the chest in a case of substantiated abuse. (From: Gibbs LM. Understanding the medical markers of elder abuse and neglect: physical examination findings. Clin Geriatr Med. 2014;30:687-712.)

Fig. 181.2 Pattern bruise on the left buttock from unknown object. (From: Gibbs LM. Understanding the medical markers of elder abuse and neglect: physical examination findings. Clin Geriatr Med. 2014;30:687-712.)

whether injury patterns exist that are suggestive of, or specific for, elder mistreatment (analogous to findings in child abuse, such as shaken infant syndrome and bucket-handle metaphyseal fracture). Unfortunately, it can be difficult to distinguish between elder mistreatment and the sequelae of unintentional trauma or medical illness. This difficulty may be due to normal physiologic changes that occur with aging, such as osteopenia, thinning of the skin with easy bruising, as well as the impact of medications commonly used, including anticoagulants. Studies have found that abuse victims, in comparison to other older adults, have bruises that were more often large (>5 cm) and on the face, lateral right arm, or posterior torso.[1] Physical abuse and assault-related injuries most commonly occur on the head/face, neck, and upper extremities[4] (Fig. 181.1). Abuse victims are more likely than older adults presenting to the ED with a fall to have injuries to the left cheek/zygoma, with neck and ear injuries occurring commonly in abuse victims but generally not after a fall. Additionally, physical elder abuse victims are more likely to have maxillofacial/dental/neck injuries combined with no upper and lower extremity injuries, suggesting that the simultaneous presence and absence of injuries may be helpful in differentiating intentional from unintentional injuries in older adults.[4] Patterned injuries, wrist or ankle lesions suggesting possible inappropriate restraint, burns suggesting immersion injury or cigarette burns, or fractures of different ages should suggest elder physical abuse (Figs. 181.2 to 181.5). These and other findings may be used to develop clinical prediction rules in the future to assist ED providers in identifying injury patterns suspicious for abuse.

Sexual assault of older adults occurs, is underrecognized, and should be considered. Perineal injury should illicit concern for sexual assault in the elderly and should prompt reporting (Figs. 181.6 to 181.7). If sexual abuse is suspected or reported, a complete sexual assault examination is recommended.

Fig. 181.3 Pattern bruising on lower leg from a ligature. (From: Gibbs LM. Understanding the medical markers of elder abuse and neglect: physical examination findings. Clin Geriatr Med. 2014;30:687-712.)

Fig. 181.4 Burn injuries on the back and buttocks from scalding water. (From: Gibbs LM. Understanding the medical markers of elder abuse and neglect: physical examination findings. Clin Geriatr Med. 2014;30:687-712.)

Neglect needs to be considered when the elder in the care of others shows signs of poor care such as poor hygiene, advanced pressure ulcers, advanced medical disease that may have responded to early intervention, and neglected dental disease (Figs. 181.8 to 181.11).

DIAGNOSTIC TESTING

No laboratory tests exist to definitively detect abuse, but medical and laboratory findings may suggest elder mistreatment. These include biomarkers of malnutrition, dehydration, anemia, hypothermia/hyperthermia, and rhabdomyolysis. In addition, serum or urine drug levels may provide clues to medication by a caregiver. Perpetrators may divert controlled substances, such as narcotic pain medications, for their own use or to sell. Elevated serum levels of prescription medications may suggest intentional or unintentional overdose, and the presence of toxins or drugs that have not been prescribed may indicate poisoning. Platelet count and coagulation studies may be helpful in ruling out a medical etiology for unexplained or abnormal bruising. Evidence of sexually transmitted diseases in an older adult not known to be sexually active may suggest sexual abuse.

Fig. 181.5 A 70-year-old man was brought from his caregiver's home to the emergency department (ED) by police after his daughter found him severely bruised. He had multiple contusions at varying stages of healing on his chest and arms, as well as a linear patterned injury across his left anterior chest. The central and bilateral locations of the contusions, varying colors, and linear pattern of the bruise on the left side of his chest are highly suggestive of physical abuse. (Courtesy Dr. D.C. Homeier.)

Fig. 181.6 A 65-year-old woman in a nursing home with posterior fourchette and perineum laceration from rape by resident. (From: Speck PM, Hartig MT, Likes W, et al. Case series of sexual assault in older persons. Clin Geriatr Med. 2014;30:779-806.)

Diagnostic Imaging

Unlike child abuse, there is very limited literature on imaging correlates for elder abuse, and diagnostic radiologists typically receive no formal training in elder abuse detection. Findings suggestive of elder abuse or neglect include co-occurring old and new fractures, high-energy fractures despite low-energy mechanism, distal ulnar diaphyseal fractures, and small bowel hematomas. Any concern for elder abuse should be verbally communicated to the radiologist reading the images with a request that they consider whether the imaging findings are consistent with the purported history. They may also consider additional screening imaging tests, such as maxillofacial CT scan and chest x-ray, analogous to the skeletal survey used in child abuse to assess for occult acute and chronic fractures.

Screening

Though ED screening often consists of a single question about home safety, it is generally accepted that this is inadequate and represents a

Fig. 181.7 A 69-year-old woman with severe dementia who resided in a skilled nursing facility was brought to the emergency department (ED) after her daughter noticed that the patient had bruises on her bilateral inner thighs. When the daughter inquired about the bruises, she was told by the facility staff that the patient had fallen. These bruises are in a location that raises suspicion for sexual abuse. The emergency clinician consulted the hospital's adult protection team, which contacted local law enforcement; the long-term care ombudsman was also notified for further investigation. The hospital's sexual assault response team was consulted and conducted a sexual assault forensic examination for evidence collection. (Courtesy Dr. D.C. Homeier.)

Fig. 181.8 Case of elder neglect showing moisture-associated skin damage (MASD) and ulcers in the sacrum, buttocks, and thighs. (From: Gibbs LM. Understanding the medical markers of elder abuse and neglect: physical examination findings. Clin Geriatr Med. 2014;30:687-712.)

missed opportunity. Multiple more robust screening tools have been developed, though none have yet been validated for use in the ED. The Elder Abuse Suspicion Index (EASI) is a short tool validated for cognitively intact patients in ambulatory care and may be appropriate for use in the ED. The ED Senior AID (Abuse Identification) tool is a promising recently developed ED-specific screening tool that is highly sensitive and specific and is currently undergoing multi-site validation.[5]

The American Medical Association, the American College of Emergency Physicians, and the Joint Commission have strongly supported routine assessment for all types of family violence, including elder mistreatment, but their choice of words has stopped short of recommending universal screening. Additionally, though screening for elder abuse has the potential to identify occult cases so that intervention may be

Fig. 181.9 A 65-year-old developmentally delayed but ambulatory woman was brought to the emergency department (ED) by her family on account of "unruly behavior." Examination of her left heel revealed a pressure ulcer, and her left ankle revealed an erythematous rash in a circumferential pattern. This may represent the use of a restraint, resulting in the pressure ulcer. (Courtesy Dr. D.C. Homeier.)

initiated, evidence of improved outcomes to support screening for elder mistreatment does not yet exist. The US Preventative Services Task has not recommended screening for elder abuse in health care settings.[6]

Targeted screening of only high-risk patients may be a desirable alternative to universal screening, reducing resources that need to be devoted to the screening process and increasing the proportion of patients who screen positive. High-yield demographic factors have yet to be identified. Future strategies may use data elements from the electronic health record or other health care utilization data combined with machine learning approaches to perform automated prescreening to identify high-risk patients.

MANAGEMENT

A multidisciplinary team-based approach is required to improve the recognition and management of elderly mistreatment. Key to success is empowering all members of the team to share observations and recommendations in a safe context. Large EDs typically have social workers or case managers in the department, while smaller EDs usually have access to them in the hospital or on-call. These professionals assess the patient's home situation, support system, financial resources, and social service needs, and also provide counseling. Their assessment may identify evidence or risks for mistreatment that is not detected by medical providers. If possible, dependent older adult ED patients being considered for discharge and any patient for whom a concern about elder abuse or neglect exists should be seen by a social worker or case manager. The Emergency Department Elder Mistreatment Assessment Tool for Social Workers (ED-EMATS), a structured assessment tool for ED social workers who have less experience evaluating patients for elder mistreatment, was recently developed.[7]

Nurses and patient care technologists (PCTs) are also instrumental members of the team since they have more face-to-face contact with patients, caregivers, and family than medical providers and may observe interactions that arouse suspicion requiring further investigation. Also, nurses and PCTs provide personal care (e.g., diaper changes) that may identify otherwise missed suspicious physical findings. Patient escort and radiology technicians are yet other personnel who may be confided in by the patient: Radiologic technicians may be particularly well-positioned to identify abuse, as they can privately assess and interview patients in the radiology suite while conducting imaging examinations.

Emergency Medical Services

Older adults are four times more likely than younger patients to use EMS, and these providers are the first clinicians to evaluate acutely

Fig. 181.10 A 72-year-old woman was brought to the emergency department (ED) by paramedics for "not eating for 5 days" according to her family. The paramedics noted she was covered in urine and feces. The following signs were of concern for neglect: elongated toenails (A), pressure sores (B), poor hygiene, and a delay in seeking medical care. (Courtesy Dr. D.C. Homeier.)

Fig. 181.11 Poor dentition in a substantiated case of dependent adult neglect. (From: Gibbs LM. Understanding the medical markers of elder abuse and neglect: physical examination findings. Clin Geriatr Med. 2014;30:687-712.)

injured or ill older adults, typically in the patient's home. EMS providers can identify unmarked medication bottles or expired medications, as well as multiple bottles of a single medication. They can check whether any food is available in the refrigerator or pantry. EMS providers have an opportunity to observe hazards including vermin infestation, extreme clutter/hoarding, inappropriately hot or cold temperature, or utilities that aren't working. Given that EMS activation is usually unplanned, an abusive or neglectful caregiver is often not able to clean up the patient or home before EMS arrives. EMS providers may observe unusual or inappropriate interpersonal dynamics between caregivers and older adults as well as evidence of drug or alcohol use. Further, EMS may provide care to older adult patients who decline ED transport.

The Detection of Elder Abuse Through Emergency Care Technicians (DETECT) screening tool has recently been developed and has been shown to be feasible for EMS providers to integrate into their practice.[8] As EMS practice is heavily protocolized, changes to improve elder abuse and neglect detection could be implemented broadly through changes at a system level. Hopefully, use of integrated electronic medical records and the development of standardized screening tools and protocols, will facilitate increased detection of elderly mistreatment by EMS and communication with hospital providers.

Management of suspected elder abuse or neglect includes treating acute medical and psychological issues, ensuring patient safety, and proper reporting to the authorities. Traumatic injuries and metabolic abnormalities including dehydration are common and should be stabilized and treated. Management of worsening chronic medical conditions may be required due to an abuser's failure to provide appropriate care. In some circumstances, hospitalization may be necessary to provide extended treatment and observation.

If a mistreatment victim is in immediate danger, the patient should be prevented from having any contact with the suspected abuser. In extreme cases, this may require a security watch for the patient and even having the abuser removed from the ED. In these cases, law enforcement, hospital social workers, and administrators should be alerted. Alternative living arrangements may need to be arranged for the patient, with a reliable family member or friend or in an appropriate emergency shelter. If none of these options are available, the patient may require hospital admission to ensure safety.

If the patient refuses intervention, a determination must be made whether the patient has the capacity to make this decision. A psychiatric consultation may be helpful. The wishes of an older adult with decision-making capacity who desires to return to an abusive situation must be respected, as in cases of intimate partner violence among younger adults. If possible, the patient should be educated about the potential for escalation in violence and abuse and provide appropriate referral materials for future use. If an older adult does not have decision-making capacity, treatments that are in the patient's best interest, including hospitalization, should be provided.

In some cases, a patient may not have decision-making capacity, and the suspected abuser may be the patient's official health care proxy

or power of attorney. Under these circumstances, hospital administration, legal, and/or the ethics committee should be involved to assist with health care decision making and guardianship.

In suspected cases of elder mistreatment without an imminent threat to a patient's safety, interventions are individualized. If the patient wants to return home and may be safely discharged, follow-up should be coordinated with the patient's primary care physician. Social workers may be able to offer support resources to both the patient and the caregiver. Ideally, elder mistreatment cases are managed in the community by a case manager or a team and involve home visits and advocacy.

A multidisciplinary ED-based consultation team, modeled on child protection team interventions, may assist in optimizing the care and ensuring the safety of these vulnerable patients. This team coordinates medical, forensic, and social work evaluations, and assist with a safe disposition. The team's presence can lessen the burden on ED providers who are generally multitasking and caring for multiple patients. ED providers may be more willing to pursue suspicions about elder abuse and neglect because of the availability of a team to assist with care, which may lead to higher rates of identification. These multidisciplinary ED elder protection consultation teams have been developed and are undergoing impact evaluation.

Trauma-Informed Care

Trauma-informed care to older adult victims of abuse or neglect involves being sensitive to the profound impact of traumatic and stressful life experiences on a patient's mental and physical health. Ongoing abuse or neglect, which may occur daily for years, and also previous—even remote—traumatic experiences may cause depression, anxiety, or posttraumatic stress disorder. Trauma-informed care is particularly important for older adults, who have had a long life to experience stressful or traumatic events.

Providing trauma-informed care focuses on the patient's need for safety, respect, and acceptance. The victim's choice and control should be maximized while minimizing re-traumatization through treatment. Recommended bedside strategies include:

- Using language and grammar that is easily understood, neutral, and not intimidating
- Limiting the number of times a victim has to talk about the assault
- Avoiding words such as violence, abuse, or criminal behavior if the victim does not initially conceive of what has occurred as abusive or criminal
- Asking permission before touching a potential victim
- Maintaining the victim's privacy and confidentiality
- Offering the support of an advocate if available
- Being mindful of culturally specific expectations regarding interactions between older adult patients and younger care providers

ED clinicians should also use these trauma-informed strategies for cognitively impaired patients, as they may still be deeply affected by ongoing or previous traumatic exposures.

Documentation

The history should be documented in the patient's own words, and avoid using biased words such as "claims" or "alleged." Pertinent social history (e.g., patient's functional status, caregiver's relationship to patient, living arrangements) should be included. The patient's general appearance on initial arrival to the ED should be described including signs of potential neglect (e.g., soiled diaper, inappropriate or dirty clothing, or dirt under nails). Injuries of any type (e.g., fractures, lacerations, and contusions) should be described, including their number, size, location, and stage of healing, and comment about whether the injuries are consistent with the reported mechanism. Providers should consider using a body diagram/traumagram to precisely document physical findings. The Geri-IDT, a practical tool to improve medical documentation of geriatric injuries for potential forensic use, was recently developed and may be helpful.[9] If possible, photographs of all injuries should be added to the medical record. The results of laboratory investigations and imaging studies should also be recorded. Careful documentation of interventions, follow-up plans, and referrals should be made. In cases of suspected elder abuse that result in legal action, thorough documentation may be critical to ensure justice for the victim.

Reporting

Suspected cases of elder abuse or neglect should be reported to the appropriate authorities. A reasonable cause to suspect abuse is all that is necessary. Health care providers are mandated reporters for elder abuse in most but not all US states and, in many states, elder abuse must be reported even if the victim does not want a report made. As laws differ, ED clinicians should be aware of their state's requirements. This information is available on a state's department of health website, and a summary is at: http://www.napsa-now.org/wp-content/uploads/2014/11/Mandatory-Reporting-Chart-Updated-FINAL.pdf.

Adult Protective Services (APS) is typically the agency that investigates these cases for community-dwelling older adults. Information on how to contact state or local APS in different areas is available at: http://www.napsa-now.org/get-help/help-in-your-area/. The scope of the APS response must be appreciated: in most US states, APS can only investigate cases where an older adult has cognitive or functional impairment, and the agency will not act on reports if they judge that the older adult does not meet these criteria. Additionally, APS functions differently than Child Protective Services and will not open their investigation while a patient is in the ED or hospital. They will only open an investigation after discharge, generally within 72 hours. Consequently, ED clinicians should consider reporting to the local police when concerned about a patient's immediate safety or that a crime has been committed.

Collaboration with the Community

EDs may benefit substantially from improving communication, connection, and collaboration with APS and other community-based service providers. In many communities, multidisciplinary teams (MDTs) have developed that meet regularly to manage complex elder abuse and neglect cases. Members of these MDTs include APS case workers, prosecutors, civil attorneys, law enforcement professionals, financial services professionals, and health care providers.

Resources

The Administration for Community Living's National Center on Elder Abuse website (https://ncea.acl.gov) is the most comprehensive online resource available on elder abuse and neglect. Also, http://www.elderabuseemergency.org is a website designed for emergency clinicians that provides access to tools, information, and resources that may be useful for reference and when on shift.

SPECIFIC ISSUES

Elder Mistreatment in Institutions

Residents of skilled nursing facilities represent a large and growing percentage of older adults who present to the ED and are at particularly high risk for mistreatment. Over the last several decades, increased regulatory scrutiny has improved care and reduced staff mistreatment of older adults in skilled nursing facilities through the Long-Term Care

Ombudsman Program to investigate complaints, mandatory staff background checks, and minimizing the use of restraints.

In addition to staff abuse and neglect of nursing home residents, resident-to-resident elder mistreatment has been recently identified as an important problem.[10] Given that dementia and associated behavioral disturbance in long-term care facilities is high, aggressive behavior can occur between residents. Additional research is needed to improve understanding and recognition of this type of elder mistreatment. When abuse or neglect of any kind in patients from nursing homes is identified or suspected, it should be reported to the long-term care ombudsman in their state (https://theconsumervoice.org/get_help), the state's department of health, or APS for further investigation.

Self-Neglect

Self-neglect includes behaviors in which an older adult threatens his/her own health or safety by failing to perform or refusing assistance with essential self-care. This may include malnutrition due to not eating, failure to take necessary medications, inattention to personal hygiene, hoarding, and not maintaining a safe home environment. Often, patients with self-neglect suffer from an underlying mental disorder, including mild cognitive impairment, depression, psychosis, or substance abuse disorders that prevents them from understanding that their health and safety are at risk and that they need to seek assistance. Self-neglect is associated with increased mortality. It is the most common form of elder mistreatment reported to social services, with reports rising. As with other types of elder mistreatment, recognition is critical because many of these older adults have virtually no other contact outside the home. EMS providers, who may note an empty refrigerator, expired pill bottles, or vermin infestation, may play a pivotal role in the patient's care. Although evidence-based strategies for intervention have not been established, a reasonable approach for an emergency clinician includes laboratory assessment for metabolic and nutritional abnormalities and social work evaluation to offer resources and services. Many of these patients will require hospital admission because it will be impossible to establish a safe discharge plan.

CHAPTER 181: QUESTIONS AND ANSWERS

1. A 70-year-old man who lives alone but has 12 hours per day of a home attendant is brought to the emergency department (ED) by his daughter, who found him in his caregiver's home with severe bruising. On examination, he had multiple bruises at varying stages of healing on the chest and arms, as well as a possible pattern injury—a bruise in the shape of a rectangle—across his left chest. What should you do?

a. Ask the daughter to make a report to adult protective services (APS) because she is the one who found him.
b. Contact the long-term care ombudsman.
c. Do not make a report because he has a long history of falls.
d. File a report with APS or law enforcement if your suspicion for abuse is high.

Answer: D. The injuries noted are of significant concern for elder abuse. The patient should be asked questions in a nonthreatening atmosphere, separate from the caregiver. If the emergency clinician still has high suspicion, a report should be made to APS and/or law enforcement. The physician has the obligation to make the report. The long-term care ombudsman should be contacted only if the suspected abuse occurs in a facility, such as a nursing home.

2. A 72-year-old female is brought to the emergency department (ED) by paramedics for "not eating for 5 days," according to her family. The paramedics noted that she was covered in urine and feces and that the house was filthy, and she was found lying on the floor. On examination, she is noted to have a stage 4 pressure ulcer on her sacrum, which appears infected. Which of the following are concerning for neglect?

a. Delay in seeking care
b. Evidence of dehydration
c. Poor hygiene
d. Pressure ulcer
e. All of the above

Answer: E. All of the above signs are potential markers for neglect.

3. A 69-year-old man with dementia presents to the emergency department (ED) with pneumonia and delirium. He is very confused, and his cognition is markedly worse than his baseline. You are called to the bedside because his adult daughter is at the bedside asking him to sign a legal form giving her the deed to his house. What are the next steps in advocating for your patient?

a. Perform an assessment of cognition and capacity and document it on the chart.
b. Request that the hospital lawyer and notary be present.
c. Tell her that there must be two witnesses present for the form to be legal.
d. Tell the daughter that if there are other children, they must be present for the form to be valid.

Answer: A. When an elderly patient has delirium or is confused because of another medical condition, he or she may lack the capacity to enter into a legal agreement or sign a legal document. The patient described is clearly too confused to understand all of the ramifications of signing his or her home over to another person. Confusion resulting from delirium or dementia is a risk factor for elder financial abuse.

4. An 85-year-old female with dementia, who lives in a skilled nursing facility, presents with bruises on her bilateral inner thighs. The facility staff states that she sustained these while being lifted from her bed to a chair. Who should you notify?

a. Adult protective services (APS)
b. Law enforcement
c. Sexual assault response team
d. The long-term care ombudsman
e. All of the above

Answer: E. The physical findings are concerning for sexual abuse, therefore law enforcement and APS should be called, as well as the sexual assault response team to collect forensic evidence. Because the patient lives in a facility, the long-term care ombudsman should also be called to investigate the possible abuse.

182

The Immunocompromised Patient

Jack Perkins Jr. and Christopher P. Waasdorp Jr.

KEY CONCEPTS

- Immunocompromised patients who present with acute infections, especially those that are neutropenic, may appear deceptively benign initially. Their symptoms and signs often mimic noninfectious complications.
- Broad-spectrum antibiotics are indicated after obtaining appropriate cultures of all potential sites of infection, especially if the patient is neutropenic.
- Immunocompromised patients can have serious local or systemic infections without fever.
- Symptoms, signs, and findings of infection may include tachypnea, tachycardia, mental status change, metabolic acidosis, increased volume requirements, rapid changes in serum glucose or sodium concentration, or acute abdominal pain.
- The incidence and severity of febrile neutropenia are inversely proportional to the absolute neutrophil count and directly proportional to the duration of neutropenia.
- In neutropenic patients, the temperature should be measured orally or tympanically, not rectally, due to theoretical risk of bacterial translocation and subsequent bacteremia.
- Febrile neutropenia is more common in hematologic malignancy (compared with solid malignancy) and is most likely to occur 7 to 10 days after chemotherapy.
- Gram-positive organisms are responsible for most serious infections in neutropenic cancer patients, but infections due to gram-negative organisms are more rapidly lethal.
- Neutropenic cancer patients with chemotherapy-induced oral mucositis can develop rapid onset of fever with shock. Viridans streptococci is a common pathogen and requires Vancomycin.
- When pneumonia develops in patients with febrile neutropenia, purulent sputum may be absent, and the initial chest radiograph may not show an infiltrate.
- Some low-risk febrile neutropenic patients may not require admission to the hospital. After calculating a Multinational Association for Supportive Care in Cancer (MASCC) risk index score and consulting with their oncologist, discharge may be reasonable.
- Diabetic patients have a high incidence of MRSA infection, osteomyelitis, and wound infections and are at higher risk of bacteremia. Severe infections may be more insidious in presentation.
- Patients with cell-mediated immune deficiency, including those on high-dose corticosteroids, may develop life-threatening infections with intracellular bacteria (*Listeria*, *Salmonella*, tuberculosis), fungi (*Cryptococcus*, *Coccidioides*, *Histoplasma*), herpes simplex virus, and varicella-zoster virus.
- Guidelines no longer support empiric antibiotic treatment of aspiration in alcoholic patients.
- In patients with cirrhosis, empirical treatment of suspected spontaneous bacterial peritonitis (SBP) with antibiotics should be started regardless of ascitic cell count.
- Patients who require hemodialysis for end-stage renal disease have high mortality if they develop pneumonia, *C. difficile* disease, or infections of the dialysis access site.
- Functional or surgical asplenia predisposes to fulminant infection with pneumococci and other encapsulated organisms (*H. influenzae*, *N. meningitidis*, and *Capnocytophaga canimorsus* after dog bites) and, when seen early, may be misdiagnosed as a viral illness, gastroenteritis, or food poisoning.

FOUNDATIONS

Emergency clinicians must recognize and treat infectious complications of cancer, organ transplantation, diabetes, renal failure, cirrhosis, asplenism, human immunodeficiency virus (HIV) infection, and other immunosuppressive conditions. Infections are more common, progressive, and severe in immunocompromised patients, and a wider variety of microorganisms may lead to infection. Immunocompromised persons presenting with acute infections may initially appear deceptively benign. Additionally, they may present with symptoms and signs that mimic noninfectious conditions, only to deteriorate rapidly if they are not evaluated and treated urgently. Many factors result in immunocompromise and predispose patients to infections. These include disruption of the body's protective surfaces, such as skin and mucosal barriers (oral and respiratory mucosa and intestinal and genitourinary surfaces); disorders that directly impair the function of the body's

immune system (e.g., lymphoma, asplenism, and myeloma); drugs and irradiation that suppress or alter immune function; alterations in body substances (hyperglycemia) or solid organ function (kidney and liver failure); and malnutrition, aging, and exposure to antimicrobial agents that inhibit the normal protective resident bacterial flora.

PHYSIOLOGY

Immunity and Immune Deficiency

The body's defense mechanisms consist of surface barriers, innate (natural) and acquired (adaptive) responses. Innate responses occur to the same extent regardless of how often the body encounters the infectious agent, whereas acquired responses improve with repeated exposure. Innate immunity is activated immediately on exposure to an infecting agent, rapidly controlling replication and allowing the requisite 3 to 5 days for the adaptive component to clone sufficient T and B cells to respond more specifically.

Non–Microbe-Specific Immunity

Physical Barriers. Physical barriers, the first line of defense against microorganisms, consist of intact skin, mucosa, cilia, biofilm, gastric acid, antimicrobial peptides and proteins on skin and mucous membranes, and resident microflora. Smoking and pulmonary disease impair physical barriers in the respiratory tract whereas mechanical ventilation or tracheostomy introduces large numbers of microbes that often overwhelm natural clearance. Gastric acid and pancreatic enzymes have antibacterial properties that prevent overgrowth in the upper gastrointestinal tract. Normal peristalsis and mucosal shedding help maintain normal gut flora. Alterations in these factors, such as broad-spectrum antibiotics, alter normal flora and permit overgrowth of pathogens such as *Candida*, multidrug-resistant organisms, and *Clostridium difficile*.

Initial Inflammatory Response and Innate Immunity. The initial inflammatory response to microbial invasion promotes phagocytosis and microbial killing while activating the immune system. This innate immune response is not dependent on prior exposure to the pathogen. The initial inflammatory response factors, mainly produced in the liver, activate many cell types to synthesize and release cytokines, chemokines, and "trigger molecules" that kill the invading organism. This response delivers humoral and cellular immune components to sites of inflammation and initiates antibody production. Cytokines, platelet-activating factor, and hormone-like proteins are secreted from various immune cells and play essential roles in mediation of this response. Cytokines cause migration and adhesion of polymorphonuclear leukocytes and monocytes to sites of bacterial invasion. These cells release granules of substances that mediate vasodilation and increased vascular permeability, leading to edema, warmth, and redness, and allow both phagocytic cells and humoral components to be concentrated at the site of infection.

Reticuloendothelial System. The reticuloendothelial system, composed of tissue macrophages and their blood-borne counterparts, monocytes, removes particulate matter, including microbes, from the lymph and blood. The tissue component is concentrated in the lymph nodes, spleen, liver, marrow, and lung and has particular affinity for encapsulated bacteria, such as pneumococci, meningococci, and *Haemophilus influenzae*. The overwhelming sepsis from encapsulated organisms that can occur in patients with asplenia demonstrates the vital importance of this non–microbe-specific system.

Adaptive (Microbe-Specific) Immunity

Humoral Immunity

Antibodies. Each B cell produces a single microbe-specific antibody type. Stimulation by an antigen (or microbe) causes proliferation of this particular B cell so that large quantities of a specific circulating antibody can be produced. B cells are also active in presenting antigens to T lymphocytes, promoting cell-mediated immunity (CMI).

Immunoglobulins. Immunoglobulin M (IgM) is the first immunoglobulin to appear in response to a new antigen. Although it has less affinity at binding antigens than immunoglobulin G (IgG), IgM provides some recognition of antigens and begins B-cell proliferation before the subsequent development of IgG. IgM is detectable earlier in serum than IgG and serves as a marker for a patient's early response to acute infection.

Secretory immunoglobulin A (IgA) is the predominant immunoglobulin present in gastrointestinal fluids, nasal and oral secretions, tears, and other mucous fluids. IgA inhibits cell adherence of viral, bacterial, and protozoan pathogens and prevents invasion by organisms through the respiratory or gastrointestinal tract.

Immunoglobulin E (IgE), which is expressed in high concentration on the surface of mast cells and basophils, is responsible for immediate-type hypersensitivity responses. Mast cells and IgE are important in defense against helminthic pathogens.

IgG, widely distributed in tissues, accounts for 75% of the total immunoglobulin mass. It crosses the placenta and provides fetal immunity during the first 6 months of life. Congenital or acquired deficiencies of IgG lead to infection with encapsulated organisms because the predominant subtype (IgG2) has affinity for the dense polysaccharides of bacterial cell capsules, such as those of *Streptococcus pneumoniae* and *H. influenzae*.

Complement. The complement cascade, a complex interaction of 30 proteins, is another crucial component of humoral response. Complement is important in producing inflammation and leukocytosis and in recruiting leukocytes to sites of infection. Complement also neutralizes viruses, enhances bacterial binding of opsonin, and lyses bacterial cell walls and membranes.

IgG and IgM activate the classical complement pathway when they are in contact with an antigen, whereas molecules with repeating chemical structures (e.g., bacterial cell walls and capsules) activate the cascade through the alternative pathway. C3 is the merging point of the classical and alternative paths and modulates the response of lymphocytes (CMI). The terminal leg of the cascade, C5 through C9, forms the membrane attack complex, which inserts into cell walls and membranes and leads to cell death.

Individuals with inherited complement deficiencies are predisposed to frequent and recurrent infections with *S. pneumoniae, H. influenzae,* and especially *Neisseria meningitidis* and *Neisseria gonorrhoeae*. The risk of meningococcal infection is increased several thousand-fold, especially in people deficient in C3 and late complement components (C5 to C8). Paradoxically, the disease is usually milder with complement deficiency, and mortality is likewise reduced fivefold to tenfold. This suggests that the host response may be, in part, responsible for the severity of disease in normal individuals and is attenuated in complement deficiency. Acquired deficiencies of complement function may develop in people with rheumatologic diseases, especially systemic lupus erythematosus (SLE). Approximately 40% of patients with SLE have an inhibitor of C5a-derived chemotaxis in their serum, resulting in enhanced susceptibility to infection.

Cell-Mediated Immunity. Cell-mediated immunity (CMI) includes immune responses mediated by T lymphocytes, natural killer (NK) cells, and mononuclear phagocytes. CMI is crucial in controlling infections caused by microbes that survive and replicate intracellularly, including most viruses and some bacterial (obligate and facultative intracellular types), fungal, and protozoan pathogens.

Only 5% of lymphocytes are in circulating blood. Most mature and are active in the marrow, thymus, spleen, and lymph nodes. The last

two sites expose T cells to circulating antigens from invading microbes. Specialized antigen-presenting cells in the lymphoid system sequester antigen and antigen-antibody complexes and present them to T cells via a cell surface molecule called the *major histocompatibility complex (MHC)*. Only with this specific presentation can a T lymphocyte become activated against a particular antigen.

Two major types of T lymphocytes are CD4 (helper cell) and CD8 (suppressor cell). CD4 lymphocytes provide help for other cells in the immune system, including enhanced B-cell antibody production and the production of cytokines. CD8 lymphocytes are generally cytotoxic and mediate the eradication of virally infected target cells and certain tumors. A decline in the number of CD4 cells, with predominance of CD8 cells, is responsible for the increased susceptibility to infection in patients with human immunodeficiency virus (HIV). Despite the cytotoxicity of CD8 cells, immunity is reduced without adequate numbers of CD4 cells.

Patients with defects in CMI are at increased risk for disseminated infection with intracellular bacteria, such as *Mycobacterium tuberculosis, Listeria monocytogenes,* and *Salmonella* species. The DNA viral infections, such as cytomegalovirus, herpes simplex, and varicella-zoster, also affect these patients more severely, as do fungal infections with *Candida, Cryptococcus, Mucor, Aspergillus,* and *Pneumocystis*. Finally, some protozoa are pathogenic in patients without intact CMI, such as *Toxoplasma gondii*. Some infections are seen only below a certain CD4 cell count. *Pneumocystis* pneumonia, for example, is seen almost exclusively in patients with CD4 counts below 200 cells/mL, whereas almost all patients with toxoplasmosis or cryptococcal meningitis have counts below 100 cells/mL. In settings where the CD4 count is not readily available, such as the ED, an absolute lymphocyte count of less than 1000 cells/mL is suggestive of a CD4 count of less than 200 cells/mL.

NK cells, closely related to lymphocytes, are important in the innate immune response and are found in high concentrations in blood and spleen. NK cells recognize infected cells and directly kill these cells while secreting cytokines that activate macrophages to destroy phagocytosed microbes. NK cells are important in defense against intracellular microbes, particularly viruses and intracellular bacteria such as *L. monocytogenes*.

Granulocytic Phagocytes. Granulocytic phagocytes are the cellular effectors of microbe killing, engulfing them and enzymatically lysing their cell membranes or walls. Two major types are polymorphonuclear leukocytes (neutrophils) and macrophages (the tissue version of circulating monocytes). Macrophages have surface receptors that recognize nonvertebrate carbohydrates, such as mannose, to identify and attack "invaders" rather than "self."

Two other types of granulocytes, eosinophils and basophils, are less involved in the ingestion of organisms. Eosinophils attack certain parasitic helminths through the release of toxic proteins. This cell type can increase from 3% to 20% during times of high parasite load. Basophils (rare in circulation) and their tissue counterparts, mast cells, have a high affinity for IgE. On exposure to bound IgE, they release granules with histamine, prostaglandins, leukotrienes, and endogenous heparin to promote blood flow and inflammatory response in combating arthropod ectoparasites or helminth endoparasites. Activation of basophils by IgE bound to pollen and other allergens may affect the allergic-inflammatory response with increased vascular permeability, bronchospasm, and vasodilation.

Half of all neutrophils that leave the bone marrow circulate in the plasma. The other half become marginated, adhering to endothelium, primarily in the lungs, liver, and spleen. During periods of stress or with endogenous or exogenous catecholamines or corticosteroids, these neutrophils demarginate and enter the circulation. If the patient is not neutropenic, demargination causes an increased peripheral neutrophil count composed of mature cells. With bacterial infection, an increased proportion of immature (band) forms is more typically seen.

Neutrophils (and tissue macrophages) bind to and ingest bacteria through phagocytosis. This process is enhanced by proteins called *opsonins* that bind to bacterial surfaces, particularly important in defense against infection with *S. pneumoniae, Streptococcus pyogenes, H. influenzae*, and *Staphylococcus aureus*. C-reactive protein, one of the initial inflammatory response proteins, fulfills this function for certain bacteria, including *S. pneumoniae*. IgG and complement protein C3b also opsonize bacteria, again illustrating the interdependence of the immune system. Actual killing takes place within granulocytes when cytoplasmic granules enzymatically produce potent oxidants. Granulocytes further control bacterial proliferation at the site of infection by elaborating lactoferrin, which locally binds free iron necessary for bacterial replication.

In addition to phagocytosis, macrophages (located in the spleen, alveoli, liver, and lymph nodes) modulate the immune response by presenting antigens to lymphocytes and releasing cytokines and complement components. Activation of macrophages to ingest bacteria depends on interaction with interferon-γ, a cytokine manufactured by T cells, again bridging different components of the immune system.

SPECIFIC DISORDERS

Immune system defects in the immunocompromised patient and the most common pathogens associated with each defect are listed in Box 182.1.

Solid Organ Transplants

For specific issues regarding medication-induced immunocompromised states in solid organ transplant patients, refer to Chapter 183.

Cancer

Patients with cancer frequently suffer from neutropenia or impaired T and B cells function due to the cancer itself or chemotherapy. Defects in the physical barriers of the skin and mucous membranes, including the cytotoxic effects of chemotherapy on cells lining the gastrointestinal tract, predispose to infection. In addition, splenic dysfunction or splenectomy, use of long-term intravascular catheters, frequent use of complex invasive diagnostic and therapeutic procedures, toxic effects of radiation therapy, and frequent colonization with antimicrobial-resistant pathogens predispose to immune system compromise. Despite many advances in supportive care, infections continue to result in severe morbidity and mortality. Furthermore, increasing resistance to antimicrobials is occurring among common pathogens along with the emergence of new opportunistic infections.

Neutropenia

Background

Definitions of neutropenia vary, but the 2018 American Society of Clinical Oncology proposed the following based on absolute neutrophil count (ANC):[1]

Neutropenia: ANC less than 1000 cells/μL
Severe neutropenia: ANC less than 500 cells/μL
Profound neutropenia: ANC less than 100 cells/μL

The nadir of the ANC is usually 7 to 10 days after the conclusion of chemotherapy. Fever in the neutropenic patient is defined as a single oral temperature of 38.3°C (101°F) or greater or a temperature of 38.0°C (100.4°F) or greater sustained over 60 minutes.[1] Febrile neutropenia (FN) usually results from cytotoxic chemotherapy or the underlying malignancy. Risk of FN is largely determined by the

type of malignancy, with FN being far more common in hematologic malignancies. Additionally, other factors include the type of chemotherapy and where the patient is in relation to their chemotherapy regimen, with FN being much more common in the first or second cycle of chemotherapy. Mortality varies widely and is affected by comorbid illness, severity of neutropenia, presence of shock, and hematologic malignancy (worse outcomes), among other variables.[1] In a nationwide study in the United States of FN among patients with metastatic solid tumors, FN occurred in 13% to 20% during their chemotherapy course with a mortality of 4% to 10% per episode of neutropenia.[2]

The incidence and severity of infection in cancer patients with neutropenia is inversely proportional to the ANC and directly proportional to the duration of neutropenia.[3] Although the incidence begins to rise as the neutrophil count falls below 500 cells/μL, most severe infections and almost all bacteremias occur when the neutrophil count is less than 100 cells/μL.[3,4]

The most common sites of infection in neutropenic patients are the lung (25%); mouth and pharynx (25%); gastrointestinal tract (15%); skin, soft tissue, and intravascular catheters (15%); perineum and anorectal area (10%); urinary tract (5%); and nose and sinuses (5%).[3,4] Pneumonia and anorectal infection are more likely to be associated with bacteremia.[5,6] Bacteremia may occur without an obvious source despite intensive investigation. The most important bacteria infecting neutropenic patients are four gram-positive cocci—*Staphylococcus epidermidis,* viridans group *streptococci*, *Enterococcus* species, and *S. aureus*—and three gram-negative bacilli—*Escherichia coli, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa.*[4,6] An increase in formerly uncommon gram-negative infections caused by *Enterobacter, Citrobacter,* and *Serratia* species has occurred, and infections caused by gram-negative organisms resistant to cephalosporins, extended-spectrum penicillins, and carbapenems are occurring more frequently. Anaerobes are uncommon but may be important in certain mixed infections (mouth, abdominal, and perianal).[3,4]

Infections caused by gram-positive organisms (coagulase-negative staphylococci, *S. aureus,* viridans streptococci, and *Enterococcus* species) are now the leading cause of bacterial infection (50% to 70% at some centers) in febrile neutropenic cancer patients in the United States, Canada, and western Europe.[4,6] Gram-negative organisms still predominate in developing countries. Most of these gram-positive organisms do not produce immediately life-threatening infections, in contrast to the rapid lethality of many gram-negative infections. However, bloodstream infections caused by viridans streptococci (especially *Streptococcus mitis*), may be life-threatening and result in rapid development of shock or acute respiratory distress syndrome (ARDS). These infections are common in many cancer centers and often respond poorly to penicillins and cephalosporins. Risk factors for serious viridans streptococcal infections include aggressive cytoreduction therapy for acute leukemia or allogeneic bone marrow transplantation, profound neutropenia, and severe oral mucositis. Other risk factors include prophylactic use of trimethoprim-sulfamethoxazole or fluoroquinolones, antacids or H_2 receptor antagonists, and pediatric age.[7]

Aspergillus and *Candida* species are the most common fungal pathogens in cancer patients with fever and neutropenia.[8-11] Infection is most likely to develop in neutropenic patients treated with broad-spectrum antimicrobials and in those whose fever persists for more than seven days.[8] *Aspergillus* species usually produce necrotizing infections in the lungs or sinuses. Pulmonary aspergillosis often manifests with pleuritic pain, hemoptysis, and localized wheezing. The chest radiograph demonstrates pleural effusions or focal infiltrates. Computed tomography (CT) is more sensitive in detecting pulmonary infiltrates compatible with aspergillosis and may demonstrate a distinct halo of low attenuation surrounding a pulmonary infiltrate. This pattern is highly suggestive of invasive aspergillosis, although zygomycosis (formerly mucormycosis) and other disorders may mimic the halo.

Invasive aspergillosis originating in the paranasal sinuses may extend to the surrounding bone and brain. Often, an initial red-purple lesion on the nasal turbinate or palate turns pale and then black as vascular invasion produces infarction of the mucosa and bone. The black eschar on the nose or palate can be misdiagnosed as dried blood. Patients presenting with headache, facial pain or swelling, or proptosis, should be rapidly evaluated for invasive aspergillosis and zygomycosis. *Candida* species produce infections of the skin, oral cavity, and esophagus, as well as fungemia. The sudden onset of generalized rash consisting of pink-purple, nontender subcutaneous nodules is characteristic of candidemia.

Mucositis involving the mouth and other mucous membranes is a painful and debilitating condition that commonly occurs in cancer patients receiving intense chemotherapy. It is a frequent prelude to viridans streptococcal bacteremia, which can produce sudden onset of acute respiratory distress syndrome, a toxic shock–like syndrome, rash, and pneumonia. Importantly, mucositis predisposes the patient to gram-positive infections, and vancomycin is appropriate in addition to a broad-spectrum gram-negative agent. History is helpful because mucositis tends to recur throughout the chemotherapy course.

Febrile Neutropenia Evaluation Pitfalls

- **Fever is the only sign of infection.** Fever is frequently the only sign of infection, partly because these patients are unable to mount a full inflammatory response.[4-6] Usual symptoms and signs of infection may not be present, especially when the neutrophil count is less than 100 cells/μL. Furthermore, aggressive education before and during chemotherapy makes these patients much more likely to present early in the course of an infectious illness when fever is the only symptom. Some patients may harbor a serious infection yet not be able to mount a febrile response (chronic prednisone therapy, bone marrow transplant) or may present with hypothermia.
- **Assuming the patient does not harbor an infectious pathology if they are afebrile.** While most neutropenic patients are still able to mount a febrile response to infection, some patients will have serious infectious pathology and be afebrile.[4-6] Oral temperatures are unreliable, and rectal temperatures are contraindicated in FN, making it difficult to accurately identify patients who do not present with a complaint of fever at home.[12] Bone marrow transplant patients, patients on chronic corticosteroids, and elderly patients are all at higher risk of not mounting the expected febrile response to infection. Such infections may be manifested instead by unexplained tachypnea or tachycardia, mental status changes, metabolic acidosis, increased volume requirements, rapid changes in serum glucose or sodium concentration, or acute abdominal pain.
- **Physical examination that is misleading.** The FN patient with a localized infection may have shaking chills and a toxic appearance without localized findings. Areas of cellulitis may have minimal induration and redness and little or no purulent drainage. Tenderness may be the only finding in perineal and anal infections. Peritoneal signs may be absent even with surgical pathology due to a lack of the inflammatory response that results in the traditional peritoneal findings.
- **Failing to consider noninfectious causes of fever.** Noninfectious causes of fever need to be considered, including drug toxicity, drug allergy, transfusion reactions, and pulmonary emboli.
- **Overestimating sensitivity of diagnostic testing in febrile neutropenia.** When pneumonia develops, purulent sputum may be absent, and the initial chest radiograph may not show an infiltrate.[13,14] Pyuria may be absent in patients with a urinary tract infection.
- **Misinterpreting leukocytosis in a patient who has received a colony-stimulating factor.** Oncologic patients who are expected to become neutropenic after their course of chemotherapy may be administered colony-stimulating factor to boost their white blood cell production. Consequently, the emergency clinician may encounter a patient with a marked leukocytosis and fail to recognize that these patients should be evaluated and treated in the same manner as if they presented with neutropenia and fever.[3,6] Emergency clinicians should routinely inquire about the use of colony-stimulating factors during their initial history.
- **Obtaining a rectal temperature in neutropenic patients.** In neutropenic patients, the temperature should be measured orally, not rectally. Although no randomized controlled trials have ever been conducted, there is a theoretical risk of bacterial translocation with any rectal stimulation.[3]

Evaluation and Management

Box 182.2 describes a step-by-step approach to the evaluation and management of the adult patient with febrile neutropenia.

Unfortunately, only about 50% of FN episodes will have an identified focus of fever.[4-6] Up to 25% of patients have a microbiologically identified source of infection such as blood, urine, or wound cultures. Another 25% of patients have a clinically evident source of infection such as pneumonia but no microbiologic data confirms the precise pathogen. Consequently, many patients with FN are not able to have their antibiotics narrowed to minimize the risks of developing resistant bacteria or *Clostridium difficile*.

Antibiotic Therapy. The Infectious Disease Society of America and the American Society of Clinical Oncology recommend antibiotic therapy within 60 minutes of presentation to ED triage for patients with FN.[1] Afebrile neutropenic patients who have unstable vital signs (e.g.,

BOX 182.2 Evaluation and Management of the Adult Cancer Patient With Febrile Neutropenia in the Emergency Department

- Fever (or reported history of fever by patient) of single oral temperature ≥ 38.3°C (101°F) or temperature ≥ 38.0°C (100.4°F) sustained over 60 minutes. Some neutropenic patients will harbor serious infection without fever.
- Neutropenia = Absolute neutrophil count (ANC) < 1000 cells/μL
- If patient is septic, rapidly administer intravenous fluids and maintain mean arterial pressure ≥ 65 mm Hg.
- Contact oncologist early in ED course to assist in guiding evaluation and management especially regarding unique chemotherapy side effect considerations and unusual pathogens (e.g., fungal, viral).
- Query patient about previous episodes of neutropenic fever, recent travel, exposure to animals, vaccinations, and any current antimicrobial use.
- Obtain blood for measurement of electrolytes, renal and hepatic function, serum lactate.
- Obtain blood cultures from each lumen of any existing central venous catheters and from at least one peripheral site, or two blood cultures from separate venipunctures of peripheral veins if no central venous catheter is present.
- Review records for information pertaining to previous episodes of neutropenic fever, prior culture results and sensitivities, echocardiogram, and current chemotherapy regimen.
- Perform a careful physical examination to search for subtle symptoms or signs of infection, with particular attention to the mouth, nose and sinuses, lower esophagus, lung, and skin, including nails, perineum including anus, bone marrow aspiration sites, and vascular catheter sites.
- Understanding that peritoneal signs may be absent in neutropenia and that chest radiograph has marked limitations, consider CT of chest/abdomen/pelvis searching for a source if routine evaluation does not yield a likely source of fever.
- Obtain chest radiograph, understanding it is poorly sensitive for infiltrate with neutropenia.
- Obtain urinalysis with urine culture.
- Send influenza testing if appropriate (by season), understanding that rapid antigen testing has insufficient sensitivity to exclude influenza. Influenza PCR is a superior test to exclude influenza. Neutropenic patients are at high risk for morbidity and mortality from influenza and may present without fever. Empiric treatment (if PCR testing is unavailable) should be considered with oseltamivir based on clinical presentation.
- If diarrhea is present, send for culture, ova and parasites and *Clostridium difficile.*
- Lumbar puncture is not recommended as a routine procedure; however, classic findings such as meningismus may be absent in neutropenic patients.
- Evaluate joins for potential effusion and consideration of aspiration.
- Antibiotics (cefepime, a carbapenem, meropenem, imipenem, or piperacillin/tazobactam) should be initiated within 60 minutes of presentation. The specific agent will depend on institutional antibiogram for gram-negative pathogen sensitivities.
- For patients with a history of severe penicillin allergy, initiate empiric therapy with aztreonam and vancomycin. Avoid empirical use of a fluoroquinolone as coverage for gram-negative pathogens in penicillin-allergic patients.
- Once the initial antibiotic has been administered, consider additional antimicrobials based on suspected source.
  - Add coverage for atypical organisms in suspected community-acquired pneumonia.
  - Add metronidazole or clindamycin for suspected intra-abdominal infections (if broad-spectrum gram-negative agent does not have anaerobic activity such as cefepime).
- For patients with a minor penicillin allergy, empirical treatment with cefepime, meropenem or imipenem-cilastatin can usually be given safely.
- Empiric use of vancomycin is not routinely indicated for all febrile neutropenic patients. Vancomycin should be administered for: 1) suspected catheter-related infection; 2) known colonization with MRSA or penicillin-resistant pneumococci; 3) presence of shock; 4) severe mucositis; 5) prior fluoroquinolone prophylaxis; and 6) institutions in which MRSA, vancomycin-susceptible enterococci, and *Streptococcus mitis* (viridans streptococcus group) are frequent pathogens.
- Empirical antifungal therapy is only rarely indicated in the ED and should not be initiated by the emergency medicine provider without consultation with an infectious diseases specialist.
- Do not initiate outpatient therapy in low-risk patients without contacting the patient's oncologist or an infectious diseases specialist.
- Calculate the MASCC score if outpatient therapy is being considered in a stable patient.
- Patients being considered for early discharge and outpatient management should have a MASCC score ≥21 and have no other high-risk features. They should be observed for at least four hours after the initial antibiotic dose to monitor for stability.
- Low-risk patients may be monitored in an ED observation unit where they can be evaluated by an oncologist and/or infectious diseases specialist to determine whether early discharge to home is feasible.
- Avoiding an inpatient admission is advantageous for the stable low-risk patient because hospitalization exposes the patients to potential iatrogenic complications and antimicrobial-resistant nosocomial pathogens, and outpatient admission allows an improved quality of life.

hypotension), are ill-appearing, or have symptoms or signs of infection (e.g., abdominal tenderness) should be treated empirically regardless of the presence of fever.[1,7] The three most commonly used antibiotics are cefepime, piperacillin/tazobactam, or anti-Psuedomonal carbapenem. Use of a single antibiotic agent is preferred in most patients, because there is no conclusive evidence of benefit from multiple drugs.[1] Each hospital should have a preferred antibiotic agent based on the hospital antibiogram. The most common agents are cefepime, piperacillin/tazobactam, or an anti-Psuedomonal carbapenem, and they are typically used for empirical treatment of both sepsis and febrile neutropenia. Review of patient records for previous pathogens and sensitivities can help identify patients at higher risk of resistant organisms requiring adjustment in empiric therapy. It should be noted that monotherapy with cefepime, a carbapenem, or piperacillin-tazobactam will not be

Drug	DOSAGE: Adult	DOSAGE: Child (Age >28 Days)	Precautions and Comments[a]
Aminoglycosides			
Gentamicin or tobramycin	2 mg/kg loading dose, then 5 mg/kg/day IV every 8 to 12 hours, *or* 5 to 7 mg/kg IV once daily	Same as adult	Decrease maintenance dose in elderly or with renal dysfunction
Amikacin	Conventional: 10 mg/kg IV load then 5–7.5 mg/kg every 8 hours High-dose extended interval: 15 mg/kg every 24 hours	Same as adult	Only active against aerobic gram-negative bacilli Some gram-negative bacilli may be resistant to gentamicin and tobramycin
Extended-Spectrum Penicillins and β-Lactamase Inhibitors			
Piperacillin-tazobactam	4.5 g IV every 6 to 8 hours (depending on extended infusion)	240 to 400 mg/kg/day IV of piperacillin component every 6 hours	Broad activity against gram-positive organisms, *Pseudomonas aeruginosa,* and anaerobes
Cephalosporins			
Cefepime	1 to 2 g IV every 6 to 8 hours	150 mg/kg/day IV every 8 hours	Active against many gram-positive organisms, *P. aeruginosa* and many resistant gram-negative bacilli, but not anaerobes
Carbapenems			
Imipenem-cilastatin	0.5 to 1 g IV every 6 hours	60 to 100 mg/kg/day IV every 6 hours	Adjust dose in elderly or with renal dysfunction. Reduces VPA levels
Meropenem	1 g IV every 8 hours	60 to 120 mg/kg/day IV every 8 hours	Seizures are associated with imipenem May be cross-allergenic with penicillin Broad-spectrum activity against gram-positive and gram-negative organisms, including *P. aeruginosa* and anaerobes
Other			
Aztreonam	1 to 2 g IV every 8 hours	120 mg/kg/day IV every 6 hours	Active against gram-negative bacilli including *P. aeruginosa* Not active against gram-positive organisms or anaerobes Safe in penicillin-allergic patient
Vancomycin	15 mg/kg IV every 12 hours	40 mg/kg/day IV every 6 to 12 hours	Infuse during 2 hours (flushing, hypotension with rapid infusion). Rapid infusions associated with flushing and hypotension (red man syndrome)
Amphotericin B	0.5 to 1.5 mg/kg/day IV once daily	Same as adult	Refer to infectious disease or pharmacology text
Acyclovir			Infuse during 1 hour
• Herpes simplex, mucocutaneous[b]	5 mg/kg IV every 8 hours *or* 400 mg PO three times a day	250 mg/m^2 IV every 8 hours *or* 15 mg/kg/day PO every 4 hours	
• Herpes zoster			
• Not severe[c]	800 mg PO five times a day	20 mg/kg PO four times a day	
• Severe	10 mg/kg IV every 8 hours	500 mg/m^2 IV every 8 hours	
• Primary varicella	10 mg/kg IV every 8 hours	10 to 20 mg/kg IV every 8 hours	

[a]Antibiotics require renal/gestational age adjustments.
[b]Alternative for herpes simplex: valacyclovir 1 g two times a day PO.
[c]Alternative for herpes zoster: valacyclovir 1 g three times a day PO.
IV, Intravenous; *PO, per os* (by mouth).

active against vancomycin-resistant *Enterococcus* species or methicillin-resistant staphylococci.

For patients who are allergic to β-lactam antibiotics, coverage of gram-negative bacilli, including *P. aeruginosa,* can be provided by aztreonam. Because aztreonam is not active against gram-positive organisms, it should be combined with vancomycin. If anaerobes are suspected (oral, abdominal, or perianal infection) in the β-lactam–allergic patient or in the patient receiving cefepime monotherapy, an anti-anaerobic drug (clindamycin or metronidazole) should be administered. Empirical treatment with intravenous fluoroquinolones is not recommended in the febrile neutropenic cancer patient because of frequent prophylactic use of these agents in the cancer patient, risk for

rapid emergence of resistance in gram-negative bacilli, and predisposition to *C. difficile* infection.[1]

When a focus of infection is identified, empirical therapy should cover the most likely pathogens causing infections at the site (Table 182.1). Patients with pneumonia may need coverage for *Legionella* (azithromycin or a fluoroquinolone), *Pneumocystis* (trimethoprim-sulfamethoxazole), or fungi (amphotericin B, micafungin, voriconazole), in addition to standard antibacterial coverage. Agents effective against anaerobes (clindamycin, metronidazole, meropenem, imipenem, or piperacillin-tazobactam) should be considered for patients with perianal or oral infection and those with abdominal pain, who may have appendicitis, diverticulitis, or typhlitis (neutropenic enterocolitis). Acyclovir should be considered for patients with ulcerative or vesicular lesions who may have herpes simplex or varicella-zoster virus infections. In patients with severe mucositis and FN, meropenem, imipenem, or piperacillin-tazobactam, often combined with vancomycin, are preferred for empirical treatment because of superior efficacy against viridans streptococci.[1]

"Routine" empirical use of vancomycin for all febrile neutropenic cancer patients is not recommended because of concern for the development of vancomycin-resistant organisms.[1,15] Indications for initial empirical vancomycin therapy include serious catheter-related infections (e.g., with hypotension), known colonization with penicillin-resistant pneumococci or methicillin-resistant *Staphylococcus aureus* (MRSA), and positive blood culture for gram-positive organisms before final identification and susceptibility testing.[1,15] Other indications include shock, severe mucositis, prior fluoroquinolone prophylaxis, and institutions in which MRSA, vancomycin-susceptible enterococci, and *S. mitis* are frequent pathogens.[1,15] Patients previously colonized or infected with MRSA, vancomycin-resistant enterococci, extended-spectrum β-lactamase–producing gram-negative bacteria, and carbapenemase-producing organisms may require modifications to initial empirical therapy.[1,7]

Amphotericin B (and its lipid formulations) is the drug of choice for treating invasive fungal infections in patients with neutropenia.[8-10] Due to amphotericin toxicity, micafungin or voriconazole may be considered for treatment of specifiic fungal infections. Up to one-third of febrile neutropenic patients not responding to one week of antibiotics have systemic fungal infections, usually *Candida* or *Aspergillus*.[8-11]

Risk Assessment and Disposition

Febrile neutropenic cancer patients can be classified into high-risk and low-risk groups. Some of the factors associated with high risk include the following: status as an inpatient when fever and neutropenia developed; presence of serious comorbid medical conditions; uncontrolled cancer; acute leukemia; hemodynamic instability; evidence of organ failure; presence of pneumonia, severe soft tissue infection, infection of a central line, abdominal pain, neurologic or mental status abnormalities; and neutropenia expected to last more than 10 days.[16-17] These patients should be treated in the hospital with intravenous antibiotics.

Outpatient empirical antibiotic therapy is safe and efficacious in carefully selected FN adults who are not at high risk for medical complications.[1,7,16-17] The Multinational Association for Supportive Care in Cancer (MASCC) risk index score (available at www.mascc.org/mascc-fn-risk-index-score) is an easy to use, validated clinical prediction rule for classification of low-risk adults (Table 182.2, Box 182.3). However, it should not be used as the sole factor to decide on low-risk status or outpatient management.[1,7,16-17] Three clinical practice guidelines, including the Infectious Diseases Society of America, the American Society of Clinical Oncology, and the National Comprehensive Cancer Network, support outpatient or short-stay oral antibiotic therapy in carefully selected low-risk patients with FN.[1,7,16] The only oral antibiotic regimen recommended is a fluoroquinolone *plus* amoxicillin-clavulanate (or *plus* clindamycin in penicillin-allergic patients).[1]

TABLE 182.2 Multinational Association for Supportive Care in Cancer Scoring System to Identify Patients With Cancer and Febrile Neutropenia at Low Risk of Medical Complications

Characteristic	Weight[a,b,c]
Burden of febrile neutropenia with mild or no symptoms	5
No hypotension (systolic blood pressure >90 mm Hg)	5
No chronic obstructive pulmonary disease	4
Solid tumor or hematologic malignancy with no previous fungal infection	4
No dehydration requiring parenteral fluids	3
Burden of febrile neutropenia with moderate symptoms	3
Outpatient status	3
Age younger than 60 years old	2

[a]Maximum score is 26. Higher score is better.
[b]Scores ≥21 indicate a low risk for medical complications.
[c]Burden of febrile neutropenia: The general clinical status of the patient as influenced by the febrile neutropenic episode is evaluated on the following scale: no or mild symptoms (score of 5); moderate symptoms (score of 3); and severe symptoms or moribund (score of 0). Choose only one score for burden of febrile neutropenia symptoms (5, 3, or 0).

BOX 182.3 Considerations for Outpatient Management of Cancer Patients With Febrile Neutropenia

Adult patients may be considered for outpatient therapy if:

- Patient has a MASCC score ≥21.
- Patient is medically stable without acute or chronic organ dysfunction or comorbid conditions and does not have acute leukemia.
- No focus of infection identified: Patient does not have pneumonia, infection of a central line or a severe soft tissue infection, and does not have acute abdominal pain or an intra-abdominal infection.
- Patient has access to a telephone and transportation to return to hospital available 24 hours a day and has a caregiver at home.
- Patient has a history of compliance with follow-up and treatment protocols.
- Patient is not on fluoroquinolone prophylaxis and there is a low prevalence of fluoroquinolone-resistance in the community.
- Patient's oncologist agrees to outpatient management.
- The emergency clinician should contact the patient's oncologist and/or an infectious diseases specialist before considering outpatient therapy.

Patients being considered for outpatient therapy should be observed for at least 4 hours in the ED (or in an ED observation unit) after the initial antibiotic dose, which should be administered intravenously as soon as possible after initial cultures are obtained.

The only recommended outpatient oral antimicrobial therapy for these patients is ciprofloxacin or levofloxacin *plus* amoxicillin/clavulanate (or *plus* clindamycin for those with penicillin allergy).

ED, Emergency department; *MASCC,* Multinational Association for Supportive Care in Cancer.

BOX 182.4 Unique Considerations for Evaluation and Management of Children With Febrile Neutropenia and Cancer

- Because intravenous catheter infections are a common source of fever in children, obtain blood cultures from *all* lumens of indwelling central venous catheters.
- Obtain a peripheral vein blood culture if possible (may not be possible in small children).
- Obtain urinalysis and urine culture, because urinary tract infections are frequent causes of fever in neutropenic children.
- Obtain chest radiograph only in children with symptoms or signs of respiratory disease.
- Initiate monotherapy with an anti-pseudomonal beta-lactam or carbapenem as empirical therapy (cefepime, meropenem, imipenem-cilastatin, or piperacillin-tazobactam) as soon as cultures have been obtained. Avoid empirical use of ceftazidime monotherapy.
- Some low-risk children with febrile neutropenia who have access to close follow-up may not require hospital admission and may be discharged home after a period of observation, but this should only be attempted after consultation with the patient's oncologist and/or an infectious diseases specialist.
- Transfer of the pediatric cancer patient with febrile neutropenia to a hospital experienced in the management of children with cancer is recommended.

Recently, a second prognostic score has been developed and is termed the Clinical Index for Stable Febrile Neutropenia (CISNE). Importantly, it was derived and validated in patients with FN and solid tumor malignancy. Recent studies suggest that the CISNE and MASCC scores both perform well in FN patients with solid tumor malignancy.[1,18-19]

In the setting of a favorable MASCC score, the decision to pursue outpatient therapy for FN should be made in conjunction with the patient's oncologist when the patient lives within 60 minutes of a hospital, can seek care reliably, has the assistance of a caregiver at home, no barriers to obtaining antibiotics, and agrees to return for outpatient visits. While numerous criteria should be met for outpatient management, avoiding inpatient admission and exposure to nosocomial pathogens is advantageous for low-risk patients.[1]

Children With Cancer and Febrile Neutropenia

Box 182.4 lists unique considerations in the evaluation and management of children with cancer and febrile neutropenia.

Non-Neutropenic Conditions in the Cancer Patient

The Solid Organ Cancer Patient Without Neutropenia

Most solid organ cancer patients who have fever and infection are not neutropenic. Infections in these patients may occur after surgical procedures and can include wound infection, deep abscess, or perforated viscus. Infections may be associated with central venous or urinary catheters, stents, and prosthetic devices. In addition, solid tumor patients with large tumor lesions may have obstructive infections (e.g., bronchus, bile duct, or ureter). The spectrum of microorganisms includes a wide variety of community-acquired organisms (bacterial, fungal, and viral), as well as nosocomial multi-antibiotic–resistant pathogens.

Prompt initiation of antimicrobial therapy in the febrile non-neutropenic solid cancer patient is not always indicated. In febrile non-neutropenic cancer patients who are not ill-appearing and have no identified focus of infection, it may be appropriate to obtain culture specimens and to observe the patient. After consultation with an oncologist, some patients can be discharged home with close follow-up. Indications for urgent antibiotics include signs of sepsis, mental status changes, lactic acidosis, shock, abdominal pain, history of splenectomy, and identification of a focal site of infection.[1,7]

Impaired Cell-Mediated Immunity

The T-cell defects resulting from impaired CMI in cancer patients usually result from cancer chemotherapy or corticosteroid treatment. The cancer itself impairs CMI in patients with Hodgkin disease, non-Hodgkin lymphoma, and hairy cell leukemia.

Bacterial Infections. *L. monocytogenes* is one of the more common bacterial organisms infecting cancer patients with impaired CMI. *Listeria* infection is also seen in patients with organ transplants, diabetes, cirrhosis, AIDS, late pregnancy, and those receiving high-dose corticosteroids or biologic therapies. No early characteristics distinguish *Listeria* infection from bacteremias caused by other organisms. Meningitis, which may be accompanied by cerebritis or brain abscess, is the most common focus of infection and may manifest with personality changes or focal neurologic signs. Cerebrospinal fluid examination frequently does not reveal the organism on Gram stain, but protein is elevated and pleocytosis is present. Ampicillin is the treatment. Trimethoprim-sulfamethoxazole is an alternative for patients with penicillin allergy. Vancomycin is not effective in the treatment of *Listeria* infections even when in vitro susceptibility is shown. Cephalosporins, such as ceftriaxone, are not active against *Listeria*. If meningitis is suspected, empiric ampicillin is recommended in any patient with impaired CMI regardless of age.

Infections caused by *Salmonella* species are common in patients with impaired CMI and usually are manifested with fever. Enteritis may or may not be present. Bacteremia can result in infection of bones, joints, central nervous system, and endovascular devices. Multidrug-resistant *Salmonella* species are increasing. Treatment usually includes a third-generation cephalosporin, like ceftriaxone, or a fluoroquinolone because many isolates are resistant to ampicillin and trimethoprim-sulfamethoxazole.

Patients with solid tumors, lymphoma, and leukemia (especially hairy cell leukemia) are at increased risk for pneumonia from *Legionella* species, with the highest risk in cancer patients receiving high-dose corticosteroids. Non-*pneumophila* species of *Legionella* (*Legionella micdadei* and *Legionella bozemanii*) are particularly common in these patients. Clinical and radiographic manifestations of *Legionella* infection in the immunocompromised patient often differ from those in the immunocompetent host. For example, pleuritic chest pain may be a prominent symptom in the immunocompromised patient and may mimic pulmonary embolism. These patients can have fever without any other symptoms of pneumonia despite the presence of radiographic pulmonary infiltrates. In addition, the chest radiograph may reveal an expanding pulmonary nodule or cavitation of a nodule or infiltrate rather than the usual lower lobe alveolar filling defects. Hyponatremia with a serum sodium less than 130 mEq/L [mmol/L] is particularly common.[20] Although gastrointestinal and neurologic findings are common in patients with *Legionella* infections, these are not more common in patients with *Legionella* than in other causes of pneumonia.[20] The treatment of choice for immunocompromised patients with suspected *Legionella* infection is a respiratory fluoroquinolone or azithromycin.

Nocardiosis is an uncommon but often severe bacterial infection caused by a weakly acid-fast gram-positive branching filamentous rod. It occurs in cancer patients, in those receiving high-dose corticosteroids, and in others with defective CMI. Subacute pneumonia with nodular infiltrates is the most common manifestation, usually without fever.[21] *Nocardia* may also produce cellulitis, subcutaneous abscesses, meningitis, and brain abscesses. Diagnosis requires biopsy, tissue stains, and culture. Treatment is with sulfonamides often combined with other agents.

Mycobacterial Infections. Tuberculosis and other mycobacterial diseases may produce severe disease in those with defective CMI and be manifested as fever of undetermined origin, pneumonia, lymphadenopathy, meningitis, or skin lesions. It is easily mistaken for signs caused by the

patient's underlying disease or treatment. Disseminated nontuberculous mycobacterial infections are more common in patients with hairy cell leukemia or chronic myelogenous leukemia.

Fungal Infections. Infections with *Cryptococcus neoformans* and *Cryptococcus gattii* occur in patients with Hodgkin and non-Hodgkin lymphoma, chronic myelogenous leukemia, and chronic lymphocytic leukemia, especially those taking high-dose corticosteroids.[22] Patients with HIV infection, solid organ transplants, diabetes, renal insufficiency, and cirrhosis are also at risk, as are patients receiving prolonged high-dose corticosteroids for connective tissue diseases. Meningitis is the most common manifestation, often with the insidious onset of low-grade fever and subacute and often intermittent headache. Many other organ systems can become infected, including the lungs, skin, bones, and joints. Diagnosis is made by measuring cryptococcal antigen in the serum and cerebrospinal fluid, fungal cultures, and tissue biopsy. An opening pressure should be measured when obtaining cerebrospinal fluid in the evaluation of *Cryptococcal* meningitis as it is frequently elevated due to obstructive hydrocephalus by the *Cryptococcal* capsule.

Impaired CMI may result in reactivation of *Histoplasma capsulatum* and *Coccidioides immitis* with resultant disseminated disease. Infections with *Candida* species are also common in cancer patients with defective CMI, but disseminated disease is less likely than in patients with neutropenia. Invasive aspergillosis may develop in cancer patients receiving high-dose corticosteroids but not as commonly as in those with organ transplants or prolonged neutropenia.

Pneumocystis jirovecii (formerly *carinii*) pneumonia is most common in patients with AIDS, leukemia, lymphoma, and solid tumors taking high doses of corticosteroids. The presentation is often indolent and is characterized by progressive malaise, dyspnea on exertion, and a multitude of potential chest radiograph abnormalities.[23] Patients classically have hypoxia with ambulation which can raise clinical suspicion of pulmonary embolus.[23] High-risk patients (e.g., bone marrow transplant) may take antibiotic prophylaxis consisting of trimethoprim-sulfamethoxazole.

Parasitic Infections. Reactivation of central nervous system infection with the protozoan *T. gondii* occurs most often in patients with hematologic cancers and in patients with HIV. *Strongyloides stercoralis,* an intestinal nematode, is the only helminthic organism producing severe infection in patients with deficient CMI, almost exclusively in those receiving high-dose corticosteroids. Larvae of the parasite disseminate from the intestines to the lungs and other organs, including the central nervous system and skin, causing the *Strongyloides* hyperinfection syndrome, with very high mortality. Wheezing, cough, dyspnea, hemoptysis, and hemorrhagic rash are common. Chest radiographs may show focal or diffuse infiltrates. Dissemination is often accompanied by bacterial infection, usually caused by enteric gram-negative bacilli carried by the parasites from the intestinal tract. Diagnosis is made by examining stool, sputum, tissue or fluid obtained by bronchoscopy or endoscopy, or cerebrospinal fluid for larvae of the parasite. The treatment of choice is oral ivermectin.

Viral Infections. The most common viruses producing serious infections in cancer patients with defective CMI are varicella-zoster, herpes simplex, and cytomegalovirus. Visceral dissemination is common in primary varicella (chicken pox) in nonimmune immunocompromised children and adults, with development of pneumonia, encephalitis, hepatitis, and hemorrhagic lesions. When a nonimmune immunocompromised patient is exposed to varicella, varicella-zoster immune globulin (VariZIG in the United States) should be administered as soon as possible after exposure, up to 10 days postexposure, to ameliorate the disease.[24] Herpes zoster infection is common in cancer patients, particularly those with Hodgkin and non-Hodgkin lymphoma and leukemia. Disease usually remains localized to the primary dermatome, but dissemination occurs in approximately 11% of patients.[25] Dissemination is usually limited to the skin, but visceral involvement (lung and liver) occasionally occurs. Skin lesions in primary varicella or zoster often become hemorrhagic in these patients.

Reactivation of herpes simplex virus is common, resulting in severe mucocutaneous infection in oral or genital areas. Spread may occur to the esophagus, lungs, or other organs. Herpetic lesions in cancer patients tend to be larger and deeper than those in the immunocompetent patient. Acyclovir given intravenously is the treatment of choice for varicella-zoster and herpes simplex infections in immunocompromised patients, but some stable patients may be treated with oral valacyclovir.[22]

Cytomegalovirus infection may occur in cancer patients treated with corticosteroids. Measles virus, although uncommon, may produce severe infection in those with defective CMI. Fever, rash, pneumonia, and encephalitis are common manifestations. Immune serum globulin may be given after exposure to ameliorate disease. Common community respiratory viruses, such as respiratory syncytial virus, influenza, and adenovirus, may produce severe or fatal pneumonia.

Influenza vaccination is indicated for all patients who are immunocompromised, and vaccination may attenuate symptoms and reduce mortality even if the patient develops influenza.[23] Influenza may mimic bacterial pneumonia, and patients with CMI who are diagnosed with influenza pneumonia should be concurrently treated for bacterial pneumonia due to the likelihood of coexisting disease.[26] Fever is not necessary to suspect or diagnose influenza. Recent Infectious Diseases Society of America (IDSA) guidelines recommend testing any patient who presents to the ED with influenza-related symptoms.[26] All patients with CMI would fall into the higher risk category for influenza-related morbidity and mortality, which warrants early treatment with oseltamivir.[26]

Humoral Immune (B-Cell) Defects

Hypogammaglobulinemia is common in patients with chronic lymphocytic leukemia and multiple myeloma. Low immunoglobulin levels predispose to infections with encapsulated bacteria, such as *S. pneumoniae, H. influenzae,* and *N. meningitides.*[24] Pneumonia is the most common manifestation, but sepsis, otitis media, cellulitis, and urinary tract infection may occur. After receiving cytotoxic agents and corticosteroids for treatment, these patients become susceptible to infections associated with impaired CMI, as well as bacterial infections caused by *S. aureus* and gram-negative bacilli, often with high mortality.[24] Regular infusions of intravenous immune globulin may decrease the incidence of infection but do not prolong survival. Patients should receive pneumococcal vaccine, but many do not respond.

Disruption of Natural Barriers

Disruption of natural anatomic barriers (mucous membranes and skin) by ulcerating tumors, chemotherapy, radiation therapy, diagnostic and therapeutic procedures, and catheters can lead to infection by gram-positive and gram-negative organisms, including anaerobes. Oral mucositis, a debilitating and intensely painful condition associated with radiation therapy and high-dose chemotherapy, frequently results in serious local and systemic infections, including life-threatening sepsis with viridans streptococci. Cancers may cause partial or total obstruction of body lumens and cavities, as may swelling and scarring from radiation therapy. Bronchial obstruction by tumor can lead to pneumonia. Obstruction of the urinary tract may result in infection. Gastrointestinal tract obstruction can lead to perforation and peritonitis.

Opportunistic Infections Mimicking Neoplasm

Infectious agents can produce laboratory, radiologic, or physical findings that resemble those caused by the spread of tumors. For example, mass lesions in the brain caused by *Nocardia* or *Toxoplasma* can

be mistaken for cancer metastases. *Aspergillus, Mucor, Rhizopus,* and related fungi invade blood vessel walls and produce thrombosis, which may result in Budd-Chiari syndrome (hepatic vein obstruction), nephrotic syndrome, or oculomotor palsy that may be misattributed to the spread of tumor. Renal vein thrombosis can be caused by infection with gram-negative bacilli. *Candida* fungus balls may develop in one or both ureters, producing a picture of postrenal obstructive uropathy. *Histoplasma, Pneumocystis, Legionella, Aspergillus, Nocardia,* and other organisms can produce pulmonary nodules and be mistaken for pulmonary metastases.

Diabetes

Diabetic patients have increased susceptibility to infection because of defects in immune function, excess substrate for fungal and bacterial growth, vascular insufficiency related to microangiopathy and atherosclerosis, and sensory neuropathy that leads to wound neglect (see Chapter 115). Neutrophil and monocyte-macrophage functions are directly impaired in diabetic patients. These defects are exacerbated by hyperglycemia and improved by tight glucose control. Cellular immunity is affected by a decrease in proliferative response but otherwise remains primarily intact. As immunity is impaired, people with diabetes may present with infections but have atypical symptoms in their presentation. For example, they may present with malaise but lack fever, or may present with purulent wound discharge without pain.

Most diabetic wounds are appropriately managed with preventive techniques and outpatient wound care. Infectious complications include cellulitis, necrotizing skin and soft tissue infection (NSSTI), and osteomyelitis. The decision to treat with antibiotics should be based on signs and symptoms of infection such as purulent drainage, wound inflammation, pain, or systemic symptoms. Mild to moderate wound infections should target gram-positive cocci such as staphylococci and streptococci. These may be treated with oral agents such as cephalexin 500 mg every 6 hours or trimethoprim-sulfamethoxazole 160 mg/800 mg twice a day in the outpatient setting with close surgical follow-up.[25] More severe infections, deeper infections, or infections in patients with risks for multidrug-resistant organisms (MDRO) should be treated with broad-spectrum parenteral antibiotic agents and surgical consultation. X-ray can be specific for deeper infection, but CT is more sensitive for NSSTI and MRI is more sensitive for osteomyelitis. Biomarkers such as CRP and ESR may be elevated in infection but are not specific. Uninfected ulcers do not benefit from antibiotic therapy.[25] Wound swabs may assist in guiding antibiotic therapy in superficial wounds but become unreliable in deeper infection.[25] Procalcitonin testing has shown promise in differentiating infected from noninfected wounds in some small studies,[27] but its role in the ED is still to be determined.

Other infections often attributed to diabetes include: urinary tract infections including emphysematous cystitis and pyelonephritis; emphysematous cholecystitis; polymicrobial NSSTIs, especially involving the perineum (Fournier gangrene) and lower extremities; malignant otitis externa caused by *P. aeruginosa;* and the rare rhinocerebral zygomycosis caused by *Rhizopus* and *Mucor* species. The combination of organism risk, poor circulation, and impaired immune function often leads to an increased risk of tuberculosis. Patients with diabetes are at increased risk of candidiasis, including vulvovaginal candidiasis in women, psoas abscess, spinal epidural abscess, postoperative surgical site infections, and *S. aureus* and gram-negative pneumonia. Diabetic patients with pneumococcal pneumonia are more likely to become bacteremic and to have a higher mortality rate. With increased risk, diabetic patients often need broad-spectrum parental agents. Glycemic control is crucial in reestablishing proper immune function to promote healing.

Alcohol Use Disorder and Cirrhosis

Alcohol consumption predisposes to infection through direct suppression of the immune system, alterations in blood flow, depression of mental status, and delay in seeking medical care. Patients with alcohol use disorder also often have coexisting malnutrition, cigarette smoking, and chronic lung disease. Alcoholic cirrhosis results in deficient hepatic clearance and destruction of bacteria by reticuloendothelial cells, as well as splenic hypofunction. Complement deficiency occurs because the liver is the primary site of C3 synthesis. Neutrophils show impaired recruitment to infected sites and defective chemotaxis and phagocytosis. Cellular immune deficiency occurs and is often exacerbated by malnutrition. Bactericidal activity of IgM antibodies against gram-negative pathogens such as *E. coli* and *H. influenzae* is decreased.

Acute ethanol intoxication is associated with granulocytopenia and diminished leukocyte mobilization that is reversible with abstinence. Additionally, intoxication inhibits respiratory reflexes and mucous clearance leading to aspiration; concomitant withdrawal seizures or encephalopathy increase this risk. Prior data showed increased oropharyngeal colonization by gram-negative bacteria in alcoholics, but recent studies have demonstrated no increased risk of gram-negative infections in individuals with alcohol use disorder.[28] Recent guidelines from the American Thoracic Society and the IDSA include alcoholism as a comorbidity for combination antibiotic therapy in community-acquired pneumonia but recommend no deviation in routine inpatient therapy and no routine coverage of aspiration in the absence of empyema or lung abscess.[29]

Common infections in patients with cirrhosis include spontaneous bacteremia and sepsis caused by *E. coli, K. pneumoniae, Salmonella,* streptococci, *Vibrio vulnificus,* and *Aeromonas;* spontaneous bacterial peritonitis, usually caused by *E. coli, K. pneumoniae, S. pneumoniae,* or enterococci; pneumonia related to pneumococci, gram-negative bacilli *(E. coli, K. pneumoniae,* and *H. influenzae),* and anaerobes; tuberculosis; meningitis caused by *S. pneumoniae* and *L. monocytogenes;* and skin and soft tissue infections with *S. aureus,* streptococci, and gram-negative bacilli. Cirrhotic patients who present to the ED after a recent hospitalization often have health care–associated infections, including catheter-related and *C. difficile* infections, spontaneous bacteremia, urinary tract infections, and pneumonia, often with high mortality.

In cirrhotic patients with ascites and fever, abdominal pain, or concern for infectious encephalopathy, spontaneous bacterial peritonitis should be ruled out with ascitic fluid sampling and cell count. Patients with a PMN count of 250 cells/mm^3 or greater should be treated empirically with broad-spectrum coverage, such as ceftriaxone or ciprofloxacin, until cultures result. Additionally, patients receiving treatment for SBP have been shown to have increased survival and decreased incidence of hepatorenal syndrome when administered albumin 1.5 g/kg at presentation and 1 g/kg on day 3 of treatment.

Alcoholic patients with leukopenia may have delayed inflammatory responses; these patients should be watched more carefully and may warrant a higher level of care when infected. For example, leukopenic alcoholic patients with community-acquired pneumonia are more likely to have a delayed manifestation of septic shock or ARDS.

Renal Failure

Infections are a significant cause of death in patients with chronic renal failure and are the second most common cause of mortality after coronary artery disease. These patients often have diabetes, which increases their risk for severe morbidity and mortality from infections. Disruption of cutaneous barriers at vascular access sites and peritoneal dialysis catheter sites and numerous immune system defects are responsible for the increased incidence of infection. Uremic pruritus with excoriation, epidermal and sweat gland atrophy, dryness, and vesicular eruptions

also compromise the cutaneous barrier. Reduced renal clearance of unknown toxins, nutritional deficiencies, and administration of immunosuppressive medications lead to aberrant immune regulation early in the course of renal failure.

Chronic kidney failure leads to a state of generalized immune hyporesponsiveness. Neutrophils show reduced mobility, chemotaxis, adherence, phagocytosis, and intracellular bactericidal activity. Leukopenia is common. CMI is severely impaired, with decreased activation and proliferation of T lymphocytes and reduced NK cell activity, which cannot be reversed by hemodialysis. Furthermore, humoral immunity is adversely affected, resulting in deficient production of specific IgG subclass antibodies. Inadequate response to vaccines is typical but can be improved by reinforced vaccination schedules, increased vaccine dosage, and adjunct immunomodulators. Additional predisposing factors to infection in uremic patients include low serum albumin, iron overload, increased intracellular calcium, circulating low-molecular-weight uremic toxins, metabolic acidosis, circulating inhibitors to chemotactic factors, decreased production of endogenous pyrogens, and invasive vascular procedures for dialysis access.

Severe infections with antibiotic-resistant bacteria are common, and empirical therapy for a suspected serious infection should include broad-spectrum antimicrobials active against MRSA and antibiotic-resistant gram-negative bacilli. Skin and soft tissue infections, especially those caused by *S. aureus,* are particularly severe in diabetics and in those with peripheral vascular disease or peripheral neuropathy. Vascular access site infections are usually caused by *S. aureus* but occasionally by gram-negative bacilli and enterococci. Patients using central venous catheters for dialysis have much higher rates of sepsis compared with fistulas or grafts. Infections of dialysis access sites, often due to *S. aureus,* are life-threatening and frequently associated with hematogenous seeding of infection to distant sites, including osteomyelitis (usually involving the ribs or thoracic vertebrae), endocarditis, meningitis, epidural abscess, and septic arthritis. Pneumonia may be severe, and there is an increased incidence of *Legionella* pneumonia. Pneumonia may be challenging to diagnose by chest radiograph in these patients due to changing pulmonary fluid dynamics. Because mortality is high, early antimicrobial treatment should be administered after appropriate cultures have been obtained if acute pneumonia is considered, considering antimicrobial coverage for health care–associated pathogens.

Tuberculosis and fungal infections caused by *Candida* species, *Cryptococcus, Histoplasma,* and *Coccidioides* occur with increased frequency. Diagnosis of tuberculosis may be difficult because of nonspecific symptoms and increased incidence of extrapulmonary disease. In addition, *C. difficile* infection occurs more frequently and is more severe with high mortality.

Infections of the urinary tract are more prevalent in patients who continue to produce urine, with urinary bladder catheterization being the most frequent predisposing factor. There is a poor correlation between the presence of pyuria and urinary tract infection in these patients. *Candida* infection of the urinary tract may develop in patients with chronic renal failure treated with broad-spectrum antibiotics.

Antibiotic selection and dosing should consider a kidney disease patient's lack of renal clearance. If a renally cleared regimen is selected, agents may often be dosed with dialysis treatments. In patients who are otherwise well and nontoxic but require parenteral agents due to drug resistance, this may be facilitated by outpatient dialysis if clinical stability and logistics allow.

Up to two-thirds of patients receiving chronic peritoneal dialysis have peritonitis in their first year, and one-third may be forced to discontinue dialysis because of recurrent infections. *S. aureus* and *S. epidermidis* predominate, followed by streptococci, gram-negative bacilli, and *Candida* species. Fortunately, peritoneal dialysis patients have much lower rates of sepsis than those on hemodialysis. Patients presenting with fever, abdominal pain, or signs of local site infection should be evaluated for peritonitis including testing of effluent cell count and culture. Those with cell counts greater than 100 WBC/mL or PMNs greater than 50% for individuals using night-time dwells should be treated with renally dosed vancomycin and ciprofloxacin. Patients with recurrent infections or candidal infections will likely need to transition to hemodialysis.

Splenectomy, Hyposplenia, and Functional Asplenia

The spleen is the most crucial organ in the reticuloendothelial system and is the primary site for IgM synthesis, the first early immune response of the body. Opsonin production in the spleen facilitates phagocytosis of bacteria by intracellular macrophages. Patients without a spleen also have decreased production of neutrophils, NK cells, and immunomodulating cytokines.

The spleen is the principal site of clearance of *S. pneumoniae* from the blood. Splenectomy or functional asplenia predisposes to overwhelming pneumococcal infection and fulminant infection with other encapsulated organisms (*H. influenzae, N. meningitidis,* and *Capnocytophaga canimorsus* after dog bites) and gram-negative bacilli *(E. coli* and *P. aeruginosa).*[28,29] Asplenic patients who become infected with *Babesia microti,* a malaria-like protozoan transmitted by tick bite in the United States, may develop severe and often fatal hemolysis (see Chapter 123). Human granulocytic anaplasmosis (formerly ehrlichiosis), another tickborne infection, is severe and sometimes fatal in asplenic patients. In addition, the gram-negative coccobacillus *Bordetella holmesii* produces a non–life-threatening acute febrile illness with bacteremia in patients with asplenia. Pneumococcal sepsis represents 50% to 90% of cases. Most healthy adults who die after fulminating pneumococcal sepsis have had a splenectomy or have a congenitally small or abnormal spleen.

The incidence of overwhelming postsplenectomy sepsis in these patients is low; but when it occurs, the mortality rate is high—especially in children with hematologic disorders. The risk is more significant in children than in adults, with children younger than 2 years old at greatest risk. The risk is highest in the first few years after splenectomy but persists throughout life into old age. People undergoing splenectomy for a hematologic disorder or lymphoma are at much higher risk for overwhelming postsplenectomy infection than are those undergoing splenectomy for trauma. This is probably because of the occurrence of splenic implants (splenosis) or accessory spleens in traumatized patients. Patients with functional asplenia from sickle cell anemia or thalassemia major are at high risk for overwhelming bacterial infections.

Functional hyposplenism occurs in a variety of conditions besides sickle cell disease, including sickle cell–hemoglobin C disease, ulcerative colitis, celiac disease, sarcoidosis, amyloidosis, rheumatoid arthritis, and SLE. The presence of anatomic or functional hyposplenism may be recognized by the finding of Howell-Jolly bodies in red blood cells on a peripheral blood smear.

When overwhelming postsplenectomy infection occurs, often no obvious source of infection is found. Prodromal symptoms such as fever, rigors, malaise, myalgias, headache, vomiting, and diarrhea may be present for 1 or 2 days. Patients seen at this time may be misdiagnosed as having a viral illness, gastroenteritis, or food-borne illness. Abrupt deterioration then occurs over hours, with rapid progression to septic shock with disseminated intravascular coagulation, purpura, and multiorgan dysfunction. The mortality rate is high (50% to 70%), with younger children having the highest mortality rate. In addition, meningitis without overwhelming infection or shock is a common

presentation of pneumococcal infection in asplenic patients. When fever develops in a person at risk for this disorder, treatment with an antimicrobial agent effective against *S. pneumoniae* should be initiated without delay. After a blood culture is performed, adults and children should receive ceftriaxone at meningitic doses, with the addition of vancomycin in areas where penicillin resistance is prevalent. Clindamycin, levofloxacin, or moxifloxacin are alternatives for patients with severe penicillin allergy. Children with a history of serious penicillin allergy should receive vancomycin plus levofloxacin.

Use of pneumococcal vaccine in patients at risk is especially important now that antimicrobial-resistant *S. pneumoniae* is prevalent, but the efficacy of this vaccine in these patients is unclear. Persons with functional hyposplenism related to severe underlying diseases often respond poorly to pneumococcal vaccination. Asplenic people should be immunized against pneumococcus, *H. influenzae* type b, *N. meningitidis,* and influenza virus. Although there is no evidence to support this, guidelines recommend that children should receive prophylaxis with oral penicillin or amoxicillin up to the age of 5 years and for at least 1 or 2 years after splenectomy, provided they have not had an invasive pneumococcal infection and have received pneumococcal immunizations. Long-term antimicrobial prophylaxis is generally not recommended in adults. These patients should have standby oral antibiotics at home (amoxicillin-clavulanate, levofloxacin, or moxifloxacin) with instructions to self-administer at the first sign of infection, and they should be provided with information and a medical alert bracelet. Fatal pneumococcal infection has occurred in patients immunized with pneumococcal vaccine who were also taking penicillin.

IMMUNOSUPPRESSIVE THERAPY

Corticosteroids

High doses of corticosteroids alter the distribution and function of neutrophils, monocytes, and lymphocytes. Corticosteroids suppress inflammation, impair mobilization of neutrophils and monocytes, inhibit neutrophil adherence, and decrease chemotaxis of neutrophils and monocytes. They also inhibit phagocytosis and intracellular killing, severely impair CMI, inhibit lymphocyte proliferation, inhibit complement activation, and cause hyperglycemia that contributes to infection.

Acute administration of corticosteroids produces marked alterations in circulating leukocyte numbers. Basophils, eosinophils, and monocytes decrease, whereas neutrophils increase. These changes occur within 4 to 6 hours and abate by 24 to 48 hours after a single steroid dose. Lymphocytes (predominantly T cells) redistribute out of the circulation, resulting in lymphocytopenia. Corticosteroid therapy has little effect on serum immunoglobulin levels.

The most common infections occurring in patients receiving high-dose corticosteroids are caused by pyogenic bacteria (*S. aureus,* streptococci, and gram-negative bacilli). Despite the profound depression of CMI in patients taking corticosteroids, these patients generally have few infections commonly recognized as associated with defective CMI. The most common are tuberculosis and severe or disseminated infections caused by varicella-zoster and herpes simplex viruses. Patients receiving moderate doses of corticosteroids for asthma and other disorders are at increased risk for lethal primary varicella infection. Other infections seen with corticosteroid use include those caused by *Listeria, Salmonella, Legionella, Nocardia, Candida, Aspergillus, Cryptococcus, Histoplasma, Coccidioides, Pneumocystis, Toxoplasma, Cryptosporidium,* and *Strongyloides*. Patients with neurologic diseases have much higher rates of infectious complications than do patients with intestinal, hepatic, or renal disease. The infectious complications related to corticosteroid use increase with doses of prednisone equivalents of more than 20 mg/day in adults, with total doses of more than 700 mg, and with treatment longer than 30 days. The risk of adrenal suppression can be decreased by use of prednisone doses less than 7.5 mg/day, administration of doses early in the day, avoidance of split doses, and use of alternate-day dosing.

Corticosteroids decrease leukocyte accumulation at inflammatory sites, and the whole cascade of responses leading to local manifestations of infection is slowed. These effects result in delayed presentation of serious infections. In addition, prolonged administration of corticosteroids results in delayed wound healing. For example, skin sutures should be left 50% to 100% longer than in other patients. Short-term steroid treatment has little effect on wound healing.

Use of corticosteroids greatly increases the risk of hospital admission for complications of diverticular disease.[30] The diagnosis of peritonitis resulting from perforation of colonic diverticula, appendicitis, peptic ulcer, or another primary intra-abdominal condition is particularly challenging. These patients have abdominal discomfort, but they may have few abdominal findings and need rapid investigation for life-threatening abdominal disease. CT scan of the abdomen and pelvis and surgical consultation may be needed emergently in these patients, along with timely administration of broad-spectrum antimicrobials to cover for gram-negative enteric bacilli and anaerobes.

Other Immunosuppressive Medications

Commonly used immunosuppressives include cyclosporine, tacrolimus, sirolimus, mycophenolate, azathioprine, methotrexate, and cyclophosphamide. They treat a wide variety of conditions, including rheumatoid arthritis, psoriasis, nephrotic syndrome, and inflammatory bowel disease, and they are used in the prevention and treatment of organ transplant rejection. These drugs depress immune function, especially CMI. In addition, they have a narrow therapeutic window, wide-ranging toxic side effects, and many significant drug-drug and drug-food interactions. Patients may present for evaluation of symptoms caused by an adverse drug reaction or an infection. Before altering current medications or adding new ones, the emergency medicine clinician must check carefully for drug interactions.

Immunomodulating agents are available to treat a variety of immune-mediated inflammatory diseases, including rheumatoid arthritis, psoriasis, and psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease. Some of these drugs include inhibitors of tumor necrosis factor alpha (infliximab, adalimumab, certolizumab, golimumab, etanercept), inhibitors of interleukins (tocilizumab, anakinra), inhibitor of pyrimidine synthesis (leflunomide), and inhibitor of T-cell activation (abatacept). These agents, particularly the tumor necrosis factor inhibitors, are associated with increased susceptibility to infection, particularly disseminated infection with various intracellular pathogens.[31] Reactivation of latent infection with *M. tuberculosis,* nontuberculous mycobacterial infection, histoplasmosis, and coccidioidomycosis is frequently disseminated and extrapulmonary at presentation. Additional infections seen at increased frequency include cryptococcosis, listeriosis, legionellosis, salmonellosis, aspergillosis, candidiasis, and pneumocystosis. The clinician should be alert to unusual manifestations of infection in patients taking these agents because misdiagnosis and delayed diagnosis increase mortality. These drugs may also cause impaired wound healing, so skin sutures should be left in place longer than usual.

CHAPTER 182: QUESTIONS AND ANSWERS

1. What is the most common site of infection in febrile neutropenic patients?
   - **a.** Gastrointestinal tract
   - **b.** Perineum and anorectal area
   - **c.** Respiratory tract
   - **d.** Skin and soft tissue

Answer: C. The respiratory tract is the most common site of infection, with 25% of infections in the lung and another 25% in the mouth or pharynx (and an additional 5% in the nose or sinuses). Still, all neutropenic patients with fever need to have a thorough physical examination because an undiagnosed infection can cause severe morbidity or mortality.

2. A 49-year-old man with diabetes who has been receiving chemotherapy for non-Hodgkin lymphoma presents with fever and facial pain. Six weeks ago, he was treated with broad-spectrum antibiotics for fever but had negative cultures of blood and urine. He is taking ciprofloxacin as prophylaxis against infection. Examination is normal except for a purple-black lesion on his hard palate that looks like dried blood. A complete blood count shows severe neutropenia. In addition to blood cultures and chest radiography, what action should be taken immediately?
   - **a.** Administer intravenous clindamycin or ampicillin-sulbactam.
   - **b.** Administer intravenous levofloxacin.
   - **c.** Observe in the emergency department (ED) because he may be a candidate for home antibiotic therapy if other laboratory tests are normal, if he appears stable after an initial dose of antibiotics, and if his oncologist agrees.
   - **d.** Obtain a computed tomography (CT) scan of the paranasal sinuses and initiation of intravenous antifungal therapy in the hospital.

Answer: D. This patient has invasive aspergillosis or mucormycosis until proven otherwise. These fungi invade tissues and produce life-threatening necrotizing infections in cancer patients with neutropenia, as well as in diabetic patients, especially those who have received broad-spectrum antibiotics. CT scan will often show deep extension of the infection into the sinuses, orbit, or brain. The initial lesion in the palate or nose is often mistaken for a benign process. The antibiotics listed in A and B are incorrect. The most appropriate empirical antibiotic regimen is cefepime or piperacillin-tazobactam, with or without an aminoglycoside, in addition to antifungal therapy. He is not a candidate for home therapy.

3. A 27-year-old man presents to the emergency department (ED) with acute onset of fever, chills, headache, myalgias, vomiting, mild abdominal cramping, and diarrhea for 8 hours. A splenectomy was performed 15 years earlier when he was treated for lymphoma, which has been in remission since then. He is not taking any medications and has been well. Vital signs are as follows: pulse, 125 beats/min; blood pressure, 110/60 mm Hg; respiratory rate, 20 breaths/min; and temperature, 39.5°C. His mental status is normal and he has mild generalized abdominal tenderness. What is the most appropriate treatment for this patient at this time?
   - **a.** Blood cultures followed by immediate administration of ceftriaxone or cefotaxime, with or without vancomycin
   - **b.** Hydration, antipyretic, antiemetic, and observation in the ED
   - **c.** Immediate hospital admission with observation and frequent abdominal examinations
   - **d.** Lumbar puncture

Answer: A. This patient is at high risk for overwhelming postsplenectomy sepsis, usually caused by *Streptococcus pneumoniae.* Persons who have undergone splenectomy for a hematologic disorder or lymphoma are at much higher risk for overwhelming postsplenectomy infection than are those undergoing splenectomy for trauma. The initial prodromal symptoms may be misdiagnosed as a viral illness, gastroenteritis, or food poisoning before there is abrupt deterioration with development of septic shock with disseminated intravascular coagulation, purpura, and multiorgan dysfunction. After blood cultures are obtained, he should immediately receive antimicrobials active against pneumococci, meningococci, and *Haemophilus influenzae.* He can be investigated for other possible etiologies of his symptoms after this initial critical action is taken.

4. Which answer is correct regarding the diagnosis and management of patients on long-term high-dose corticosteroid therapy?
   - **a.** Acute, short-term administration of high-dose corticosteroids, but not long-term administration, can make the diagnosis of peritonitis particularly difficult.
   - **b.** After laceration repair, sutures should be left in place for 50% to 100% longer than usual.
   - **c.** Complications of chronic corticosteroid use include pancreatitis, pseudotumor cerebri, avascular necrosis of bone, cataracts, myopathy, spontaneous vertebral fractures, psychosis, and hypoglycemia.
   - **d.** Long-term corticosteroid use is frequently accompanied by peripheral blood neutrophilia.

Answer: B. Corticosteroids interfere with wound healing, so sutures need to remain in place longer than is usual for the type of laceration. Despite the profound defect in CMI that occurs with long-term corticosteroid use, infections with organisms associated with defective CMI are unusual. Most serious infections in these patients are caused by pyogenic bacteria, such as *Staphylococcus aureus,* streptococci, and gram-negative bacilli. Both short-term and long-term administration of corticosteroids interfere with the diagnosis of peritonitis. These patients will have poorly localized abdominal discomfort with minimal findings on examination. All the conditions listed in B are associated with chronic corticosteroid use—except hypoglycemia. Corticosteroid use is associated with hyperglycemia, hyperosmolar nonketotic diabetic coma, and diabetic ketoacidosis.

5. A 34-year-old woman on chemotherapy for lymphoma presents to the emergency department with severe oral pain and difficulty swallowing. She has no fevers, cough, abdominal pain, or dysuria. On physical exam, her oral mucosa is erythematous, friable, and edematous. Her labs reveal an ANC of 600 cells/μL. What is the most important next step?
   - **a.** Administer 30 mL/kg of crystalloid for sepsis.
   - **b.** Draw blood cultures and start empirical vancomycin and cefepime.
   - **c.** Start IV analgesics to allow oral rehydration.
   - **d.** Draw blood cultures and start empiric metronidazole and cefepime.

Answer: B. This patient is a neutropenic patient presenting with mucositis. Mucositis is a frequent prelude to viridans streptococcal bacteremia, which can produce sudden onset of acute respiratory distress syndrome, a toxic shock–like syndrome, rash, and pneumonia. Importantly, mucositis predisposes the patient to gram-positive infections, and vancomycin is appropriate in addition to a broad-spectrum gram-negative agent.

The Solid Organ Transplant Patient

Christine E. Koval and Michael P. Phelan

KEY CONCEPTS

- The solid organ transplant recipient's altered anatomy, denervated allograft, and immunosuppression frequently result in atypical disease presentations both related and unrelated to the transplanted organ.
- An understanding of the solid organ transplant recipient's altered anatomy, including vascular and nonvascular anastomoses, is critical to evaluating early post-transplantation complications.
- Rejection can manifest at any point post-transplantation with constitutional symptoms and signs of allograft insufficiency, requiring prompt recognition and augmented immunosuppression to salvage the transplanted organ.
- Timing post-transplantation, the net state of immunosuppression, and ongoing antimicrobial prophylaxis should be incorporated into the evaluation of a solid organ transplant recipient with fever and other concerns for infection.
- In addition to affecting a specific arm of the immune system, each antirejection agent is associated with unique toxicities which may be independently responsible for a solid organ transplant recipient's clinical condition.
- Cardiac allograft vasculopathy, a form of chronic rejection and similar to coronary artery disease in presentation, has emerged as a common complication of orthotopic heart transplantation as transplant recipients live longer.
- Especially in lung transplant recipients with underlying cystic fibrosis or bronchiectasis, prior imaging and culture data should help guide initial management of new respiratory symptoms.
- Recurrent allograft pyelonephritis post-transplantation merits thorough evaluation for ureteral stones and strictures, perinephric abscesses, and urinary retention to identify potentially actionable contributors to infection.
- Hepatic artery thrombosis is an uncommon but devastating early complication of liver transplantation resulting in allograft dysfunction, biliary necrosis, and sepsis if left undetected and untreated.
- Allograft rejection, bacterial or viral enteritis, and altered intestinal transit time can all contribute to diarrhea in the intestinal and multivisceral transplant recipient.
- As chronic corticosteroids are incorporated into immunosuppression regimens for the majority of solid organ transplant recipients, adrenal insufficiency should be considered in the differential of transplant recipients presenting with hypotension and fever.
- In addition to the organ-specific complications described in the sections above, solid organ transplant recipients experience graft-versus-host disease, malignancy, trauma, and psychosocial distress post-transplantation requiring heightened awareness and assembly of multidisciplinary teams.

INTRODUCTION

Solid organ transplantation has undergone significant advancement since the first successful kidney transplant in 1956. In 2019, over 39,000 solid organ transplants were performed in the United States (US).[1] As improvements in medical and surgical treatments allow more individuals to undergo transplantation and increase the life expectancy for transplant recipients, emergency clinicians should expect to encounter patients with illnesses complicated by their history of transplantation. This chapter provides a basic knowledge of organ transplant pathologies and their initial management as well as an appreciation for the utility of consultation with transplant surgeons and other subspecialists.

Pathophysiology

Altered anatomy and ongoing immunosuppression change how transplant recipients present with disease. Allografts are denervated, and thus pain is an unreliable sign of illness. Normal inflammatory and immunologic responses are impaired, limiting the recipient's ability to mount a fever or elevated leukocyte count.[2] Subtle signs and symptoms may be harbingers of serious complications. Transplant-related illness can generally be placed into one of four categories: anatomy, rejection, infection, and drug toxicity (Fig. 183.1). Rejection and infection may present similarly. Changes in baseline allograft function and time since transplantation guide the differential diagnosis. It is imperative to consider infectious risk and drug toxicity when recipients present with issues not directly involving the allograft.

Anatomy

Anatomic complications can involve vascular anastomoses, nonvascular anastomoses, or surgical wounds, and typically manifest within the first few months post-transplantation. Vascular anastomotic complications can include arterial or venous structures. Of these, arterial complications are more acutely devastating. Arterial stenosis or thrombosis may lead to fulminant organ failure. Pseudoaneurysms or mycotic aneurysms can precipitate hemorrhagic shock. Nonvascular organ anastomoses can develop leaks or obstructions from scarring or stent migration, which may provoke acute allograft dysfunction or infection. Early identification of these complications by laboratory investigation of allograft function, imaging, and prompt consultation of transplant specialists is vital to salvage the allograft.

Infection

Infection is the primary cause of mortality after transplantation. Timing since transplantation may predict the most likely pathogens and guide empirical antibiotic selection (Fig. 183.2).

Early Period: 0 to 4 Weeks Post-Transplantation. Infections within the first month of transplantation often relate to postoperative intensive care and surgical site complications.[2] Typical pathogens include nosocomial and multidrug-resistant organisms as well as the transplant recipient's colonizing bacteria identified pre-transplantation. Wound infections, pneumonias, urinary tract infections, and *Clostridioides difficile* colitis are encountered. Bloodstream infection may present without typical signs of sepsis syndrome.

Both donors and recipients undergo extensive serologic and nucleic acid testing pre-transplantation, but expected and unexpected pathogen transmissions from donor to recipient can occur.[2] Expected transmissions in some donor/recipient pairs include cytomegalovirus (CMV), Epstein-Barr virus (EBV), and hepatitis C virus (HCV). Transplant center–specific strategies to monitor and pre-emptively treat such infections effectively prevent end-organ disease. Unrecognized donor infection prior to transplantation can rarely result in unexpected transmissions and lead to tissue-based or systemic illness (e.g., rabies encephalitis, disseminated disease due to fungi, *Mycobacterium tuberculosis* [MTB], or *Strongyloides stercoralis*). While the focus should remain on addressing the more likely postoperative infections in this time period, consideration of donor-derived infections may be instrumental for diagnosis. Unexpected donor derived infections are reported to United Network for Organ Sharing (UNOS) for the safety of other transplant recipients.

Intermediate Period: 1 to 12 Months Post-Transplantation. Infections occurring within the first year of transplantation are generally divided into two categories: reactivation of latent infections and opportunistic infections.

Reactivation of CMV, the most prevalent viral infection observed during this time period, increases the risk of other infections, allograft rejection, and mortality due to CMV's immunomodulatory properties.[2,3] As all transplant centers provide valganciclovir prophylaxis or serum CMV deoxyribonucleic acid (DNA) monitoring, symptomatic CMV infection does not usually emerge until after prophylaxis is stopped.[4] Duration of prophylaxis varies based on the type of allograft, donor/recipient serostatus, and transplant center, but typically ranges from 3 to 12 months post-transplantation. Common presentations of CMV reactivation include "CMV syndrome," characterized by fever, leukopenia, and viremia, and CMV gastrointestinal disease presenting with diarrhea, abdominal pain, or odynophagia with or without viremia. Other tissue-based infections (e.g., hepatitis, pneumonitis) involve their respective allografts, present with viremia, and are differentiated from alternative etiologies by allograft biopsy.

Reactivation of herpes simplex viruses (HSV) 1 and 2 and varicella zoster virus (VZV) can be prevented by valganciclovir or other acyclovir-derivatives. When these agents are stopped beyond the prophylaxis period, transplant recipients may present with localized or disseminated disease including multidermatomal zoster. Facial zoster involving the cornea and multidermatomal zoster require hospital admission. Multidermatomal zoster merits airborne and contact precautions. Timely treatment with acyclovir decreases post-herpetic neuralgia. Some adults may be VZV seronegative at the time of transplantation and are at risk for complications of primary varicella infection, including life-threatening pneumonia and encephalitis with or without classic skin lesions. Treatment includes intravenous acyclovir and sometimes varicella immune globulin.

Effective prophylaxis can also prevent many opportunistic infections post-transplantation. Thus, such infections merit particular consideration in transplant recipients who cannot tolerate prophylactic antimicrobials. For example, trimethoprim/sulfamethoxazole (TMP/

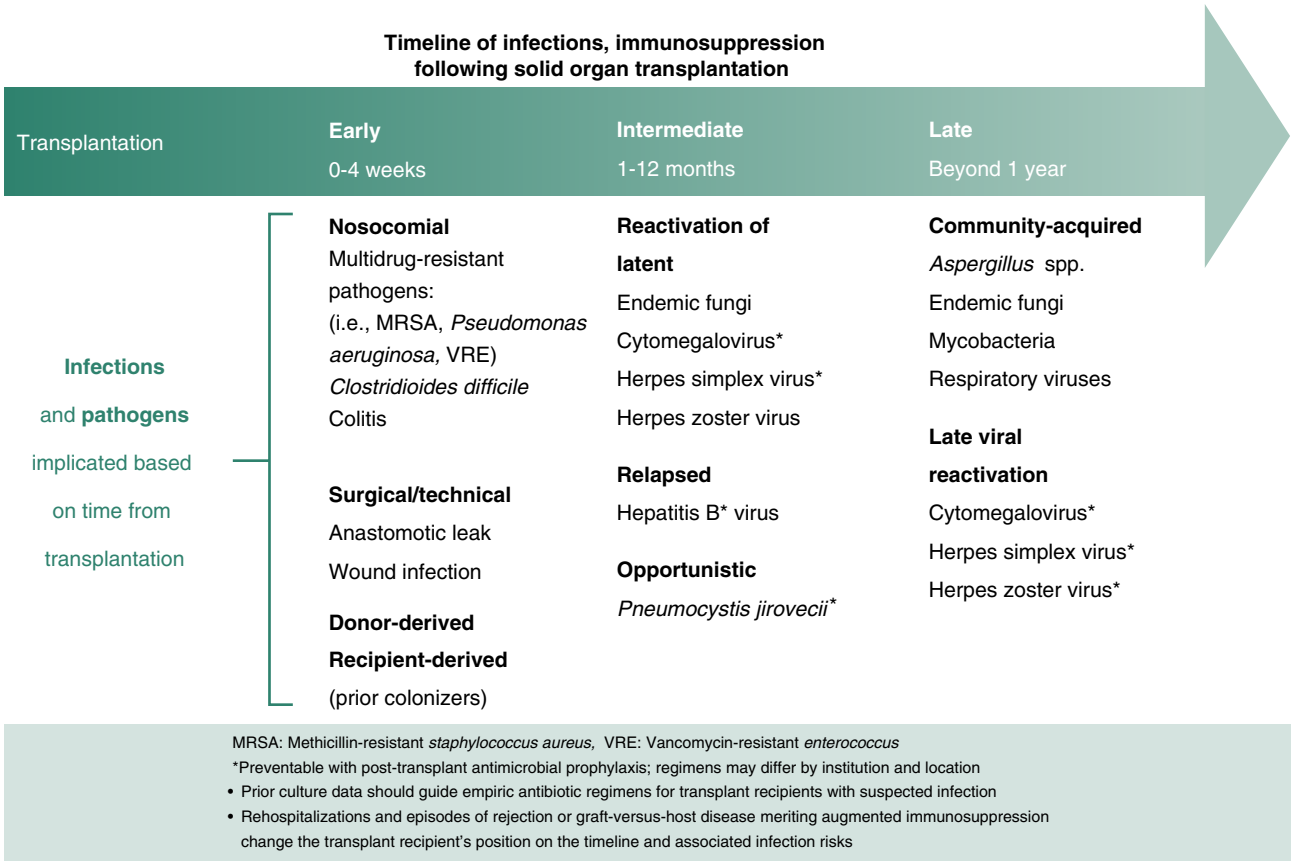

Fig. 183.2 Timeline for infectious complications after solid organ transplantation. (Adapted from: Fishman, J. Infection in organ transplantation. *Am J Transplant.* 2017;17:856-879. Reprinted with permission, The Cleveland Clinic Center for Medical Art & Photography © 2020. All Rights Reserved.)

SMX) is the drug of choice to prevent *Pneumocystis jirovecii* pneumonia (PCP) and concomitantly covers *Toxoplasma*, *Nocardia*, and *Listeria* species. Those with sulfa allergies or significant intolerance may be prescribed alternative agents (inhaled pentamidine, oral dapsone, or atovaquone) for PCP prophylaxis but these alternative agents do not sufficiently protect against these other pathogens.

Pneumocystis typically presents with a subacute, progressive, nonproductive cough and dyspnea and is accompanied by diffuse pulmonary infiltrates on imaging. Diagnosis is best made by molecular testing of induced sputum or bronchoalveolar lavage fluid. Optimal treatment is with 5 mg/kg of TMP/SMX every 6 to 8 hours, based on renal function. There is no proof that adjunctive steroid use is beneficial in patients with PCP but without human immunodeficiency virus (HIV), and high doses of steroids may be harmful, but data are extremely limited.[5]

Mycobacterial infections such as tuberculosis (TB) mostly represent reactivated disease, but can also represent primary disease from a new exposure. Transplant recipients may develop pulmonary TB or disseminated infection, presenting with nonspecific systemic symptoms or evident meningitis, peritonitis, or vertebral infection. Treatment is challenging due to public health concerns, serious drug-drug interactions with immunosuppression, and allograft toxicities.

Lung and liver transplant recipients are at highest risk for fungal infections post-transplantation.[6] Invasive aspergillosis frequently presents as pulmonary nodules but may disseminate to any organ system. Endemic mycoses (histoplasmosis, blastomycosis, and coccidiomycosis) manifesting with fever and respiratory symptoms should be considered based on geographic location and exposure history. These infections are uncommon but are more likely to disseminate from an original pulmonary source.[7] Amphotericin B may be appropriate for disseminated disease but newer azoles can be effective for pulmonary infection and are specifically indicated for certain fungi.

Toxoplasmosis is uncommon in solid organ transplantation. Risk is greatest in toxoplasma seronegative recipients who acquire an organ from a seropositive donor and do not receive TMP/SMX prophylaxis.[8] Toxoplasmosis presents as myocarditis in heart transplant recipients, resembling rejection, but can disseminate to cause pulmonary infiltrates, hepatosplenomegaly, and central nervous system (CNS) disease. Treatment involves intravenous sulfadiazine and pyrimethamine or TMP/SMX.

Cryptococcus neoformans presents as a meningoencephalitis with altered mental status. Serum cryptococcal antigen can diagnose disease. However, lumbar puncture for opening pressure and cryptococcal antigen is required to address CNS involvement. If the opening pressure is greater than 25 mm H_2O, relief of cerebrospinal fluid to reduce the opening pressure to less than 20 mm H_2O, or by 50% if the pressure is extremely high, is immediately warranted.[9] Repeated lumbar punctures or percutaneous drains may be required over subsequent days. Initial antimicrobial therapy for meningoencephalitis includes the lipid formulation of amphotericin and flucytosine.

Strongyloides stercoralis is an intestinal nematode that can present with hyperinfection syndrome, causing a necrotizing hemorrhagic enterocolitis and hemorrhagic pneumonia. Disseminated strongyloidiasis presents with severe abdominal pain, obstructive symptoms, hemorrhage and secondary peritonitis, sepsis from enteric pathogens,

meningitis, and pneumonia. Diagnosis is by stool or bronchoalveolar lavage sample microscopy. Treatment of disseminated strongyloidiasis is with ivermectin and albendazole, although mortality is high if not detected early.[10]

Late Period: Beyond 1 Year Post-Transplantation. One year after transplantation, transplant recipients' susceptibility to infection is predominantly dependent on their net state of immunosuppression. Healthy transplant recipients have a functioning allograft and can generally be maintained on low doses of immunosuppression such that they achieve immunologic control of CMV and other herpes viruses. They face a mildly increased susceptibility to community-acquired infections, such as influenza and pneumococcal pneumonia, and still develop certain reactivated or opportunistic infections (i.e., VZV, TB, aspergillosis) with aging or environmental exposures. They remain at risk for more severe forms of community-acquired infections and endemic mycoses. In contrast, transplant recipients with chronic immune dysregulation require aggressive immunosuppression for rejection and are unable to develop adaptive immunity to CMV. They face high risk for life-threatening opportunistic infections, as well as standard community-acquired and nosocomial infections, and may require prolonged antimicrobial prophylaxis.

Rejection

Rejection is the process by which T cell receptor–mediated pathways lead to cytotoxic activity and B cell memory and antibody formation lead to allograft cell death.[11] This immune response to the allograft waxes and wanes, mandating lifelong surveillance. Hyperacute rejection occurs in the immediate postoperative period, caused by preformed antibodies against major histocompatibility complex or ABO blood type antigens. This complication is rare with careful donor-recipient matching or with aggressive desensitization strategies. Acute cellular rejection (ACR) and antibody mediated rejection (AMR) are both associated with constitutional symptoms and signs of allograft insufficiency occurring days to weeks after transplantation or any time immunosuppression is deliberately or accidentally decreased. ACR is mediated by T cells whereas AMR is due to circulating donor-specific antibodies, complement deposition, and neutrophilic inflammation of the allograft. Chronic rejection occurs over months to years and results in allograft failure.

Immunosuppressive therapy requires correctly timed drug combinations to establish a balance between rejection and infection. Regimens are transplant center–specific, but most include a calcineurin inhibitor (usually tacrolimus), an antimetabolite (usually mycophenolate mofetil), and steroids. Recognition of the side effects, toxicities, and potential drug-drug interactions of immunosuppressant medications is important for the care of any transplant recipient (Table 183.1). Consultation with a clinical pharmacist trained in transplant pharmacotherapy can help optimize the use of immunosuppressive and antibiotic agents.

Desensitization Regimens and Therapies for Antibody-Mediated Rejection. Desensitization regimens decrease circulating antibodies likely to react with donor antigens in patients sensitized to incompatible donors. These pretransplant regimens include plasmapheresis to remove antibodies, rituximab to deplete B cells, bortezomib to reduce antibody production, intravenous immune globulin (IVIG) to trigger antibody clearance, and eculizumab to target the complement cascade.[11]

Induction Agents. Induction immunosuppression is employed in the pre- or peri-transplantation period. Antithymocyte globulin (ATG) and alemtuzumab are both lymphocyte depleting agents, with ATG targeting T cells and alemtuzumab both T and B cells. ATG is also used to treat steroid-refractory acute cellular rejection. Lymphodepletion can last for 3 to 6 months, conferring increased risk of opportunistic infections and post-transplantation lymphoproliferative disorder (PTLD). Non-lymphodepleting agents include basiliximab and daclizumab, anti-IL-2 monoclonal antibodies used in recipients at lower risk of rejection.[12]

Maintenance Immunosuppression

Calcineurin Inhibitors. The calcineurin inhibitors tacrolimus and cyclosporine have greatly improved patient- and allograft-related outcomes. However, calcineurin inhibitors (CNIs) have narrow therapeutic indices, variable pharmacokinetics, and adverse side effects.[12] Serum trough levels should be checked in patients with worsening renal function, because CNIs are cleared by the kidney and can cause kidney injury. Both CNIs have been associated with gout and pseudogout. CNI concentrations are altered by common post-transplantation medications including antibiotics; the initiation of such medications merits close communication with the transplant team to plan for CNI dose adjustments and prospective drug monitoring.

Tacrolimus is a macrolide compound that binds to lymphocyte proteins and inhibits cytokine synthesis. Adverse effects include dose-dependent nephrotoxicity as well as neurotoxicity, characterized by tremors, headache, and posterior reversible encephalopathy syndrome (PRES).[12] When combined with steroids, tacrolimus can lead to hyperglycemia and diabetes.

Cyclosporine inhibits both cellular and humoral immunity by binding to proteins which inhibit lymphocyte signal transduction between helper-inducer T cells and B cells. Cyclosporine is similarly associated with dose-dependent nephrotoxicity which is enhanced when used with other nephrotoxins, such as amphotericin or aminoglycosides.[12] Renal tubular injury and direct renal artery vasospasm can result in systemic hypertension. Rarely, cyclosporine toxicity can result in a neurologic syndrome of confusion, quadriplegia, and coma if left untreated.

Mammalian Target of Rapamycin Inhibitors. Sirolimus and everolimus are two drugs in the mammalian target of rapamycin (mTOR) class. mTOR is key in the pathway for T cell clonal activation. Adverse effects include delayed wound healing, hyperlipidemia, cytopenias, diarrhea, and sirolimus-induced lung injury.[12]

Antimetabolites. Azathioprine is an antimetabolite derivative of 6-mercaptopurine and inhibits both DNA and ribonucleic acid synthesis to suppress lymphocyte proliferation.[12] Transplant recipients may exhibit dose-dependent neutropenia, hepatic dysfunction, and gastrointestinal upset.

Mycophenolate mofetil (MMF) is an antimetabolite with more potent and selective inhibition of lymphocyte proliferation as well as a relatively low side effect profile.[12] The most common adverse effects are diarrhea and leukopenia. Because magnesium and aluminum antacids interfere with MMF absorption, care should be exercised in treatment of GI symptoms. MMF is usually switched to azathioprine in the setting of pregnancy to reduce risk of teratogenicity.

Corticosteroids. Corticosteroids have a wide range of effects on the immune system. Every effort is made to minimize corticosteroid use to prevent long-term consequences such as gastrointestinal bleeding, diabetes, and osteonecrosis. High-dose steroids to treat rejection may precipitate altered mental status. Acute withdrawal or severe illness may lead to Addisonian crisis, presenting with fevers, hypotension, and metabolic derangements and merit initiation of stress-dose steroids (e.g. hydrocortisone 100 mg IV).

Other Agents: Belatacept, Rituximab, Eculizumab. Belatacept is a fusion protein that blocks T cell co-stimulation at CD28 and is used primarily in kidney transplantation to avoid the nephrotoxicity of CNIs.[12] It is dosed on a monthly basis. It is associated with increased rates of PTLD and is contraindicated in EBV-seronegative recipients. Rituximab is a monoclonal antibody directed against the B-cell surface marker CD20 and

TABLE 183.1 Immunosuppression Agents Used in Solid Organ Transplantation

Agent	Mechanism	Metabolism	Drug-Drug Interactions	Toxicities and Other Considerations
Alemtuzumab	CD52 inhibitor	–	–	Lymphocyte depletion for 6–12 months
Antithymocyte globulin	Polyclonal T cell depletion	–	–	Lymphocyte depletion for 3–6 months Serum sickness, fevers with infusions
Azathioprine	Antimetabolite	Hepatic	↑ by allopurinol May ↓ anticoagulant effect of warfarin	Hepatotoxicity Bone marrow suppression, ↑ by valganciclovir
Basiliximab	IL-2Rα inhibitor	–	–	Duration of activity may last 4–6 weeks
Belatacept	CD80/86 inhibitor	–	–	Post-transplant lymphoproliferative disorder
Bortezomib	26S proteasome inhibitor	Hepatic CYP2C19, CYP3A4	↓ by phenytoin, carbamazepine, rifampin ↑ by azoles, CCBs, macrolides, PIs	Peripheral neuropathy
Cyclosporine A	Calcineurin inhibitor	Hepatic CYP3A4 and P-glycoprotein	↓ by phenytoin, carbamazepine, rifampin ↑ by azoles, CCBs, macrolides, PIs, letermovir	Nephrotoxicity, ↑ by AG, AMB, NSAIDs Hypertension Gingival hyperplasia
Eculizumab	Terminal complement inhibitor	–	–	*Neisseria meningitides* meningitis
Everolimus	Mammalian target of rapamycin inhibitor	Hepatic CYP3A4 and P-glycoprotein	↓ by phenytoin, carbamazepine, rifampin ↑ by azoles, CCBs, macrolides, PIs	Interstitial pneumonitis Nephrotoxicity Poor wound healing
Intravenous immunoglobulin	Antibody replacement	–	–	Serum sickness, fevers with infusions
Mycophenolate mofetil Mycophenolate sodium	Antimetabolite	Hepatic and gastrointestinal	↑ by antacids, cholestyramine	Hepatotoxicity Bone marrow suppression, ↑ by valganciclovir Gastrointestinal distress
Rituximab	CD20 inhibitor	–	–	Reactivation of hepatitis B, JC virus
Steroids	Variable	Hepatic cytochrome P450 (minor)	↑ by PIs	Weight gain and associated glucose intolerance, HLD Poor wound healing ↑ risk gastrointestinal bleeding with NSAIDs
Sirolimus	Mammalian target of rapamycin inhibitor	Hepatic CYP3A4 and P-glycoprotein	↓ by phenytoin, carbamazepine, rifampin ↑ by azoles, CCBs, macrolides, PIs	Interstitial pneumonitis Poor wound healing
Tacrolimus	Calcineurin inhibitor	Hepatic CYP3A4 and P-glycoprotein	↓ by some antiepileptics, caspofungin, rifampin ↑ by azoles, CCBs, macrolides, PIs, CBD	Nephrotoxicity, ↑ by AG, AMB, NSAIDs Neurotoxicity (PRES, Tremor)

CCB, Calcium channel blocker; *PI*, protease inhibitor; *AG*, aminoglycoside; *AMB*, amphotericin B; *NSAID*, nonsteroidal antiinflammatory; *HLD*, hyperlipidemia; *PRES*, posterior reversible encephalopathy syndrome.

results in B cell depletion. It is associated with cytopenias and hepatitis B reactivation. It also carries a black box warning for progressive multifocal leukoencephalopathy, although this is rare.[12] Eculizumab is a monoclonal antibody that acts as a terminal complement inhibitor and is associated with increased risk for meningococcemia.[13]

ORGAN-SPECIFIC CONSIDERATIONS

The following sections delineate organ-specific anatomic, rejection-related, infectious, and pharmacologic complications of transplantation with occasional reference to the general concepts of solid organ transplantation described previously.

Heart Transplantation

Heart transplantation is a curative option for patients with end-stage cardiomyopathy, recurrent ventricular arrhythmias, intractable angina, or primary tumors. In 2019, over 3500 heart transplants were performed in the United States.[1] Over 40% of candidates are bridged to transplantation with ventricular assist device (VAD) technologies. Current 1-, 3-, and 5-year patient and allograft survival rates are 90%, 85%, and 80%, respectively.[14] Main reasons for readmission early post-transplantation include cardiac dysrhythmias, allograft rejection, and infection; later causes include cerebrovascular and allograft vasculopathy. Renal dysfunction and diabetes are common comorbidities.[15]

Anatomic Considerations

Orthotopic heart transplants are usually bicaval, involving a single anastomosis between the donor and recipient left atria, aortic and pulmonary artery anastomoses, and two caval anastomoses. Alternatively, the biatrial method of orthotopic heart transplantation involves anastomoses between the aorta and pulmonary artery as well as both the right and left atria.[16] Leads from previous pacemakers or implantable cardioverter-defibrillators may be retained post-transplantation, limiting the transplant recipient's ability to undergo magnetic resonance imaging safely.

The transplanted heart is denervated of both parasympathetic and sympathetic nerve fibers, which causes clinically important physiologic changes.[17] Without parasympathetic tone, the transplant recipient's early resting heart rate varies from 95 to 110 beats/minute, but decreases by one year to a mean of 92 beats/minute.[18] Variation exists based on donor and recipient factors. Without sympathetic tone, transplant recipients may experience relative bradycardia during times of physical or mental stress. Transplant recipients presenting to the ED with brady- or tachyarrhythmias generally merit admission. For immediate intervention, beta-blockers, diltiazem, and amiodarone may be used to treat supraventricular tachyarrhythmias. The allograft is sensitive to adenosine with a risk of prolonged AV block, so the anticipated dose should be reduced by half prior to administration. Atropine and glycopyrrolate have no effect on the denervated heart and should not be used in the transplant recipient.

Denervation of the allograft also prevents heart transplant recipients from experiencing classic anginal symptoms.[17] Transplant recipients suffer silent myocardial infarctions and sudden cardiac death, compelling providers to remain aware of other signs and symptoms of cardiac ischemia. The most common electrocardiogram (ECG) abnormalities after heart transplantation, incomplete right bundle branch blocks and repolarization abnormalities, are not clinically meaningful.[19] Significant ECG abnormalities include consistent Q waves as well as ST segment elevations. Heart failure may present in an atypical fashion as well. Although a transthoracic echocardiogram may report normal left ventricular function and ejection fraction, microscopic scarring of the allograft can gradually lead to a restrictive cardiomyopathy.

Infection

In addition to the nosocomial infections described earlier in this chapter, infections related to the surgical site as well as the sites of prior device placement occur in the first month after heart transplantation. Mediastinitis may present with chest pain, sternal instability, wound breakdown, or with nonspecific symptoms of fever and tachycardia. Diagnosis requires computerized tomography (CT) scan of the chest, and treatment requires broad-spectrum antibiotics and surgical débridement. Infections of VAD components can be present at the time of transplantation and may impact post-transplantation infection risk. Prior VAD infection increases the risk for post-transplantation multidrug-resistant infections and can thus inform empirical antibiotic selection.[20]

Toxoplasmosis is a particular risk for heart transplant recipients, especially in those unable to take TMP/SMX prophylaxis, and presents with signs of myocarditis resembling rejection, pneumonia, or meningoencephalitis. Trypanosomiasis is rare in the United States but is a common indication for heart transplantation in endemic countries. Unmonitored, recurrent infection can cause myocarditis, subcutaneous nodules, or disseminated disease.[8]

Rejection

Hyperacute cellular or metabolic rejection is rare but can precipitate early allograft failure, requiring the temporary use of advanced heart therapies.[21] Acute cellular rejection occurs in 27% of recipients by one year post-transplantation and is diagnosed by allograft biopsy.[14] Many episodes are low-grade, asymptomatic, and left untreated. Severe rejection manifests with fever and signs of heart failure such as dyspnea, meriting admission for anti-rejection therapies.

Cardiac allograft vasculopathy is associated with chronic rejection and serves as a major determinant of morbidity and mortality for heart transplant recipients.[21] It is identified via angiography with diffuse, concentric narrowing of the coronary arteries. CAV may be asymptomatic or present with symptoms of heart failure, myocardial infarction, or sudden cardiac death. The definitive treatment for CAV is re-transplantation.

Drug Toxicity

Calcium channel blockers and amiodarone can increase cyclosporine, tacrolimus, and sirolimus levels. In contrast, cyclosporine can increase the drug levels of statin medications to result in muscle cramping and rhabdomyolysis. Sirolimus use in the early post-transplantation period can result in sternal wound dehiscence and is avoided early post-transplantation. Drug-drug interactions between antibiotics and warfarin require attention to ensure safe anticoagulation.

Kidney Transplantation

Kidney transplantation is a life-saving option for patients with end-stage renal disease compared to prolonged time on dialysis. Over 23,000 kidney transplants were performed in the United States in 2019.[1] One-, three-, and five-year patient survival post-deceased donor kidney transplantation is generally estimated at 97%, 94%, and 90%, respectively, with living donor outcomes exceeding these.[22] Up to 40% of transplant recipients present to the ED in the first year, usually due to allograft dysfunction, infection, or exacerbation of diabetes or hypertension.[23]

Anatomic Considerations

The renal allograft is usually transplanted in the right or left iliac fossa, with native kidneys and ureters left in situ. Allograft pyelonephritis presents with pain at the allograft in the lower abdomen rather than the flank pain observed with native pyelonephritis. However, denervation

can prevent the development of pain altogether.[24] Rarely, nephrolithiasis and urinary tract infections still occur in the transplant recipient's retained native kidneys.[25]

Donor renal vessels are anastomosed to recipient iliac vessels. Although rare, vascular complications such as bleeding and thrombosis can occur up to a week post-transplantation.[23] Intra-abdominal hematomas can initially manifest with urinary obstruction and hydronephrosis. Renal artery and vein thromboses can also present with decreased urinary output and acute kidney injury. Vascular complications occurring months to years post-transplantation are typically due to arterial stricture or stenosis observed in the context of underlying peripheral vascular disease. Doppler ultrasound is the preferred method of evaluating vascular patency.

Nonvascular anastomoses are created between the donor ureter and either the recipient's ureter or bladder. Ureteral stents are endoscopically inserted during transplantation and remain in place for 6 weeks. Retention of the stent during episodes of infection may lead to recurrent urinary tract infections due to biofilm formation. Ureteric complications occur in up to 15% of transplants and include stent migration as well as ureteric leak or stricture. Unlike the native system, the transplanted ureter does not have a one-way valve at the insertion site in the native bladder to prevent reflux-associated injury to the allograft.

Delayed allograft function requires temporary dialysis until reasonable function is established. During dialysis, attention must be paid to central catheters, fistulas, and grafts, which may be potential sources of infection or thrombosis.

Infection

Urinary tract infections including allograft pyelonephritis are the most common infections post-transplantation. Classic presenting symptoms include fever, allograft tenderness, and pyuria, but symptoms may be nonspecific, including confusion, malaise, or weakness. Associated volume depletion can elevate creatinine, mirroring allograft rejection. If there is evidence of sepsis, obtain blood and urine cultures and initiate empirical antibiotic therapy until culture data are available.

Recurrent urinary tract infections can lead to allograft failure and merit a thorough investigation (including imaging) of potentially actionable contributors to disease such as perinephric abscesses, nephrolithiasis, residual ureteral stent, and urinary retention. Oral antibiotics may suffice to treat uncomplicated cystitis, though intravenous options are recommended in the setting of allograft pyelonephritis or urinary tract infections complicated by bacteremia or sepsis. Asymptomatic bacteriuria does not require routine treatment.[26]

Attention to remaining dialysis access sites may identify a source for bloodstream infections. BK virus infection results in chronic nephropathy in up to 10% of kidney transplant recipients but is rarely an emergent problem.[27] Reduction of immunosuppression is the only proven strategy for decreasing the risk of significant BK nephropathy and usually takes months to resolve.

Rejection

Acute rejection is a common complication of kidney transplantation, with an incidence of 10% at 1 year and associated reductions in allograft survival.[22] Renal allograft rejection manifests with fever, tenderness over the allograft, and signs and symptoms of allograft dysfunction including decreased urine output and elevated creatinine. Early consultation with the transplant nephrologist or urologist is prudent to pursue timely renal biopsy and empirical treatment.

Chronic transplant rejection occurs after long-term loss of adequate function due to nephrosclerosis or fibrosis of the blood vessels supplying the allograft. This process involves proliferation of the vascular intima of renal vessels with marked decrease in the lumen size. Findings include proteinuria, hypertension, and allograft dysfunction.

Drug Toxicity

Drug toxicities are a particular risk to the renal allograft. Supratherapeutic CNI concentrations can cause acute and chronic kidney injury.[12] Other nephrotoxic drugs can potentiate injury in the setting of CNIs or volume depletion. Nonsteroidal antiinflammatory drugs (NSAIDs) are not recommended in kidney transplant patients because even short courses for acute pain management have been demonstrated to result in acute allograft injury.[28] Amphotericin and foscarnet should be administered with caution.

Liver Transplantation

Over 8800 liver transplants were performed in the United States in 2019.[1] Since 2015, nonalcoholic steatohepatitis (NASH) has superseded hepatitis C as the primary indication for liver transplantation. One-, three-, and five-year patient survival is reported as 91%, 84%, and 76%, respectively.[29] Vascular and biliary complications, allograft dysfunction, and infection are common, with up to 45% of transplant recipients presenting to the ED in the first year post-transplantation and 78% of these requiring admission.[30]

Anatomic Considerations

Liver transplantation requires surgical anastomoses at biliary and vascular sites. Biliary anastomosis can be duct-to-duct or by choledochojejunostomy. Choledochojejunostomy (CDJ) is performed when donor or recipient ducts are not amenable to direct anastomosis, joining the allograft remnant bile duct directly into the roux limb of the recipient small bowel. CDJ increases the risk of intra-abdominal infections. The gallbladder is always removed during transplantation.

All vascular and biliary anastomoses can serve as sites of stenosis, obstruction, or leak. Hepatic artery rupture, caused by bacterial or fungal arteritis, can result in hemorrhagic shock. Portal vein thrombosis occurs in 1% to 2% of liver transplant recipients and presents with encephalopathy and refractory ascites characteristic of allograft failure.[31] Hepatic artery thrombosis (HAT) is the most common vascular complication and can result in immediate hepatic or biliary necrosis, manifesting with fever, jaundice, and right upper quadrant pain with or without elevated transaminases and hyperbilirubinemia.[31] Liver transplant recipients presenting to the ED in the first month post-transplantation should be screened for HAT with Doppler ultrasound. Treatment of acute HAT may require immediate thrombectomy or emergent re-transplantation.

Biliary complications including stricture, obstruction, leaks, and necrosis frequently manifest with fevers, abdominal pain, and relative hyperbilirubinemia.[31] Extrahepatic biliary leak presents with perihepatic collections or peritonitis. Intrahepatic biliary necrosis or stricture can present with intrahepatic bilomas and cholangitis. Biliary stricture typically manifests within 1 year post-transplantation.[31] Stents placed endoscopically may ameliorate the stricture but can themselves become obstructed and may require revision.

Living donor allografts are comprised of either the right or left lobe of the liver. Transplantation of these partial allografts may be complicated by small-for-size syndrome, or functional hepatic impairment occurring within one week postoperatively with coagulopathy, cholestasis, encephalopathy, and ascites.[32] Portal hypertension, a risk factor for small-for-size syndrome, is assessed intraoperatively and modulated with shunt formation or splenectomy. The vascular and biliary complications described in this section are more commonly observed in living donor liver transplant recipients due to complexities of both vessel and bile duct division

during allograft donation and the creation of smaller anastomoses during transplantation.

Infection

Over 50% of bacterial infections causing sepsis in this population occur within the first two weeks of transplantation, usually due to pre-transplantation risk factors or surgical complications.[33] Later intra-abdominal infections are due to biliary strictures or preceding HAT. About 50% of living-donor liver transplant recipients experience infection within 1 year, usually due to biliary and vascular complications.[29] Fever, malaise, or abdominal pain should prompt laboratory evaluation with a complete blood count and differential and comprehensive metabolic panel, as well as blood cultures. Niduses of infection, including retained biliary stents, gallstones, and hepatic or intra-abdominal abscesses, should be identified via ultrasound and CT of the abdomen to coordinate surgical or procedural interventions as appropriate.

Enteric organisms, including *Enterococcus* species, gram-negative, and anaerobic organisms are typical pathogens meriting empirical coverage with beta-lactam/beta-lactamase inhibitor regimens. Pre-transplantation colonization with multidrug-resistant organisms may warrant even broader antibacterial coverage. Many recipients have received vaccinations against encapsulated organisms (*Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*) in planning for possible splenectomy at the time of transplantation, but such infections should remain on the differential diagnosis. Overlying incisional wound infections may warrant coverage for *Staphylococcus aureus* (including methicillin-resistant strains). However, incisional infections and wound dehiscence often portend an underlying intra-abdominal source.

Liver transplant recipients are susceptible to some invasive fungal infections, mostly due to *Candida* species in the early post-transplantation period.[2,33] Risk is associated with biliary and operative bleeding complications and CDJ anastomosis. Invasive aspergillosis and endemic fungal infections usually emerge later but can occur within the first month in high-risk settings such as fulminant hepatic failure, re-transplantation, or severe renal failure post-transplantation. Empirical antifungal therapy is warranted for patients with these risk factors or with septic shock.

Rejection

Acute rejection occurs in up to 20% of liver transplant recipients within one year of transplantation.[29] Chronic rejection is more indolent and can be diagnosed years after initial presentation. Both acute and chronic allograft rejection may present with asymptomatic transaminase elevations or with fever, jaundice, and right upper quadrant pain. Eosinophilia may be noted. Anatomic complications, infections, and drug toxicities can mimic the clinical syndrome of acute rejection. Allograft biopsy is necessary to diagnose rejection but may be occasionally treated empirically in the setting of low tacrolimus concentrations and normal hepatic blood flow.

Drug Toxicity

Liver transplant recipients may be particularly vulnerable to hepatotoxic medications used in the post-transplantation period such as rifamycins or isoniazid used for TB treatment or azole antifungal agents. Up to 4 grams per day of acetaminophen is allowed, but NSAIDs are discouraged.[34]

Lung Transplantation

Over 2700 lung transplantations were performed in the United States in 2019 to treat patients with advanced lung diseases, including idiopathic pulmonary fibrosis, obstructive pulmonary disease, pulmonary hypertension, and cystic fibrosis.[1] Despite ongoing challenges with surgical complications, infections, and chronic allograft lung dysfunction, lung transplantation can significantly improve survival as well as quality of life. One-, three-, and five-year patient survival is estimated at 85%, 68%, and 56%, respectively.[35] Up to 45% of lung transplant recipients present to the ED and 67% face readmission in the first year.[36] Airway complications, infection, and atrial fibrillation are common causes for readmission.

Anatomic Considerations

Lung transplantation may involve a single lung transplant with bronchial anastomosis, bilateral lung transplant with tracheal anastomosis, sequential bilateral lung transplant with bronchial anastomoses, lobar transplant, or heart-lung transplant. Bilateral lung transplantation is indicated for patients with existing lung infection (i.e., cystic fibrosis and bronchiectasis) or significant pulmonary hypertension. Single lung transplantation is often pursued in older and more debilitated individuals as it is a shorter procedure associated with better early postoperative outcomes.

Single and sequential bilateral lung transplantation both require anastomoses of the main bronchi and pulmonary arteries as well as an anastomosis between the donor's pulmonary veins to the recipient's left atrium. Bronchial anastomotic complications such as stenosis, ischemia, tissue degeneration, and dehiscence can occur in up to 15% of transplant recipients, provoking prolonged air leak with pneumothorax or mediastinitis.[37] Vascular anastomotic complications can result in ischemia and allograft failure as well as hemothorax. Postoperative pleural complications such as pleural effusions and empyemas are most frequently observed within 1 week of transplantation.[38] In evaluating a lung transplant recipient with new respiratory symptoms, an initial chest radiograph may be helpful but a non-contrast CT scan of the chest will best evaluate the parenchyma, airways, and pleural spaces.[38]

Infection

Infection occurs in up to 60% of lung transplant recipients in the first year and remains a major cause of mortality.[33,35] Surgical denervation impairs the cough reflex and mucociliary clearance, disruption of vascularization and lymphatic channels results in stagnancy, and immunosuppression blunts appropriate responses to environmental pathogens. Gastroesophageal reflux affects a significant proportion of transplant recipients and contributes to aspiration-related infection events. Some patients such as those with cystic fibrosis also harbor bacteria in the sinuses which may infect the lower airways.

Infections are most commonly pulmonary in origin throughout the post-transplantation course. Early infections are typically hospital-acquired or ventilator-associated.[2] Native lung and allograft parenchyma alike can be affected by donor-derived and nosocomial organisms. Consideration should be given to previously grown pathogens to help guide empirical therapy of a lung transplant recipient with new fever, dyspnea, and cough. Community respiratory viruses are more likely to cause lower respiratory tract infections and inflammation, leading to chronic allograft dysfunction (CLAD).[39] Thus, available antivirals for influenza, respiratory syncytial, and even parainfluenza viruses are often used in conjunction with tapered courses of systemic steroids to control the immune response.[40]

Lung transplant recipients are prone to reactivation of CMV infection and manifest with CMV pneumonia. CT of the chest most often identifies ground-glass opacities and may resemble acute rejection or PJP. Definitive diagnosis requires lung biopsy, but detection of CMV viremia and clinical findings often warrants presumptive therapy, usually with intravenous ganciclovir. PJP is rare in the setting of prophylaxis, but invasive aspergillosis and other mold infections remain

relevant throughout the post-transplantation course and should be considered in the setting of nodular or cavitary opacities on imaging or anastomotic wound infections.[41]

A final pair of donor-derived organisms affecting lung transplant recipients are *Mycoplasma hominis* and *Ureaplasma urealyticum*. These two urea-splitting bacteria alter the production and metabolism of ammonia in the allograft, resulting in hyperammonemia syndrome within 10 to 14 days post-transplantation.[42] This condition, characterized by altered mental status and elevated serum ammonia levels, can cause cerebral edema, coma, and eventual death over days to weeks if left unchecked.[43] Any lung transplant recipient, particularly early post-transplantation, with altered mental status should have a serum ammonia level checked. Treatment is multifaceted and includes direct measures to reduce ammonia as well as antibiotics.

Rejection

Approximately 18% of lung transplant recipients experience acute cellular or humoral rejection in the first year post-transplantation.[35] Surveillance spirometry is intended to detect early functional decline that directs further testing. Symptoms of acute rejection can present at any time point post-transplantation with fever, dyspnea, cough, and generalized malaise. While subtle findings of rejection may not be well-evaluated by chest x-ray, this imaging modality may demonstrate airspace disease, interlobular septal thickening, or pleural effusions.[38] Non-contrast CT of the chest reveals ground-glass opacities. Acute rejection is diagnosed by transbronchial biopsy.

CLAD is a manifestation of rejection characterized by airway scarring and fibrosis with resultant progressive deterioration of lung function.[44] Both restrictive and obstructive patterns of disease are described, with a variety of posited triggers, including infections and prior rejection. Clinically, CLAD presents with progressive cough, dyspnea, spirometry readings, and oxygen requirements over months to years. It is the leading cause of morbidity and mortality beyond the first year of transplantation.[35] Azithromycin can effectively prevent CLAD.[45]

Drug Toxicity

Sirolimus may be used in the setting of CLAD. It should not be used early post-transplantation due to its adverse effects on wound healing. Sirolimus itself can also cause pulmonary toxicity, presenting with a range of severity from ground-glass opacities to necrotizing consolidations.

In dosing empirical antibiotic therapy for lung transplant recipients with suspected infection, special attention must be paid to cystic fibrosis patients, who demonstrate elevated metabolic rates. Inhaled antibiotics can be used in addition to systemic antibiotics to provide directed therapy for suspected pneumonias or anastomotic infections.

Pancreas Transplantation

Pancreatic transplantation can provide complete insulin independence for patients with long-standing diabetes mellitus. It may be performed with simultaneous or sequential kidney transplantation in those with advanced renal disease due to diabetic glomerulonephritis. There were 143 pancreas-only and 872 kidney/pancreas transplants performed in the United States in 2019.[1]

The donor organ with its native duodenum is most often anastomosed to the recipient small intestine to allow for exocrine drainage.[46] Previous strategies to manage the exocrine secretions of the organ included anastomosis at the recipient bladder, but this led to non–anion gap acidosis, reflux pancreatitis, chronic pyuria, and recurrent urinary tract infections such that bladder anastomosis has largely been abandoned. Vascular anastomoses are at the right internal iliac vessels. Complications due to bleeding or thrombosis usually manifest in the first week post-transplantation. Fistulas and intra-abdominal abscesses may occur later with abdominal pain, hyperamylasemia, leukocytosis, and elevated serum creatinine.

Infections are usually bacterial but may contain *Candida* species. CMV infection risk warrants valganciclovir prophylaxis and monitoring. Rejection occurs in 11% to 19% of transplant recipients in the first year post-transplantation but long-term steroid use is avoided to prevent hyperglycemia, resulting in increased use of induction agents and higher CNI target troughs.[47] Assessment of allograft rejection includes laboratory evaluation of serum amylase and lipase as well as allograft function (glucose, insulin production) in addition to allograft biopsy.

Patients presenting with fever or allograft tenderness should be evaluated for intra-abdominal infections, CMV tissue-invasive disease of the gastrointestinal tract, and rejection. CT imaging may be particularly helpful. Most hospital readmissions post-transplantation, however, are due to dehydration and metabolic derangements.

Intestinal and Multivisceral Transplantation (IMVT)

IMVT is a life-saving option for patients with irreversible intestinal failure. There were 81 IMVTs performed in 2019 in the United States.[1] Transplant-related outcomes vary widely based on transplant recipient age as well as type of IMVT performed. One- and five-year patient survival range between 66% to 89% and 49% to 76%, respectively, while 1-, 3-, and 5-year allograft survival are reported as 72% to 78%, 57% to 61%, and 45% to 50%, respectively.[48] Over 90% of IMVT recipients require readmission in the first year post-transplantation due to allograft rejection, infection, and dehydration.[49]

Isolated intestinal transplantation is performed for patients with irreversible intestinal failure and is comprised of jejuno-ileum.[50] Combined intestine-liver transplantation is performed in the context of irreversible intestinal failure complicated by parenteral nutrition-associated liver failure. Multivisceral transplants are comprised of intestine, stomach, duodenum, and pancreas with or without the liver. The intestinal allograft is usually left as a stoma for several months post-transplantation to facilitate protocolized endoscopic evaluations for allograft rejection. Early post-IMVT complications are most often due to anastomotic leaks, organ ischemia, vascular thrombosis or bleeding. Attempts to manage pain or slow gut motility to increase absorptive time can result in ileus and vomiting.

Infection causes up to 50% of allograft failure and is most often bacterial.[50] Abdominal infection is the most likely, though bloodstream infections associated with catheters placed for fluid or nutritional support even after transplantation, pneumonia associated with reflux and aspiration, and urinary tract infections also occur. CMV and adenovirus enteritis, EBV-associated PTLD, and graft-versus-host disease (GVHD) are all of particular concern with IMVT recipients and require specialized care to identify and treat.

Rejection occurs in 25% of adults and 58% of children in the first year and can precipitate bacterial translocation and septicemia.[48] IMVT recipients presenting to the ED should be assessed for volume status, electrolytes, and liver and renal function. Any fever or subtle signs of infection, such as tachycardia or tachypnea, should be assessed with blood cultures, urinalysis and culture, chest radiograph, and consideration given to CT imaging of the abdomen. Prompt notification of the intestinal transplant team is imperative to directing further management strategies.

Of note, intestinal function may impact the use of enterically administered drugs and any essential therapies should be delivered by alternative means, such as sublingual or intravenous administration.

Vascularized Composite Allografts

Vascularized composite allografts including the uterus, limb, face, abdominal wall, trachea, and larynx are not essential to patient survival but rather designed to improve the patient's quality of life. Fourteen such transplants were performed in 2019 and are still under experimental status, requiring strict inclusion and exclusion criteria to guide transplantation eligibility and mandating timely adverse event reporting.[1]

OTHER CONSIDERATIONS

Post-Transplantation Malignancy

Solid organ transplant recipients face a two- to three-fold higher risk of malignancy compared to the general population, particularly for lung, colon, skin, and liver cancer as well as lymphoma. This has been attributed to underlying illnesses, long-term exposure to immunosuppression and antimicrobial agents, and chronic viral infections. Virus-associated malignancies including EBV-associated PTLD and HPV-associated cancers (cervical, anal, and oral) are important considerations.

Post-Transplantation Lymphoproliferative Disorder

PTLD affects up to 10% of solid organ transplant recipients.[51] It is a malignancy of T cell impairment that results in uninhibited monoclonal proliferation of EBV-infected B lymphocytes and their subsequent transformation into immortal lymphoblastoid B cells. Approximately 60% of cases occur within the first year post-transplantation, most often in EBV IgG donor-positive/recipient-negative pairs. Early disease may be asymptomatic and discovered on routine imaging or present with fever and weight loss. Cytopenias and EBV DNA may be detected with laboratory evaluation. Lymphadenopathy or hepatosplenomegaly concerning for PTLD detected on imaging in the emergency department merits discussion with the transplant team to arrange follow-up. Survival has improved since the availability of rituximab.[51]

Graft-versus-Host Disease in Solid Organ Transplantation

Graft-versus-host disease (GVHD) affects less than 10% of adult solid organ transplant recipients but is fatal in up to 70% of cases and thus requires recognition. GVHD occurs 2 to 6 weeks post-transplantation, usually in the context of immunogenic allografts such as the intestine and liver.[52,53] Donor T cells are transmitted with the organ and respond to recipient tissue-based antigens evoking apoptosis in skin, bowel, and bone marrow. Fever, rash, diarrhea, and cytopenias occur. Diagnosis is by skin or endoscopic biopsy and blood measures of donor T cell chimerism. If GVHD is confirmed, high-dose corticosteroids or T cell depleting agents are administered with antibiotic prophylaxis.

Viral Hepatitis in Solid Organ Transplantation

Patient- and allograft-related outcomes of transplant recipients with hepatitis B and hepatitis C infection have dramatically improved due to vaccination, screening practices, and antiviral therapies. Confidence in HBV and HCV management is reflected in the growing use of the organs from donors with known HBV or HCV infection and those at increased risk for such infections. Liver dysfunction in a transplant recipient with a history of pre-existing viral hepatitis, a known HBV- or HCV-positive donor, or an increased risk donor may prompt evaluation for active infection with serum HBsAg and HBV DNA as well as HCV RNA.

HBV infection can arise from a post-transplantation exposure, donor-derived transmission, or reactivation of latent disease. Transplant recipients of hepatitis B surface antigen-positive or hepatitis B core antibody-positive organs (indicating active or occult HBV infection) merit potent nucleoside analog therapy (entecavir, tenofovir, or lamivudine) and monitoring for viremia suggestive of active infection.[54] Patients with underlying HBV-related liver disease prior to transplantation receive a potent nucleoside analog and possibly hepatitis B immunoglobulin with routine monitoring of HBsAg and HBV DNA. Transplant recipients should be continued on HBV-directed nucleoside analog therapy on presentation to avoid hepatitis B reactivation.

With direct-acting antiviral agents (DAAs) facilitating prompt sustained viral remissions, solid organ transplant recipients with HCV have experienced a marked decrease in morbidity and mortality.[54] HCV-positive organs have been successfully transplanted into HCV-negative recipients with subsequent cure of donor-derived HCV in most, allowing for expansion of the donor pool and reduced wait times to transplantation.

Human Immunodeficiency Virus in Solid Organ Transplantation

With effective antiretroviral therapy (ART) dramatically increasing life expectancy, more HIV-positive individuals survive to develop chronic end-stage renal, heart, lung and liver disease. Organ transplantation for kidney, liver, heart, or lung failure in this population has very good outcomes. HIV-positive solid organ transplant recipients face more allograft rejection but not more infection than HIV-negative recipients.[55] Evaluation of the HIV-positive transplant recipient should be similar to other transplant recipients, with additional attention provided to adherence to antiretroviral medications and possible drug-drug interactions. Although efforts are now made to choose ART that does not interact with immunosuppression, it is important to be aware that stopping certain drugs (ritonavir, cobicistat, and efavirenz) in the setting of acute illness can have important effects on CNI levels and allograft function. Assessing CD4 T cell count and HIV RNA viral loads helps to establish risk for opportunistic infection.

Trauma

The management of solid organ transplant trauma patients is generally no different from other trauma patients, except for a few considerations. Trauma may precipitate episodes of rejection. When possible, resuscitation with leuko-reduced and CMV-negative blood products is preferred for immunosuppressed transplant recipients to prevent transmission of viral infection. Heart transplant recipients may demonstrate clinical tamponade from scarring and adhesions, even in the absence of a pericardium. Pleural adhesions may complicate chest tube placement in a lung transplant patient. Traumatic injury of the transplanted kidney and pancreas is rare, despite their positioning in the anterior pelvis.

Eligible Organ Donors

Emergency clinicians caring for patients affected by devastating trauma or severe acute illness may address issues of organ donor eligibility of deceased individuals. Medical advancements and newer data on outcomes using organs previously considered ineligible have expanded the definition of a donor. Both donation after brain death and donation after cardiac death can yield successful outcomes for most organ types. Those dying of opioid overdose and those with known hepatitis B, hepatitis C, or HIV infection are now considered eligible donors. Immediate contraindications to organ donation include active malignancy and Creutzfeldt-Jakob disease. Questions regarding potential donor eligibility should be discussed with the local organ procurement organization.

Pregnancy and Solid Organ Transplantation

Women who undergo transplantation are able to pursue pregnancy and childbirth safely. However, pregnancy complications such as miscarriage, preeclampsia, preterm delivery, and need for caesarean section are more common in this population, affecting 1 in 2 pregnant transplant recipients.[56] Physiologic changes of pregnancy can affect allograft function (e.g., peripheral edema in a heart transplant recipient, shortness of breath in a lung transplant recipient, proteinuria in a renal transplant recipient), and should be assessed in consultation with the transplant team. Ideally, transplant recipients should attempt pregnancy with stable allograft function and no evidence of rejection in the previous year. Usual immunosuppression can be continued, though MMF will be stopped or changed to azathioprine to reduce risk of major fetal malformations.[57] Corticosteroids and tacrolimus increase risk of gestational diabetes. Most infections occurring in the pregnant transplant recipient are non-life-threatening urinary tract infections, but awareness of other infections discussed in prior sections (CMV, HSV, VZV, and toxoplasmosis) that can precipitate congenital disease is imperative.

Psychological Aspects

Transplant centers widely use psychosocial selection criteria aiming to optimize pre-transplantation mental health and psychosocial supports. While successful transplantation can improve the psychological well-being for many, the transplantation experience is challenging for most. The side effects of lifelong immunosuppression or steroid withdrawal can include anxiety, depression, delirium, and insomnia. Adherence to treatment recommendations may be markedly affected by depression and may be at issue in transplant recipients who present to the ED with allograft rejection or drug toxicities.[58] Triage to a psychiatrist with expertise in transplantation may be instrumental if depressive symptoms are identified.

DISPOSITION

Transplant recipients presenting to the ED are more likely to merit admission than members of the general population. The insidious nature of the diseases affecting this immunosuppressed population necessitates a thorough, structured approach to evaluation. If infection, rejection, or drug toxicity is suspected, transplant specialists should be consulted either in house or by phone. Transplant recipients who are deemed safe to discharge home require careful instructions, medication reconciliation, and close follow up with their transplant team.

CHAPTER 183: QUESTIONS AND ANSWERS

1. A 42-year-old man presents from home with a 3-day history of fever, cough, and shortness of breath. He underwent orthotopic heart transplantation 5 years ago, has never experienced rejection, and is maintained on minimal doses of prednisone and tacrolimus. He takes trimethoprim-sulfamethoxazole for antimicrobial prophylaxis. Chest radiograph reveals a diffuse interstitial pattern. What is the most likely cause of his pneumonia?

a. Community-acquired respiratory virus
b. Cytomegalovirus
c. *Pneumocystis jirovecii*
d. *Nocardia*

Answer: A. Not all transplant recipients are equivalently immunocompromised. Timing post-transplantation, the net state of immunosuppression, and antimicrobial prophylaxis should all be considered in developing a differential diagnosis for a transplant recipient with suspected infection. His 5-year rejection-free post-transplant course and minimal immunosuppression make opportunistic infections much less likely than community-acquired respiratory viral infections. Given his ongoing use of trimethoprim-sulfamethoxazole, *Pneumocystis jirovecii* pneumonia is unlikely.

2. A 57-year-old deceased donor kidney transplant recipient is sent to the ED from her primary care physician's office 3 months postoperatively because routine blood work revealed a creatinine of 3.45 (baseline creatinine 1.0). Which of the following medications may be responsible for her acute kidney injury?

a. Albuterol
b. Tacrolimus
c. Pancrelipase
d. Prednisone

Answer: B. Tacrolimus is associated with dose-dependent nephrotoxicity. A serum level of tacrolimus should be obtained in any solid organ transplant recipient maintained on this immunosuppressive agent presenting with acute kidney injury. It is important to recognize that tacrolimus can both cause and be affected by renal insufficiency, so it may not have been the initial trigger but may have ultimately worsened the renal injury. Alternatively, a new drug (fluconazole, azithromycin, etc.) may have been initiated which resulted in higher serum concentrations of tacrolimus and resultant renal injury.

3. A 35-year-old woman with cystic fibrosis status post bilateral lung transplantation 2 weeks ago is brought to the ED by her husband. He reports that she was discharged several days prior to presentation with confusion attributed to intensive care unit delirium. Instead, she has developed worsening episodes of alternating agitation and lethargy. She is afebrile and normotensive on presentation, with a 2-liter oxygen requirement to maintain saturations above 90%. No leukocytosis or abnormalities of liver or kidney function are noted. A blood gas test does not demonstrate hypercarbia. What is the next best test?

a. Lumbar puncture
b. Magnetic resonance imaging
c. Serum ammonia
d. Electroencephalography

Answer: C. Hyperammonemia syndrome affects 1% to 4% of lung transplant recipients, resulting from systemic infection with *Mycoplasma hominis* or *Ureaplasma urealyticum*. These urease-splitting organisms metabolize urea as an energy source and produce ammonia as a by-product, which can accumulate in tissues such as the trachea and lung to cause unexplained agitation, lethargy, and new-onset seizures. If ammonia levels are elevated, whole blood or plasma and bronchoalveolar samples should be obtained and tested for *Mycoplasma hominis* and *Ureaplasma urealyticum* polymerase chain reaction (PCR). While awaiting these results, empirical antibiotic therapy against these organisms, such as doxycycline or ciprofloxacin, should be initiated. Hemodialysis, intravenous sodium benzoate, and sodium phenylacetate can help to clear ammonia from the blood and tissues but will be incompletely effective if the underlying infection is not addressed.

4. A 30-year-old liver transplant recipient presents to the ED 10 days post-transplantation with fevers, right upper quadrant pain, and jaundice. Laboratory evaluation reveals leukocytosis, transaminase elevations, and hyperbilirubinemia, which have all worsened since hospital discharge. Which of the conditions responsible for this presentation is most important to diagnose emergently?

a. Rejection
b. Cholangitis
c. Donor-derived hepatitis B infection
d. Hepatic artery thrombosis

CHAPTER 183: QUESTIONS AND ANSWERS—cont'd

Answer: D. The hepatic artery serves as the sole blood supply to the liver allograft and thus hepatic artery thrombosis has devastating consequences to allograft survival. This complication develops within days to weeks post-transplantation and requires immediate recognition and management in close collaboration with transplant surgeons because thrombectomy or urgent re-transplantation may be required. Diagnosis is with Doppler ultrasound. Consideration should be given to assessing the hepatic blood flow for any liver transplant recipient presenting to the ER in the first weeks after transplantation.

5. A 53-year-old intestinal transplant recipient with a history of Crohn disease status post multiple bowel resections resulting in short gut syndrome has been maintained on tacrolimus and prednisone for the last 2 years since transplantation without previous significant infection complications. He presents to the ED with 5 days of nausea, vomiting, cramping abdominal pain, and diarrhea, and states that his 2-year-old son had been ill with similar symptoms that have since resolved. The recipient has not been able to consistently take his medications for the last 3 days. He is febrile and hypotensive with blood pressures in the 80s/50s. His lab work is significant for acute kidney injury and hyponatremia. Which of the following is unlikely to contribute to this patient's clinical presentation?

a. Community-acquired gastroenteritis
b. Acute rejection
c. Adrenal insufficiency
d. CMV enteritis

Answer: D. Intestinal transplant recipients may develop diarrhea from a wide variety of causes and, in fact, dehydration is the most common reason for recurrent presentations to the ED and readmission in this population. While rejection, bacterial overgrowth, and CMV infection are common reasons for diarrhea in the first year after transplant, later causes for diarrhea are more likely to be community-acquired. This patient's history of an exposure to a child with a like illness suggests a new infection with a typical pathogen. Acute rejection can be precipitated by the inability to ingest and absorb immunosuppressive drugs and could now be a part of this patient's disease process. Given the use of chronic corticosteroids in this population, endogenous steroid production by the adrenal glands is often impaired and seemingly minor insults such as viral infections and hypovolemia may lead to signs of adrenal insufficiency. CMV is unlikely to emerge as a new infection this late post-transplant.

The Morbidly Obese Patient

Matthew M. Hall

KEY CONCEPTS

- Obesity has reached epidemic proportions in the United States (US), as well as much of the world, with nearly 40% of American adults classified as obese.
- Obesity results in several physiologic changes including aberrations to lung physiology and predisposes patients to obstructive sleep apnea and obesity hypoventilation syndrome.
- Drug dosages can be challenging in obese patients because some medications are lipophilic and will need to be dosed based on total body weight while hydrophilic medications are dosed closer to ideal body weight. Many medications require specific scalers for appropriate dosing.
- Many drugs lack large-scale trials in the obese population to guide appropriate dosing.
- Obese trauma patients suffer greater rates of chest and abdominal injuries from blunt trauma than healthy-weight patients.
- Bariatric surgery is the only weight loss strategy that consistently results in long-term significant weight loss.
- Laparoscopic gastric banding, sleeve gastrectomy, and Roux-en-Y gastric bypass are the most common weight loss surgeries in the United States, and each presents its own short-term and long-term complications.
- Procedures common in the emergency department (ED), such as lumbar puncture, venous access, CPR, and intubation, may be more difficult in the obese patient.
- The increased body mass of the obese patient presents several challenges to obtaining interpretable radiographic images.

FOUNDATIONS

The last several decades have seen a dramatic increase in rates of obesity in children and adults in the United States and around the world.[1,2] In 2015 to 2016, it was estimated that 39.8% of adults and 18.5% of children in the United States were obese, with as many as 7.6% of Americans classified as severely obese.[1,3] Obesity is often defined as a body mass index (BMI, calculated as weight in kilograms divided by the square of the height in meters) greater than 30 (see Table 184.1). A range from 25 to 29 is considered overweight, and obesity can be further subdivided into grade I (BMI 30.1–34), grade II (BMI 35–39), and grade III or severe obesity (BMI ≥ 40).[4] The obese patient presents a host of management challenges including difficulties related to size and weight but also changes in physiology, procedural challenges, and drug pharmacokinetics.

PATHOPHYSIOLOGY

Changes to Respiratory Mechanics

Increased chest wall mass in conjunction with substantial abdominal fat mass leads to reduced lung compliance and collapse of small airways resulting in increased airway resistance (Table 184.2).[6] These changes in turn result in a decrease in functional residual capacity (FRC) leading to increased atelectasis.[6-8] Obese patients also preferentially aerate the upper portion of the lung and perfuse the more dependent portions leading to ventilation perfusion (V/Q) mismatch.[6] Each of these changes is exacerbated when the patient is supine and ameliorated when sitting upright.[6,7,9]

These physiologic perturbations lead to increases in work of breathing and oxygen consumption; obese patients consume 50% more oxygen than healthy-weight individuals.[6,7] Additionally, obese patients produce significantly more carbon dioxide than non-obese individuals, leading to an increased respiratory rate with a resting rate of 15 to 21 breaths per minute compared to 10 to 12 for those of a healthy weight.[6,7]

Obstructive Sleep Apnea and Obesity Hypoventilation Syndrome

Obstructive sleep apnea (OSA) is an obesity-related disorder characterized by upper airway collapse during sleep. Increases in adiposity of upper airway structures leads to reduced airway caliber and reduced pharyngeal muscle tone.[10,11] Symptoms include snoring and apneic episodes during sleep, daytime sleepiness, and morning headaches.[10] Diagnosis is usually confirmed with polysomnography. Treatment consists of continuous positive airway pressure (CPAP) at night and weight loss.[10,11]

Obesity hypoventilation syndrome (OHS), or Pickwickian syndrome, occurs when the physiologic changes described in the preceding paragraph lead to increased daytime hypercarbia. The Academy of Sleep Medicine defines OHS as daytime alveolar hypoventilation ($Paco_2 > 45$ when awake and at sea level) in individuals with a BMI greater than 30 when other etiologies of hypercarbia are excluded, such as chronic obstructive pulmonary disease, mechanical respiratory dysfunction such as severe kyphoscoliosis, and neuromuscular disease.[2,11,12] It is also prudent to screen for pharmaceutical and recreational substances that affect respiratory drive such as opioids, sedative-hypnotics, and alcohol.[12] While not all, or even most, patients with OSA will have OHS, 90% of those suffering from OHS also suffer from OSA with as many as 70% with severe OHS (characterized by more than 30 apnea-hypoxia events per hour during sleep).[2] Patients with OHS have increased rates of pulmonary hypertension, congestive heart failure (CHF), acute or chronic hypercapnic respiratory failure, and mortality compared to those with only OSA.[11] One recent study identified 600 patients in a 5-year period with OHS and noted 15% died on the index visit with another 16% dying in the approximately 3-year follow-up period.[13]

The American Thoracic Society recently issued a clinical practice guideline regarding evaluation and treatment of OHS. They suggest that patients with sleep disordered breathing but a low/moderate (<20%) pretest probability of OHS should undergo screening with serum bicarbonate levels. Patients with bicarbonate levels over 27 mmol/L or those with a high pretest probability of OHS should undergo confirmatory testing of arterial carbon dioxide levels. They also recommend immediate treatment with noninvasive ventilation and suggest evaluation for bariatric surgery.[2]

TABLE 184.1 Body Mass Index Classifications

BMI	WHO Classification
<18.4	Underweight
18.5–24.9	Normal Weight
25–29.9	Overweight
30–34.9	Grade I Obesity
35–39.9	Grade II Obesity
>40	Grade III Obesity[a]

[a]Alternative terms include Morbid Obesity and Extreme Obesity.[4,5]

TABLE 184.2 Changes to Pulmonary Physiology Observed in the Obese Patient

Parameter	Obesity-Related Change
Chest Wall/Abdominal Mass	Increased
Lung Compliance	Reduced
Airway Resistance	Increased
Functional Residual Capacity	Decreased
Atelectasis	Increased
V/Q Mismatch	Increased
Work of Breathing	Increased
Oxygen Consumption	Increased
CO_2 Production	Increased
Respiratory Rate	Increased
Safe Apnea Time	Decreased

Changes in Pharmacokinetics

The clinician faces several challenges regarding proper medication dosing in the obese patient. The volume of distribution (V_d) of a drug is the principal factor involved in the loading dose while subsequent maintenance dosing will primarily be governed by total body clearance (Cl).[14] The V_d is affected by many factors including drug lipophilicity, plasma binding, regional blood flow, body composition, molecular size, and degree of ionization.[9,14-18] Hydrophilic drugs will tend to not enter adipose tissue to a great extent resulting in lower V_d and will therefore tend to be dosed based upon ideal body weight (IBW). Lipophilic drugs will dissipate into fat tissue to a significant extent, leading to increases in the V_d and a situation where total body weight (TBW) may be appropriately used for dose calculations. Other drug loading doses will use an adjusted body weight (ABW) where a fraction of the adipose tissue, often 30% or 40%, is utilized in dose calculations (see Table 184.3 for scalers often used in medication dosage calculations).[14,15]

Drug maintenance doses are primarily determined by Cl, the sum of contributions from each organ involved in drug metabolism or excretion. As obese patients often have increased liver and kidney mass, as well as increased renal blood flow, obesity will often affect Cl.[14] Additionally, critically ill patients will have changes in vascular permeability, cardiac output, and hepatic and renal function that will impact both V_d and Cl.[16] Care in the emergency department (ED) will primarily involve the loading dose of a medication, but maintenance dosing may be required in departments faced with prolonged inpatient boarding where consultation with a pharmacist may be helpful.

Antibiotics

There is limited data on beta-lactam and cephalosporin use in obesity, but several trials have illustrated lower than normal drug concentrations and cure rates in obese patients when standard dosing is utilized. Until more data are available, we recommend initial dosing at the upper limit of the recommended dose and suggest extended infusion times (Table 184.4).[14-16]

Fluoroquinolones also have very limited pharmacokinetic data in the setting of obesity. There are insufficient data to provide clear recommendations for ciprofloxacin. Levofloxacin 750 mg/day has been shown to be effective against gram-negative infections in small studies of obese patients with preserved renal function, but further data is required before firm recommendations can be made for fluoroquinolones. Therefore, we recommend usual dosing.[14-16]

Vancomycin has both increased V_d and Cl in obese patients and obese patients have been found to have lower vancomycin troughs. The large V_d necessitates a loading dose recommended at 20 to 25 mg/kg TBW; doses >4 g/day are associated with vancomycin-induced nephrotoxicity. Variable Cl in conjunction with the large V_d makes maintenance dosing difficult and it is prudent to individualize subsequent doses to peak and trough levels so as to achieve therapeutic levels but avoid nephrotoxicity.[14,16]

Linezolid is noted to have subtherapeutic levels in obese patients, but data have not illustrated worse clinical outcomes. Expert recommendations are mixed at this time and there are insufficient data to give clear guidelines regarding linezolid dosing in obese patients; therefore, we recommend usual dosing.[14,15]

Aminoglycosides are hydrophilic but do have an increased V_d in obese patients, suggesting that the drug does distribute into fat tissue but not to nearly the same concentrations as other tissues. Limited evidence suggests dosing by ABW with a correction factor of 0.4 for the loading dose with maintenance dosing individualized for the patient.[14,15]

Sedatives and Induction Agents

Recent studies have demonstrated that both obese and non-obese children and adults often receive incorrect anesthetic and paralytic medications, with one investigation reporting only 75% of obese patients receiving an appropriate dose of etomidate and 60% being administered the correct dose of succinylcholine.[19,20] Propofol is highly lipophilic; in fact, one of the great advantages of this drug, its short duration of action, is not due to metabolism but rather to rapid redistribution into muscle and fat.[18] Historically there has been controversy regarding the appropriate scaler for propofol, but recent research has suggested that using ABW with a correction factor of 0.4 results in successful sedation (Table 184.5).[17,18,21-23] Although etomidate is ubiquitous in the ED, little research has been performed regarding optimal dosing in obese patients with some experts recommending TBW and others reduced doses.[6,17] One recent study did demonstrate IBW resulted in successful sedation, but currently there is insufficient evidence to give a strong recommendation regarding which scaler should be used.[24] At this time we suggest using TBW to dose etomidate. Similarly, there is a paucity of data for ketamine in the obese patient; however, given its large V_d, most experts suggest reducing from TBW with some suggesting IBW and others LBW. We suggest utilizing LBW.[6,17]

Neuromuscular Blocking Agents

Succinylcholine, a depolarizing neuromuscular blocking agent, is cleared via breakdown by plasma cholinesterase (PCE). Obese patients have increased levels of PCE proportional to total body weight and therefore succinylcholine (1.5 mg/kg IV) should be dosed

TABLE 184.3 Scalers for Various Body Weight Descriptors

Body Weight Descriptor		Formula	Example
IBW	Ideal Body Weight	Male: 50.0 + 2.3 (inches over 5 feet in height)	64 kg
		Female: 45.5 + 2.3 (inches over 5 feet in height)	59 kg
LBW	Lean Body Weight	Male: (9270 × TBW) / (6680 + 216 × BMI)	79 kg
		Female: (9270 × TBW) / (8780 + 244 × BMI)	65 kg
ABW	Adjusted Body Weight	IBW + C[a] × (TBW–IBW)	Male, C=0.3, 92 kg Male, C=0.4, 103 kg Female, C=0.3, 89 kg Female, C=0.4, 99 kg
TBW	Total Body Weight	Patients Actual Weight	159 kg
BMI	Body Mass Index	Weight × Height^2	56 kg/m^2

[a]C is correction factor, usually either 0.3 or 0.4. The example is for a 5 foot, 6 inch person (66 inches; 168 centimeters) weighing 350 pounds (159 kilograms).[14]

TABLE 184.4 Dosing Recommendations for Selected Antibiotic Classes

Drug Class	Dosing Recommendation
Beta-lactams/Cephalosporins	Limited data, upper limit of regular dose suggested
Fluoroquinolones	Limited data, upper limit of regular dose suggested
Vancomycin	Load with 20–25 mg/kg TBW; subsequent dose based on peak/trough levels
Linezolid	Limited data
Aminoglycosides	$ABW_{0.4}$

TABLE 184.5 Dosing Recommendations for Sedatives, Neuromuscular Blocking Agents, and Neuromuscular Blocking Reversal Agents

Drug	Dosing Recommendation
Propofol	Limited data, avoid TBW
Etomidate	Limited data, suggest TBW
Ketamine	Limited data, avoid TBW, suggest LBW
Succinylcholine	TBW
Rocuronium	TBW
Vecuronium	TBW
Sugammadex	TBW

by TBW.[6,17] The non-depolarizing neuromuscular blocking agents most commonly used in the ED, vecuronium and rocuronium, have both been shown to have prolonged duration of action when administered by total body weight.[6,17] One recent trial illustrated that using 0.6 mg/kg IBW of rocuronium did not result in slower time of onset than when using higher doses in obese patients.[25] However, given that the only complication of higher doses of non-depolarizing agents is prolonged duration of action and underdosing risks suboptimal intubating conditions, we recommend using TBW for these medications. Sugammadex rapidly reverses paralysis due to the non-depolarizing neuromuscular blocking agents (rocuronium and vecuronium). Recent research suggests the possibility of using IBW; however, as most trials investigating sugammadex are conducted in the operating room at the end of surgical cases as opposed to situations where it would likely be utilized in the ED, the end points of these trials allow for a time to onset that would be inappropriate in the emergency department.[17,26,27]

Anticoagulation

Unfractionated heparin remains a vital drug for the treatment of thromboembolic disease, acute coronary syndrome, and atrial fibrillation. Current recommendations suggest weight-based dosing for both an initial bolus and subsequent infusion, but are silent on dosing strategies in the obese patient.[28-30] Several studies have investigated various dosing methods in the obese, including reducing the initial bolus, capping the bolus, or using various weight scalers, but no clear superior dosing method has been described.[29] We suggest consultation with a pharmacist if local recommendations are not clear on dosing ceilings in the obese patient because many institutions have specific local guidelines in this regard. It is clear that careful monitoring of heparin activity with either activated partial thromboplastin time (aPTT) or anti-Xa levels aids in titrating heparin infusions.[28] Low-molecular-weight heparin (LMWH) can be used in many cases, but activity should be monitored in those over 190 kg by following anti-Xa levels.

Direct oral anticoagulants (DOACs) have gained popularity over vitamin K antagonists such as warfarin in recent years. To date there have not been any large, prospective randomized trails investigating their efficacy and safety in the obese population. Both the Anticoagulation Forum VTE Treatment Guidance and the International Society on Thrombosis and Haemostasis have given recommendations to avoid DOACs in patients with a BMI greater than 40 and weights over 120 kg.[31,32] There have been several recent large retrospective chart review studies that suggest DOACs, and especially rivaroxaban, have reassuring efficacy and safety profiles in severely obese patients. These studies also remind the ED physician that there are large numbers of very obese patients taking these medications.[33-36] Given the paucity of prospective investigations, it would be prudent to avoid initiating DOACs in obese patients from the ED unless alternative medications are unavailable or follow-up care has been coordinated.

TRAUMA CONSIDERATIONS

Obese patients appear to display a change in injury pattern compared to healthy-weight patients with fewer head injuries but more lower abdominal and chest injuries.[37] Increasing BMI has been identified as a protective factor against intraperitoneal injury from stab wounds to

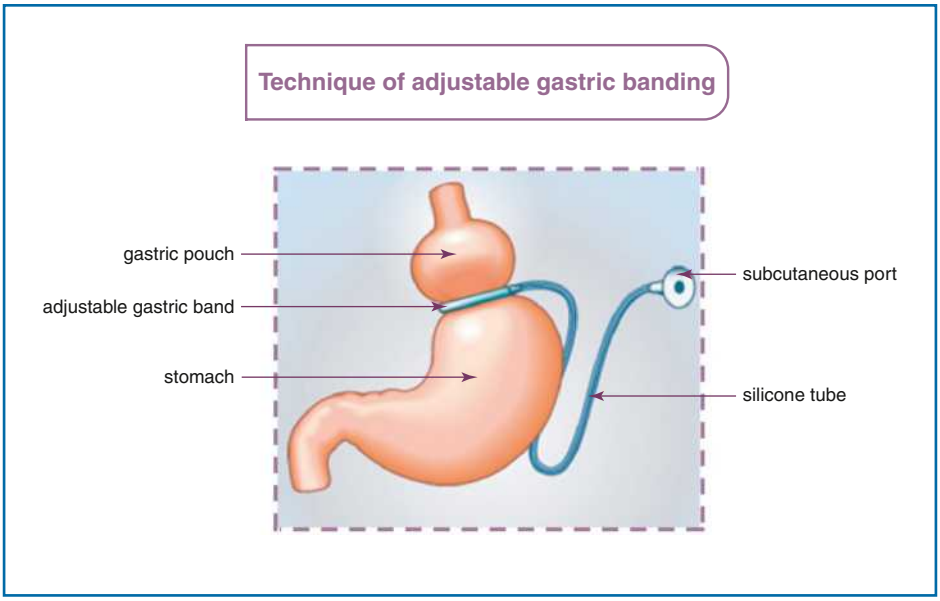

Fig. 184.1 Depiction of laparoscopic adjustable banding (LAB) procedure. (From: Contival N, Menahem B, Gautier T, Le Roux Y, Alves A. Guiding the non-bariatric surgeon through complications of bariatric surgery. *J Visc Surg.* 2018;155:27-40.)

the abdomen.[38] Morbidly obese patients have also been shown to have increased mortality and in-hospital complications as well as longer intensive care unit stays and increased time on mechanical ventilation when compared to non-obese patients.[37,39] We recommend following advanced trauma life support (ATLS) algorithms for the obese patient while paying particular attention to the respiratory status of obese patients laying supine during the primary and secondary surveys. Care should be taken when rolling the patient to protect both the patient and the staff from inadvertent injury.

BARIATRIC SURGERY

Overview

Bariatric surgery is the only intervention that has been demonstrated to produce sustained significant weight loss and treat comorbidities of obesity.[40-45] Severe postoperative complications such as pulmonary embolism (PE), acute coronary syndrome, and anastomotic leak are rare with an overall incidence of less than 1% in the first 30 days.[43] However, approximately 10% of postoperative patients will present to the ED in the first month and over one-third will do so in the first year after surgery.[41,44]

Bariatric surgery encourages weight loss through restrictive (reducing the amount of food that can be ingested at one time) or malabsorptive (reducing caloric absorption from a surgically altered small bowel) means.[45] The American Society for Metabolic and Bariatric Surgery recommends that surgery be offered to patients either with a BMI over 40 or with a BMI over 35 along with severe obesity-related comorbidities such as diabetes, OHS, and nonalcoholic fatty liver disease, among others. Although there are six different operations currently being performed in the United States, the vast majority of patients undergo laparoscopic adjustable banding (LAB), sleeve gastrectomy (SG), or the Roux-en-Y gastric bypass (RYGB). LAB (Fig. 184.1) is the insertion of an adjustable balloon circumferentially around the proximal stomach connected to a subcutaneous port allowing intermittent tightening or loosening of the band. In a SG (Fig. 184.2), the surgeon creates a small stomach remnant with a staple line excluding the greater curvature. In the RYGB (Fig. 184.3), the proximal stomach is separated with a staple line from the distal stomach, creating a small stomach pouch; the jejunum is transected and the distal portion (alimentary limb) is anastomosed to the stomach pouch while the proximal biliopancreatic limb is anastomosed to the jejunum.

Gastric bypass via RYGB results in the greatest (reported at 62% of excess weight on average) and most sustained weight loss but tends to have the most complications. LAB results in less weight loss (about 40% of excess weight) with the fewest complications whereas SG offers intermediate weight loss and complication rates.[42,45] All three surgical options can present to the ED with short-term and long-term complications (Table 184.6).

Obese patients develop thromboembolic complications at a rate that is 2 to 3 times that of the non-obese population. Open surgical approaches have higher rates of PE than do laparoscopic procedures.[45] Given the previously described challenges regarding anticoagulation in the obese population, PE should be considered in postoperative patients presenting with suggestive signs and symptoms.

Laparoscopic Gastric Band

LGB has an exceedingly low mortality rate, but patients can still suffer from early and late complications. Early complications decrease dramatically with surgical experience and are most commonly related to esophageal or gastric perforation (usually but not always diagnosed intraoperatively) and acute gastric dilation. Dilation of the stomach pouch is rare, but because gastric distention can lead to local ischemia, it can result in gastric necrosis and necessitates operative repair. Patients suspected of having these complications should receive prompt resuscitation with IV fluids, pain control, IV antibiotics such as piperacillin-tazobactam targeting intra-abdominal pathogens along with emergent surgical consultation.[45]

Late complications are fairly common with LGB. It is not uncommon for the tubing connecting the subcutaneous port to the band to become kinked or to break. More ominous is a port infection. This may be related to instrumentation from adjustments to the gastric band, but as gastric mural erosion will often present as chronic purulent drainage at the port site, this more serious complication should be ruled out. Computed tomography (CT) or upper gastrointestinal series (UGIS) usually diagnoses this complication; however, upper endoscopy is the test of choice. Aside from purulence at the port site, patients may experience epigastric pain, fever, tachycardia, and

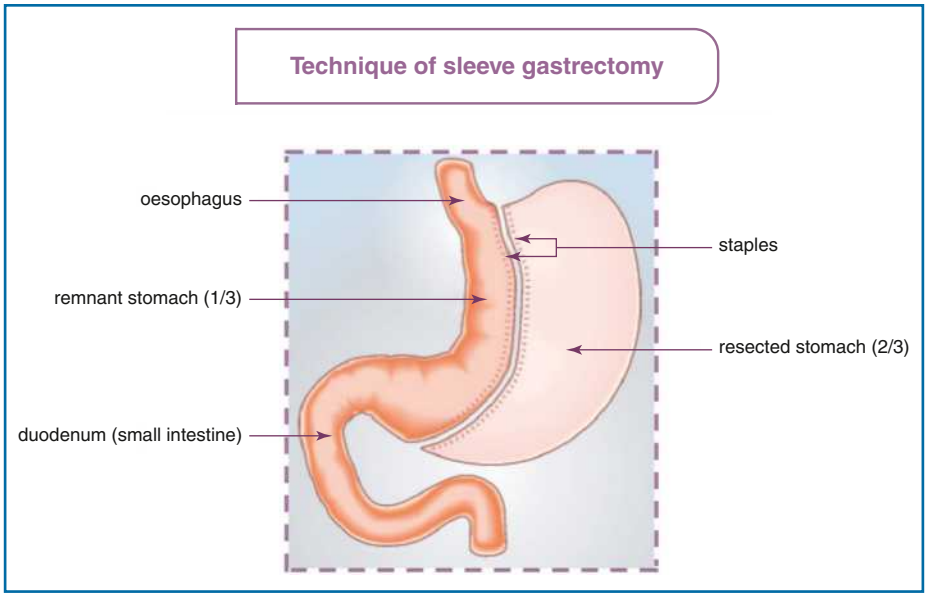

Fig. 184.2 Depiction of sleeve gastrectomy (SG) procedure. (From: Contival N, Menahem B, Gautier T, Le Roux Y, Alves A. Guiding the non-bariatric surgeon through complications of bariatric surgery. *J Visc Surg.* 2018;155:27-40.)

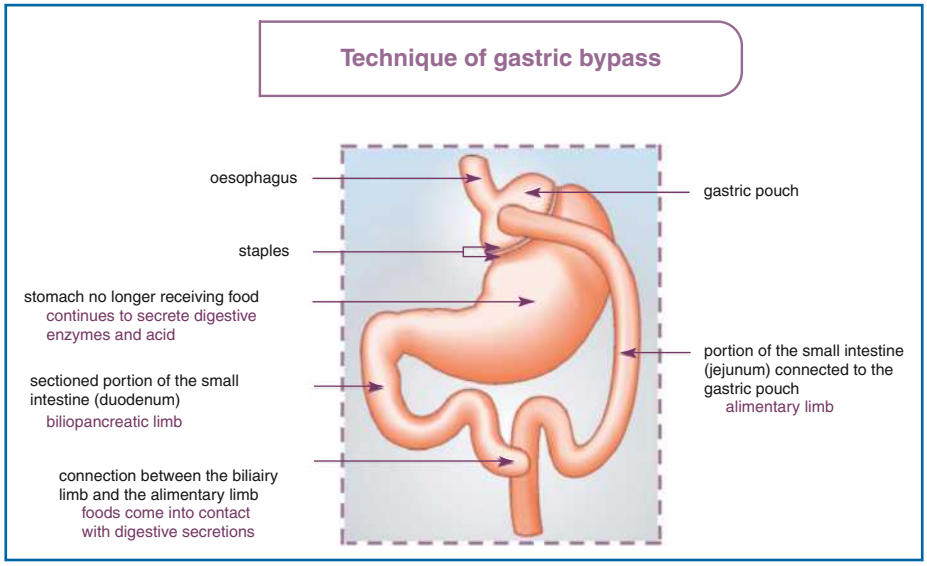

Fig. 184.3 Depiction of Roux-en-Y gastric bypass (RYGB) procedure. (From: Contival N, Menahem B, Gautier T, Le Roux Y, Alves A. Guiding the non-bariatric surgeon through complications of bariatric surgery. *J Visc Surg.* 2018;155:27-40.)

signs of GI bleeding. Pocket dilation and late slippage occurs when the band slowly and gradually slips distally, allowing for larger meals that in turn result in further slippage. Usually this is an insidious process resulting in a cessation of weight loss, but occasionally it can result in acute strangulation and gastric necrosis. It is best diagnosed via UGIS and is treated via prompt loosening of the gastric band by a surgeon. Esophageal dilation likely results from overly aggressive tightening of the band leading to accumulation of food in the esophagus. It is diagnosed via UGIS and treated by relaxation of the band.[45]

Sleeve Gastrectomy

The primary complication of SG centers on gastric leaks leading to fistula formation. It appears that leaks typically arise at the top of the staple line and occur in about 2% of patients undergoing SG. Repair of fistulas, once they appear, is a long and difficult process often requiring multiple procedures and hospitalizations. Strictures will present with signs of obstruction and are resolved either surgically or endoscopically depending upon location. Gastroesophageal reflux disease (GERD) is the most common late complication.[45] As SG has gained significant popularity only since 2010, descriptions of its complications are not as thorough as with other common surgical procedures.

Roux-en-Y Gastric Bypass

The RYGB, the most common gastric bypass surgery in the United States, results in several early and late complications. Leaks can occur at each of the staple lines, which are located at the gastric pouch, the excluded stomach remnant, the jejuno-jejunostomy, and gastro-jejunostomy as well as small bowel division sites. Leaks and fistulas in the distal jejuno-jejunostomy are life-threatening and often present with abdominal pain, peritonitis, and signs of sepsis. However, possibly

TABLE 184.6 Common Early and Late Complications for Various Bariatric Surgeries

Procedure	Early Complications	Late Complications
Laparoscopic Gastric Band	Esophageal perforation	Tubing failure
	Gastric perforation	Port infection
	Gastric dilation	Gastric erosion
		Pocket dilation with late slippage
		Esophageal perforation
Sleeve Gastrectomy	Gastric leak	Gastroesophageal reflux disease
	Fistula formation	Dumping syndrome
Roux-en-Y Gastric Bypass	Staple line leak with or without fistula formation	Marginal ulcers
	Jejuno-jejunostomy obstruction	Internal herniation with or without obstruction
	Gastro-jejunostomy obstruction	Adhesions with obstruction
	Postoperative bleeding	Cholelithiasis
	Marginal ulcers	Dumping syndrome

related to the difficulties with physical examination of the morbidly obese patient, tachycardia may be the only presenting sign. Therefore, we advise urgent surgical evaluation for recent postoperative patients with unexplained heart rates over 120 beats/minute.[45] More proximal fistulas at the gastric pouch suture line or gastro-jejunostomy can be insidious and even asymptomatic and can therefore be managed conservatively with bowel rest. Those with pain or vital sign derangements often require operative intervention.[45]

Bowel obstruction due to anastomotic stricture of the jejuno-jejunostomy is another dangerous complication. Because the 70-cm biliopancreatic limb originates in the blind stomach remnant, it will fill with digestive secretions before the obstruction fills the gastric pouch through the longer alimentary limb (150 cm). Therefore, the excluded stomach may distend and subsequently perforate before the onset of vomiting. Prompt surgical consultation is advised when this diagnosis is considered. Epigastric pain, vomiting, and progressive dysphagia suggest stenosis of the more proximal gastro-jejunostomy and appear later (weeks after surgery) than jejuno-jejunostomy strictures (days after surgery). In contrast to more serious distal strictures, gastro-jejunostomy strictures are usually managed with endoscopy and dilation.[45]

Postoperative intraperitoneal bleeding most often occurs from staple lines, resulting in blood in abdominal drains. The diagnosis can be confirmed, if necessary, via laparoscopy and therefore prompt surgical consultation is recommended. As with all bleeding, unstable patients should be transfused early, while the diagnosis is confirmed. Intraluminal bleeding from a proximal source may be suggested by hematemesis or melena and is managed via endoscopy for both diagnosis and possible treatment. Distal bleeding from the jejuno-jejunostomy or the excluded portion of the stomach, suggested when patients present with melena, is usually managed supportively.[45] Marginal ulcers, or ulceration at the gastro-jejunostomy, tend to occur in those who smoke, suffer from *Helicobacter pylori* infection, or are on nonsteroidal antiinflammatory medication.[40] Patients often present with epigastric pain especially with eating, vomiting, and occasionally with signs of upper GI bleeding. Diagnosis is made by endoscopy. Medical treatment is usually sufficient with high-dose proton pump inhibitor and risk factor modification. Rarely, marginal ulcers can lead to strictures or even perforation.[45]

Patients who have undergone RYGB can suffer from several late complications. Marginal ulcers, although more common in the immediate postoperative period, are known to develop up to 2 years after surgery. Bowel obstruction may be related to postoperative adhesions but is due to internal herniation in 60% of cases. Weight loss will predispose patients to internal hernias as potential spaces open in the small bowel mesenteries. They can be particularly difficult to diagnose because they can be intermittent and CT scans are often falsely negative. Patients may complain of intermittent pain without clear etiology which may localize to the left flank. Exploratory laparoscopy may be required to confirm the diagnosis. Rapid weight loss associated with RYGB leads to formation of gallstones, particularly 6 to 18 months following surgery. Some surgeons will perform a prophylactic cholecystectomy during the gastric bypass procedure, but this is not a universal practice. Treatment of simple symptomatic cholecystitis and biliary colic is similar to patients without bariatric surgery, but clinicians should note that following RYGB the common bile duct is no longer accessible via routine endoscopic retrograde cholangiopancreatography (ERCP). Therefore, treatment of common duct stones requires a surgical approach rather than the typical endoscopic one.[40,45]

Anatomic changes associated with RYGB and SG can predispose patients to dumping syndrome. This occurs whereby a large bolus of partially digested food is rapidly released into the small bowel.[45,46] Early dumping syndrome is thought to be related to rapid fluid shifts as water is drawn into the hyperosmolar environment of the small bowel from the vascular compartment in the first hour after a meal. This leads to GI symptoms such as abdominal pain, bloating, nausea, borborygmi, and vomiting. Rapid fluid shifts can result in flushing, palpitations, fatigue, transient hypotension, tachycardia, diaphoresis, and rarely, syncope. Late dumping syndrome, typically 60 to 180 minutes following a meal, is thought to result from an incretin-driven hyperinsulinemic response leading to hypoglycemia. The patient will often experience typical symptoms of hypoglycemia such as fatigue, weakness, and hunger along with an adrenergic surge leading to tremor, tachycardia, and diaphoresis. First-line treatments for dumping syndrome focus on diet and include frequent small meals, elimination of refined sugar, and delaying fluid intake until 30 minutes after a meal.[46]

PROCEDURAL DIFFICULTIES

Lumbar Puncture

The lumbar puncture (LP) is typically performed using a landmark-based approach. However, this can be particularly challenging in the obese patient when familiar landmarks are obscured by adipose tissue.[47,48] Ultrasound can be of assistance in mapping out landmarks when they cannot be palpated.[49] Positioning the patient in a sitting position rather than lateral decubitus position may also make the procedure easier. Extra-long 5-inch (12.7 cm) needles may be necessary to reach the subarachnoid space. In cases where the LP cannot be successfully performed at the bedside, the patient may require a fluoroscopic-guided lumbar puncture.[47]

Venous Access

Excessive subcutaneous adipose tissue can lead to difficulties in establishing intravenous (IV) access. Ultrasound can successfully identify otherwise obscured veins in the obese population and aid in the establishment of IV access.[50] Central venous access may be required for access in general or in the case of an unstable patient. Care should be taken when placing obese patients in the Trendelenburg position as it can have severe negative consequences for pulmonary function in both the spontaneously breathing and the intubated obese patient. An assistant or tape may be required to position the panniculus out of the field when placing catheters in the femoral vessels. Intraosseous (IO) access can also be rapidly established when medications or blood needs to be given expeditiously. Recent research has suggested that so long as the tibial tuberosity can be palpated, a standard 25-mm IO needle can be placed in the proximal or distal tibia. A longer 45-mm needle should be placed in the proximal humerus in obese patients and in the tibia if the tibial tuberosity cannot be palpated.[51]

Cardiopulmonary Resuscitation

High-quality cardiopulmonary resuscitation (CPR) is critical in the chain of survival from cardiac arrest. Guidelines suggest placing the hands on "the lower half of the sternum" due to the common location of the maximal left ventricular outflow tract diameter.[52,53] Recent radiographic evidence suggests that the optimal compression location for CPR in obese patients is slightly more cranial than in healthy-weight individuals and that CPR is technically more difficult on obese patients than on healthy-sized individuals.[53,54] We encourage emergency providers to pay close attention to CPR quality in obese patients and use CPR quality feedback devices when available.

Endotracheal Intubation

Although controversial, obesity has been considered a risk factor for difficult intubation.[6,7,55,56] The pathophysiologic changes that occur in the lung due to obesity result in much shorter apnea times than in healthy-weight patients. Preoxygenation with noninvasive ventilation, when time and equipment allow, is recommended over non-rebreather mask use because it has been shown to increase safe apnea time by one minute in the obese patient, likely by reducing atelectasis.[7] Increases in safe apnea times may also be seen when the patient is maintained in an upright position during preoxygenation and intubation.[6,7,57] During intubation, we recommend placing obese patients in a head up or ramped position with the goal of aligning the external auditory meatus with the sternal notch. This will serve to both increase safe apnea times and improve the laryngoscopic view.[6,7,57] Intubation of the obese patient should be considered a difficult intubation and all airway adjuncts should be readily available. Clinicians should keep in mind that obesity is associated with difficult bag-valve-mask (BVM) ventilation and be prepared for two-person BVM ventilation with oral and/or nasal airways. Cricothyrotomy is likely to be technically difficult in the obese patient owing to difficulty palpating landmarks.[37]

Ventilator Management

Obese patients suffer from increased atelectasis and V/Q mismatch owing to changes in lung compliance and FRC. They also have increased respiratory rates, even at rest, compared to nonobese patients. After intubation, tidal volumes should typically be set to 6 to 8 mL/kg IBW rather than TBW to avoid pulmonary injury.[6,7] Respiratory rates should initially be set higher than for nonobese patients owing to the increased resting respiratory rate and can be titrated based on blood gas analysis. Patients who are known or predicted to be acidemic should usually have even higher respiratory rates. Positive end-expiratory pressure (PEEP) can be difficult to manage in the obese patient. Given their propensity for atelectasis, starting obese patients with PEEP of 10 cm H_2O is recommended. However, high levels of PEEP can lead to reduced venous return and therefore lower preload and can predispose patients to hypotension. Therefore, close attention should be paid to hemodynamics and ventilator settings adjusted as needed. Providers also are urged to monitor for auto-PEEP and change ventilator settings accordingly.[6,7] As with most patients, obese patients should be maintained in either a sitting position or reverse Trendelenburg to optimize pulmonary function.

Challenges with Hospital Equipment

Emergency departments should have equipment, including hospital beds, commodes, and wheelchairs, engineered to accommodate obese patients. This includes the ability to handle not only substantial weight but also the increased girth of these patients. Appropriate monitoring equipment such as blood pressure cuffs should also be readily available. Proper mechanical lifts and safe handling plans are also prudent; the National Institute for Occupational Safety and Health recommends that nurses lift no more than 35 pounds when providing patient care and currently workers in hospitals suffer from musculoskeletal injuries at twice the national rate.[9]

Imaging Challenges

Ultrasound has the advantage of portability and therefore table weight limits do not present a challenge. Adipose tissue will attenuate sound waves; however, with the proper settings and transducer, as well as by utilizing harmonic imaging, most obese patients can be evaluated with ultrasound. X-ray imaging is limited in the obese patient due to reductions in resolution and image contrast. Obese patients also will require increased exposure times which in turn lead to greater probability of motion artifact.[58]

CT imaging in the obese patient has both mechanical and radiographic challenges. Three different measurements must be taken into account when evaluating if an obese patient can be evaluated by a particular scanner. First is the table load limit, which not only protects against mechanical table failure and subsequent risk of patient injury, but also allows for smooth and predictable speed as the patient is passed through the scanner. Second is aperture size to ensure that the patient can physically pass through the CT machine. This is much more of a challenge when abdomen/pelvis CT is required than when a CT of the head is needed and may require measuring the girth of the patient. Third is the maximum reconstruction FOV (field of view). This denotes the area within the scanner where images will be captured. It is advised that the obese patient be positioned such that the area of interest lies within the FOV. Even when the obese patient is able to fit in the scanner, large amounts of adipose tissue will create artifacts that can limit the diagnostic utility of the image.[58] Additionally, patients must lie flat in the CT scanner, which can lead to respiratory complications in an obese patient. It is prudent to offer a trial of supine positioning in the safety of the ED with staff at the ready if there is a question regarding the ability of the patient to lie flat for the time required to obtain the desired images.

Obtaining useful MRI images often encounters problems similar to those outlined for CT imaging. The MRI table must be able to safely support and pass the patient into the scanner, and the patient must be able to fit into the scanner itself. Modern scanners are often 70 cm in diameter and slightly larger than previous generations of scanners (60 cm). Some radiology departments have "open MRI" machines that may accommodate larger patients.

CHAPTER 184: QUESTIONS AND ANSWERS

1. Rates of obesity in the United States and around the world have been:
   a. Increasing in the US and decreasing around the world.
   b. Increasing in the US and staying constant around the world.
   c. Staying about the same worldwide.
   d. Increasing in the US and around the world.

Answer: D. Increasing in the United States and around the world.

2. When lying supine, obese patients tend to:
   a. Breathe normally because they have more developed chest musculature.
   b. Have trouble breathing due to stomach distention.
   c. Have trouble breathing due to changes in lung mechanics.
   d. Have trouble breathing due to chronic back pain.

Answer: C. Increased chest wall mass in conjunction with substantial abdominal fat mass leads to reduced lung compliance and collapse of small airways resulting in increased airway resistance. These changes in turn result in a decrease in functional residual capacity (FRC) leading to increased atelectasis.

3. Challenges to obtaining high-quality CT scan images in the obese patient include which of the following?
   a. Difficulty lying flat for the scan
   b. Weight limits of the gantry table
   c. Girth greater than aperture size
   d. Claustrophobia during the scan
   e. Area of interest laying outside the CT field of view (FOV)

Answer: A, B, C, and E are all correct. Claustrophobia is often a difficulty during MRI, not CT.

4. Drug dosing of obese patients is based on which of the following factors?
   a. Ideal body weight for the vast majority of drugs
   b. Total body weight for the vast majority of drugs
   c. A complex decision based on the properties of the drug and the clinical picture of the patient
   d. Total body weight if weight is less that 150 kg and ideal body weight if above that.

Answer: C. Drug dosing is a complex decision based on the properties of the drug and the clinical picture of the patient. The clinician faces several challenges regarding proper medication dosing in the obese patient. The volume of distribution (V_d) of a drug is the principal factor involved in the loading dose whereas subsequent maintenance dosing will primarily be governed by total body clearance (Cl).[14] The V_d is affected by many factors including drug lipophilicity, plasma binding, regional blood flow, body composition, molecular size, and degree of ionization.

5. Which of the following statements regarding internal hernias following Roux-en-Y gastric bypass is true?
   a. They can be intermittent and may require exploratory surgery for diagnosis.
   b. They are easy to diagnose based on history and physical examination.
   c. They are almost always visualized on CT studies.
   d. They are an exceedingly rare complication.

Answer: A. They can be intermittent and may require exploratory surgery for diagnosis Weight loss will predispose patients to internal hernias as potential spaces open in the small bowel mesenteries. They can be particularly difficult to diagnose because they can be intermittent and CT scans are often falsely negative. Patients may complain of intermittent pain without clear etiology which may localize to the left flank. Exploratory laparoscopy may be required to confirm the diagnosis.

The Combative and Difficult Patient*

Malia J. Moore and Jason D. Heiner

KEY CONCEPTS

- The emergency department (ED) should develop a written plan of action to deal with violence that integrates the roles and activities of ED staff, hospital administration, security, and local authorities.
- ED staff should be trained to recognize potentially violent individuals and to intervene with verbal de-escalation techniques prior to the use of physical or chemical restraint when possible.
- The emergency clinician should be familiar with the use of physical and chemical restraints as well as the breadth of options for chemical sedation and circumstances that may guide selection of particular medications.
- For the undifferentiated, severely agitated patient requiring rapid tranquilization, we recommend a benzodiazepine (such as lorazepam) either alone or with a first-generation antipsychotic (such as haloperidol).
- The possibility of an organic (medical) cause of aggressive behavior should be considered in all violent patients, even those with known psychiatric disease.
- Difficult patient encounters may result in undesirable implications for both patients and their ED caregivers, including compromised patient care, compassion fatigue, or professional burnout.
- Management of the difficult patient can be optimized by understanding the multiple issues contributing to the impaired clinician-patient relationship, including factors of the ED setting (such as time constraints and lack of privacy), individual clinician influences (such as personal bias or poor communication), and patient contributions to the interaction, including behavioral, social, or substance use issues.
- Pejorative stereotypes of difficult patients should be avoided. To aid in clinician strategies for challenging encounters, instead aim to characterize the patient's primary difficult behaviors.
- Understanding one's own biases and reactions and optimizing communication are helpful strategies in dealing with a suboptimal clinician-patient relationship.

THE COMBATIVE PATIENT

Foundations

Combative patients are among the most difficult patients encountered by emergency clinicians. Often brought in against their will, they can be agitated, confrontational, difficult to examine, and they may physically harm themselves or others. The emergency clinician should seek to control the patient and the situation, diagnose and treat reversible causes of violence, ensure that there is not an organic cause contributing to the behavior, and protect the patient, staff, and other patients from harm.

The emergency department (ED) is a volatile environment owing to high stress, illness, prolonged waiting times, and often perceived gaps in communication. Given that the ED is open 24 hours a day, 7 days a week, combined with the availability of potential hostages and accessibility to drugs or weapons, compound the potential for violent behavior. The assault-injury rate of health care occupations is nearly 10 times that of the general sector, and over half of all health care providers will be victims of violence of some form during their careers.

Emergency care providers throughout the world are more likely than other health care providers to experience violent events, such as verbal threats, physical assaults, or confrontations outside the workplace.[1-9] In 2018, The American College of Emergency Physicians (ACEP) conducted a poll of 3539 emergency physicians across the country in which nearly 50% reported having been assaulted while at work in the ED, with over 70% having witnessed an assault in the workplace.[7] In this survey, nearly all assaults were committed by the patient (97%), but in 28%, it was reported that family or friends acted as an accessory.[7] Similar rates of violence and aggression toward physician and nursing staff are typically observed, and both men and women generally appear to be at comparable risk.[1,4] Violent incidents are far more likely to be verbal threats or acts of intimidation than physical assaults and, in the ED, may be acted out by patients, as well as their family, friends, or other visitors.[1-7] The actions of combative patients have consequences that extend beyond the physical injury of ED caregivers, such as provider posttraumatic stress disorder symptoms or lost provider work productivity, and also serve as a major contributor to burnout.[1,6-8]

Clinical Presentation

Patient Characteristics

The pathogenesis of violent behavior is multifactorial, with potential contributing factors including environmental, historical, interpersonal, biochemical, genetic, hormonal, neurotransmitter, or substance abuse disorders.[10-12] Psychiatric illness is also a risk factor, with schizophrenia, personality disorders, mania, or psychotic depression most frequently associated with violence.[10-12] Delusional schizophrenic patients may become violent, believing that others are attempting to harm them. They may also have auditory hallucinations commanding harm to others. The patient with acute mania is unpredictably dangerous because of emotional lability, a situation in which pleasantness can quickly turn to aggression. Substance abuse disorders and drug-seeking behavior are consistently associated with violent behavior in both psychiatric and nonpsychiatric populations.

Biologically, the serotonin system largely controls aggression and inhibition, with a role of diminished serotonergic function in disinhibiting aggression against self and others.[11] Generalized brain

BOX 185.1 Selected Conditions Associated With Violence

Psychiatric
Schizophrenia
Paranoid ideation
Catatonic excitement
Mania
Personality disorders
- Borderline
- Antisocial
- Delusional depression
- Posttraumatic stress disorder
- Decompensating obsessive-compulsive disorders

Situational Frustration
Mutual hostility
Miscommunication
Fear of dependence or rejection
Fear of illness
Guilt about disease process

Antisocial Behavior
Violence with no associated medical or psychiatric explanation (these patients may be managed by the police or security)

Organic
Diseases
Delirium
Dementia
Trauma
Central nervous system infection
Seizure
Neoplasm
Cerebrovascular accident
Vascular malformation
Hypoglycemia
Hypoxia
Acquired immunodeficiency syndrome (AIDS)
Electrolyte abnormality
Hypothermia or hyperthermia
Anemia
Vitamin deficiency or toxicity (e.g., hypervitaminosis D)
Endocrine disorder

Drugs
Unanticipated reaction to prescribed medication (especially sedatives in brain-injured or elderly patients)
Alcohol (intoxication and withdrawal)
Amphetamines
Cocaine
Sedative-hypnotics (intoxication or withdrawal)
Phencyclidine (PCP)
Lysergic acid diethylamide (LSD)
Anticholinergics
Aromatic hydrocarbons (e.g., glue, paint, gasoline)
Steroids
Synthetic cannabinoids
Synthetic cathinones

dysfunction may predispose patients to violence by disruption of the regulation of aggression, particularly in the prefrontal or temporal cortex.[11] Cerebral imaging documents both functional and structural impairments in violent criminals and antisocial patients.

Violent behavior also occurs in association with head trauma, hypoxia, hypoglycemia, electrolyte imbalance, infections (particularly herpes encephalitis), drug intoxication or withdrawal or adverse reaction, or metabolic and endocrine derangements. Uncommon organic causes include seizures (e.g., temporal lobe), tumors (particularly those in the limbic system), limbic encephalitis, multiple sclerosis, porphyria, Wilson disease, Huntington disease, sleep disorders, hyperparathyroidism, or vitamin and mineral deficiencies (e.g., folate, vitamin B_{12}, niacin B_2, and pyridoxine vitamin B_6). Although drug or ethanol intoxication and withdrawal are the most common diagnoses in combative ED patients, the mnemonic FIND ME (*f*unctional [i.e., psychiatric], *i*nfectious, *n*eurologic, *d*rugs, *m*etabolic, *e*ndocrine) helps in broadly categorizing many important causes of violence (Box 185.1).

Identification of *potentially* violent patients is more difficult; male gender, prior history of violence, and drug or ethanol abuse have historically been positive predictors, whereas ethnicity, diagnosis, age, marital status, and education have been unreliable identifiers. Overall, the most accurate tools for predicting acute violent behavior likely rely largely on current behavioral patterns and clinical observations in the context of prior patterns of violence of the patient when known or previously documented.[12]

Emergency Department Influences

An annual ED census over 50,000 patients, an average waiting time over 2 hours, and ED crowding are associated with an increased incidence of violence.[13] The risk of workplace assault in the ED, however, exists across hospitals of all sizes and reflects the rate of violence in the community. Despite these risks, health care providers have not been routinely trained in the identification and management of combative patients.[14]

Patients armed with lethal weapons pose a serious threat to staff and the potential risk posed by concealed weapons exists in all settings including pediatric EDs. In areas where community violence is prevalent, conflict may spill over into the ED when those involved in violent altercations are being treated for their injuries.[8] The carriage of weapons in the ED population has previously been estimated at approximately 4% to 8%, with up to 27% of major trauma patients; however, not all EDs screen for weapons or use metal detectors. Unfortunately, prediction of weapons carriage in any particular patient is challenging, and it is therefore prudent to assume that all violent patients are armed until it is proved otherwise, especially those presenting with major trauma.

The deleterious effects of violence in the ED can be minimized by employing certain preventive measures and by training staff in techniques to de-escalate and limit violent behavior when it occurs (Box 185.2).

Initial Patient Evaluation

Evaluation of the combative patient begins with attention to safety measures. All patients should be screened for weapons before the interview. The use of metal detection is ideal upon ED entry, and additional attention may be needed for patients brought to the ED by ambulance and thereby bypassing routine security screens. The practice of undressing patients and placing them in a gown is useful as a non-confrontational survey for potential weapons that also discourages fleeing in some circumstances or, conversely, aids in identification if a violent patient suddenly flees from the ED.

The ideal setting for the patient interview emphasizes privacy without isolation, such as a seclusion room specifically designed for the

BOX 185.2 Emergency Department Preparedness and Prevention of Violence

General Emergency Department Preparedness Considerations

Physical and system factors to minimize ED violence risk:

1. Prominently displayed warning signs prohibiting weapons and alerting all entering that they may be screened for weapons
2. Nondiscriminatory inquiry about weapon carriage and searches of individuals for weapons with clear local policies for staff about searches and contraband disposal
3. A panic or alarm system to activate hospital security or local police response
4. ED placement of dedicated telephone(s) with a direct line to police or security to request additional personnel if needed
5. Control flow into the ED by limiting access to one or two entrances and consider buzzer access systems, and protective bulletproof glass or metal bar barriers at front desks
6. A secure examination room with solid ceiling, shatterproof ceiling lights, heavy indestructible chairs, well-secured restraint bed, two outward swinging doors that can be locked from the outside, an emergency distress button that can be activated unobtrusively, and consideration of a video monitoring system

Primary Prevention

Control factors encouraging the development of frustration and aggression:

1. Minimize waiting times to the extent feasible
2. Optimize waiting room environment
3. The presence of visible surveillance cameras
4. The presence of a trained visible security force reflecting both hospital needs and anticipated violence based on local community prevalence

Secondary Prevention

Response to pre-violent agitation and aggression:

1. Recognition of risk (pre-violent patients and their companions)
2. Implementation of de-escalation techniques
3. Minimize treatment delays of pre-violent individuals
4. Ongoing staff training in violent management techniques to increase caregiver confidence and comfort while decreasing the rate of aggressive incidents

Tertiary Prevention

Limitation of the actual act of violence once it has occurred:

1. Use of physical and chemical restraints
2. Appropriate security and police intervention
3. Apply familiar protocols for dealing with the violent individual

ED, Emergency department.

interview of potentially dangerous patients. Prior to the medical interview, security should be stationed strategically and the door left open to facilitate both intervention and escape for the provider. The patient and interviewer may be seated roughly equidistant from the door, or the interviewer may sit between the patient and the door. Blocking of the door, however, poses a risk of harm to the clinician if the patient feels the urge to escape. Ideally, examination room doors should swing out, and more than one exit should be available. The clinician should have unrestricted access to the door and avoid sitting behind a desk. The room should not contain heavy or potentially dangerous objects that may be thrown. There ideally should be a mechanism to alert others of danger, such as a panic button or a code word or phrase that summons security (e.g., "I need 'Dr. Armstrong' in here."). For personal protection of the provider, earrings, necklaces, and neckties should be removed. Personal accessories that may be used against the caregiver, such as a stethoscope or scissors, should also be removed. The clinician should be aware of any objects within the room or on the patient's body that might be used as weapons, such as pens, watches, necklaces, key chains, cell phones, or belts.

BOX 185.3 Patient Behaviors Suggesting Impending Violence

Provocative behavior
Angry demeanor
Loud, aggressive speech
Tense posturing (e.g., gripping arm rails tightly, clenching fists)
Pacing or frequently changing body position
Aggressive acts (e.g., pounding walls, throwing objects, hitting oneself)

Violence risk assessment of a potentially combative patient can be difficult. Violence often erupts after a period of mounting tension. The astute practitioner may identify verbal or nonverbal cues and may subsequently have the opportunity to defuse the situation. In a typical scenario, the patient first becomes angry, then resists authority, and finally becomes confrontational and violent. When clinicians have a "gut feeling" that a dangerous situation may be developing, they should take appropriate precautions. Violent behavior may also erupt without warning, especially in patients with an organic brain syndrome, so clinicians should not feel overly confident in their ability to sense impending danger. An obviously angry ED patient should be considered potentially violent. Patients with a history of violent behavior are more likely to inflict serious injury, and certain patient behaviors may suggest impending violence (Box 185.3).

To prevent escalation, the patient should be removed from contact with other agitated accomplices, as well as from other provocative patients. A quiet area enabling direct observation is optimal. Because increased waiting times correlate positively with violent behavior, consider evaluating the potentially violent patient accelerated to prevent escalation of aggression. When feasible, expeditious triage and evaluation of these patients may avoid the challenging consequences of violence for the patient at hand, the ED staff, and ultimately the care of other ED patients. Often, the perception of preferential treatment alone may serve to defuse the patient's anger.

Management

Verbal Management Techniques

Verbal de-escalation techniques should be considered in the setting of agitated or violent patients prior to implementation of physical restraints or chemical sedation. The agitated but cooperative patient may be amenable to verbal de-escalation techniques alone. This verbal interaction provides an opportunity to assess the patient's mental status and comprehension, as well as perception of the current situation. If the patient remains resistant or violent after verbal techniques, or incapable of interacting appropriately, then restraint is necessary. However, the uncooperative, actively violent or potentially violent patient may warrant immediate restraint to minimize risk to the patient and ED staff.

Successful verbal management techniques include an effort to make the patient as comfortable as possible, being honest and straightforward during the medical interview, adopting a non-confrontational demeanor, and being an attentive and receptive listener without conveying weakness or vulnerability (Box 185.4).[9,14] The interviewer should respond verbally in a calm and soothing tone of voice. It is also important to stand at least an arm's length away and to avoid prolonged

BOX 185.4 Ten Elements for Verbal De-Escalation

1. Respect personal space: Maintain a distance of two arm's lengths and provide space for easy exit for either party.
2. Purposefully avoid provocation: Keep your hands relaxed, maintain a nonconfrontational body posture, and do not stare at the patient.
3. Establish verbal contact: The first person to successfully connect verbally should lead the effort.
4. Use concise, simple language: Elaborate and technical terms are hard for an impaired person to understand.
5. Identify feelings and desires: "What are you hoping for?"
6. Listen closely to what the patient is saying: After listening, restate what the patient said to improve mutual understanding (e.g., "Tell me if I have this right ...").
7. Agree, or agree to disagree: (a) Agree with clear specific truths; (b) agree in general (e.g., "Yes, everyone should be treated with respect."); (c) agree with minority situations (e.g., "There are others who would feel like you.").
8. Set clear limits: Inform the patient that violence or abuse cannot be tolerated.
9. Offer choices and optimism: Patients feel empowered if they have some choice in matters.
10. Debrief the patient and staff: Be sure to include an opportunity for the patient and staff to speak.

Adapted from the American Association for Emergency Psychiatry De-escalation Workgroup consensus statement: Richmond JS, Berlin JS, Fishkind AB, et al: Verbal de-escalation of the agitated patient: consensus statement of the American Association for Emergency Psychiatry Project BETA De-escalation Workgroup. *West J Emerg Med.* 2012;13:17-25.

direct eye contact, approaching the patient from behind, or sudden movements. In some cases, an agitated patient may be aware of the impulse control problem and welcome limit setting by the clinician (e.g., "I can help you with your problem, but I cannot allow you to continue threatening me, the emergency department staff, or other patients."). The interviewer should act as an advocate for the patient. Offering a soft chair, food, or beverage (though not a hot liquid, which may be used as a weapon) may help in establishing trust, and patients may de-escalate as a result of the attention to their basic human needs.

A key component of interviewing a potentially violent patient is addressing the issue of violence directly. The patient should be asked relevant questions about suicidal or homicidal ideations or plans, possession of weapons, history of violent behavior, and current use of intoxicants. Acknowledgment of the obvious (e.g., "You look angry.") may enable the patient to begin sharing emotions. If the patient becomes more agitated, it may be helpful to speak in a conciliatory manner and to offer supportive statements to guide and empower the patient in what you would like them to do (such as, "You seem to want to do the right thing. How can we come up with a solution together?") to help defuse the situation. If this is not successful, a respectful offer of medication or restraints to the patient may prevent further escalation.

Counterproductive approaches to the combative patient include arguing, threats, deception, or condescension, as they fail to build rapport and may challenge patients to "prove themselves," thereby further escalating the situation. An open threat to call security personnel also invites aggression. Clinicians should be aware of their own reactions to such patients and avoid transference of anger. Deliberate deception (e.g., "I am sure you will be out of here in no time.") may serve to invite violent consequences once the false promise is uncovered and an unsuspecting nurse or colleague who follows the initial interviewer may be victimized. It is important to avoid denial or downplaying of threatening behavior, and if verbal techniques are unsuccessful and escalation occurs, the clinician should immediately seek refuge and summon help.

Physical Restraints

Physical restraints should be considered when verbal techniques prove unsuccessful. The use of restraints can be humane and effective in facilitating diagnosis and treatment while preventing injury to the patient or medical staff. Generally speaking, the liability one incurs for restraining a patient against his or her will is negligible compared with the potential liability for allowing a patient to lose control and cause physical harm to themselves or others. Restraints should not be applied for convenience or as a punitive response for disruptive behavior and should be removed as expeditiously as possible, usually once adequate chemical sedation is achieved.

Indications for emergency seclusion and restraint include the prevention of imminent harm to the patient, others, or the immediate environment, or as part of an effective ongoing behavior treatment program. Patients can typically be broadly classified into three categories: (1) those with an organic disorder for whom restraints facilitate evaluation, (2) those with functional psychosis for whom verbal techniques are less effective and restraints facilitate administration of neuroleptics, and (3) those with personality or other disorders prohibiting the utility of verbal techniques. Seclusion or restraint may be contraindicated because of the patient's clinical or medical condition. Seclusion should not be used in an unstable patient who requires close monitoring and should be avoided when the patient is suicidal (unless adequate continuous observation can occur), self-abusive or self-mutilating, or intentionally ingested drugs or poisons. The indications for the use of restraints should be documented. Specific statements (such as, "I restrained Mr. Smith because he told me he was going to beat me up and then took a swing at me.") are preferable to general statements (such as, "I restrained Mr. Smith because he was violent.").

The application of restraints should be systematic and ideally follow a predetermined ED protocol that is implemented when the examiner leaves the room after verbal techniques are unsuccessful. Whenever possible, the treating clinician should avoid active participation in restraint application to preserve the clinician-patient relationship. The restraint team ideally consists of at least five people, including a team leader. The leader, whether a physician, nurse, or security officer, should be experienced in implementing restraints and provide guidance and instruction for the restraint team. Before engaging with the patient, the leader outlines the restraint protocol and warns of anticipated danger, including the presence of objects that may be weaponized. All team members should remove personal objects that the patient could use against them. A mixed-gender restraint team should be considered to mitigate potential allegations such as sexual assault.

The team engages with the patient as a group and displays a professional rather than threatening attitude. Many violent individuals calm down at this point as a large show of force protects their ego (e.g., "I would have fought back but there were too many against me."). The leader speaks to the patient in a calm and organized manner, explaining why restraints are needed and how the course of events will transpire (e.g., "You require a medical and psychiatric examination, as well as treatment."). The patient is instructed to cooperate and to lie down on the gurney to have restraints applied. Some patients are relieved at the protection to self and others afforded by restraints when they feel themselves losing control. Even if the patient suddenly appears less dangerous once the decision to restrain is made, it is advisable to continue the process and avoid negotiation with the patient at this point.

If physical force becomes necessary, one team member restrains a preassigned extremity by controlling the major joint (knee or elbow). The team leader controls the head. If the patient is armed, two mattresses can be used to charge and immobilize (sandwich) the patient. Restraints are applied securely to each extremity and tied to the solid frame of the gurney (not side rails, as later repositioning of side rails also repositions the patient's extremities).

Leather is the optimal type of restraint, as it is a physically stronger material and less constricting than typical soft restraints. For this reason, gauze should not be used. Soft restraints may help restrict extremity use in the semi-cooperative patient, but are unlikely to be effective in the truly violent patient who is continuing to struggle and attempt escape. If chest restraints are used, it is vital that adequate chest expansion for ventilation is ensured. The application of a soft Philadelphia collar to the patient's neck may minimize head banging or biting. In this circumstance, ensuring continued adequacy of the patient's airway is similarly prudent. Although restraining patients on their sides helps prevent aspiration, we recommend the supine position with the head elevated, as it tends to be more comfortable and allows a more thorough medical examination while providing some protection against aspiration. Once the patient is immobilized, announcing "the patient is safe" may have a calming effect on the restraint team and the patient.

We recommend avoiding the prone restraint position when possible and employing chemical sedation when a patient continues to struggle against physical restraints. Sudden unexpected deaths have been reported in prone patients, particularly if left unattended during busy shifts or between multiple sign-outs with various treating clinicians. Although healthy volunteers, when restrained and undergoing physical exertion, do not appear to experience clinically significant positional asphyxia, combative ED patients often suffer from other conditions that may predispose to increased morbidity. Patients using cocaine or other stimulants who are restrained in the prone position appear to be uniquely at risk because increased sympathetic tone and altered pain sensation allow exertion beyond normal physiologic limits, and sympathetic-induced vasoconstriction may impede clearance of metabolic waste products and induce hyperthermia and rhabdomyolysis. Alteration of respiratory mechanics in an acidemic patient resulting from the position of restraint can be a contributing factor through impairment of respiratory compensation.

After restraints are successfully applied, the patient should be monitored frequently and positions changed to prevent neurovascular sequelae, such as circulatory obstruction, paresthesias, or rhabdomyolysis associated with continued combativeness. Standardized documentation is recommended for this monitoring to include the specific indication for restraint and, ideally, colleague agreement that restraints are necessary. Basic patient needs must be met (e.g., hydration, toileting needs) and physical restraints should be removed as soon as possible. Review of restraint team performance and critical discussion may reveal opportunities for improvement. Education and rehearsal by staff can improve and maintain restraint skill as well as improve comfort and confidence with this skill.

Chemical Restraints

Chemical sedation alone, or in conjunction with physical restraint, may assist in the safe management of an agitated or violent patient when verbal de-escalation techniques fail. Chemical restraints subdue patients who may otherwise harm themselves or others and serve to facilitate further medical evaluation and treatment. Clinical and administrative guidelines for their use are similar to those for physical restraints. The use of medication to calm a patient may obscure the mental status examination and clinical diagnosis. Caution should also be exercised because adverse events may result from sedation. The most commonly observed adverse event is respiratory depression or hypoxia. In one study, the rate of adverse events was 16%, and the highest risk characteristics were found to be age greater than 65 years, alcohol intoxication, and more than one type of parenteral sedation administered within 60 minutes. The risk of adverse events should be weighed, however, against the increased risk to the patient and staff without medication administration.

The ideal agent for controlling combative patients is effective, safe, well tolerated, free of significant side effects or drug interactions, rapid in onset, titratable, and available through multiple routes of administration. Several pharmaceutical agents can quickly achieve safe behavioral control, or "rapid tranquilization," without oversedation. Medications should be used judiciously and with close patient monitoring, as there remains a paucity of rigorous clinical data regarding chemical sedation in certain settings such as acute delirium, the underlying comorbid or primary conditions of violent ED patients are often unknown, and a degree of individual variation in response to any medication should be anticipated.

The primary medications commonly used in the ED for chemical sedation include benzodiazepines, first-generation (typical) antipsychotics, second-generation (atypical) antipsychotics, or ketamine.[15-30] We suggest a patient-based approach to chemical sedative selection based on suspected or known clinical features (Box 185.5).

Benzodiazepines, antipsychotics (also known as *neuroleptics*), and ketamine are commonly used either alone or in combination for rapid tranquilization. Chemical restraints should ideally be offered to the patient for voluntary use, as the offer itself has potential to restore the patient's feeling of control and may lead to subsequent de-escalation. In the uncooperative or dangerous patient refusing an oral medication, the intramuscular (IM) route is preferred, with intravenous (IV) administration an alternative depending on IV catheter status. As with physical restraints, it is imperative that patients are frequently re-evaluated for changes in their clinical status.

Benzodiazepines. Benzodiazepines, particularly lorazepam (Ativan) and midazolam (Versed), are often used in the ED for rapid tranquilization of an agitated or violent patient. Benzodiazepines enhance the activity of the major inhibitory neurotransmitter gamma-aminobutyric acid to cause anxiolytic, anticonvulsant, and sedative effects. These agents are preferred for the management of agitation caused by ethanol withdrawal or sedative-hypnotic drug withdrawal, as well as cocaine, amphetamines, or sympathomimetic drug ingestions. Benzodiazepines may be more effective than antipsychotics in reducing delirium and mortality and are useful in patients at risk for seizure or when avoiding antipsychotic-associated akathisia and hyperthermia. For these reasons, we prefer the use of benzodiazepines when sedating the patient with agitation from an unknown cause. Although they are generally well tolerated, side effects of benzodiazepines include excessive sedation, ataxia, confusion, nausea, or respiratory depression, which may be amplified in the presence of concurrent alcohol and other depressant use.

Lorazepam is frequently preferred to other benzodiazepines because of its rapid onset of action, short half-life, hepatic and renal excretion, lack of active metabolites, and effectiveness by oral, IM, or IV routes of administration. Recommended initial oral, IM, or IV doses of lorazepam range from 0.5 mg to 2 mg. Typical doses for chemical restraint in the ED begin at 1 mg to 2 mg increments IM or IV with upward titration as needed. The onset of action after administration of lorazepam is generally 20 to 30 minutes if it is given IV or 15 to 30 minutes if it is given IM, with a duration of action of 6 to 8 hours. Caution should be employed when switching routes of administration; for example, synergy may be observed when doses are given IM followed by IV, and desired clinical effects coupled with undesirable side effects, such as respiratory depression, may be noted simultaneously.

BOX 185.5 Suggested Patient-Based Approach to Chemical Restraint

The Severely Violent Patient
Droperidol 2.5 to 5 mg IM/IV, titrate as needed
or
Midazolam 2.5 to 5 mg IM/IV, titrate as needed
or
Midazolam 2.5 to 5 mg IM/IV with droperidol 2.5 to 5 mg IM/IV, titrate either as needed
or
Haloperidol 2. 5 to 5 mg IM/IV with lorazepam 1 to 2 mg IM/IV, titrate either as needed
or
Ketamine 1–2 mg IV/IM

The Undifferentiated Severely Agitated Patient or With Stimulant Intoxication
Lorazepam 1 to 2 mg IM/IV
or
Midazolam 2.5 to 5 mg IM/IV
or
Haloperidol 5 mg IM/IV with lorazepam 2 mg IM/IV

The Patient Intoxicated With a Central Nervous System Depressant (e.g., Alcohol)
Haloperidol 2.5 to 5 mg IM/IV
or
Droperidol 2.5 to 5 mg IM/IV
or
Ketamine 1–2 mg IV/IM

The Patient With a Known Psychotic/Psychiatric Disorder
Haloperidol 2.5 to 5 mg IM/IV
or
Droperidol 2.5 to 5 mg IM/IV
or
Haloperidol 2.5 to 5 mg IM/IV with lorazepam 2 mg IM/IV
or
Ziprasidone 10 to 20 mg IM[a]
or
Olanzapine 5 to 10 mg IM[a]

The Cooperative but Agitated Patient
Lorazepam 1 to 2 mg PO
or
Risperidone 2 mg PO [a]
or
Olanzapine 5 to 10 mg PO [a]

The Elderly Patient
Reduce above medication dose by half [a]

[a] The safety of atypical antipsychotics in geriatric patients remains somewhat uncertain.
IM, Intramuscular; *IV,* intravenous; *PO, per os* (by mouth).

Midazolam is another effective benzodiazepine for achievement of mild sedation and has a more rapid onset of action and a shorter duration of clinical effects than lorazepam. The IM route is used widely to calm the agitated patient with a typical initial dose of 2.5 mg to 5 mg IM. When it is administered IM, the medication usually takes effect in about 15 minutes with a mean duration of 2 hours. The choice of midazolam versus lorazepam may, in part, be guided by the duration of sedation desired and faster onset of action.

Antipsychotics. Antipsychotic medications play a prominent role in the chemical restraint of the violent ED patient. These medications include the older "typical" (or "classic") antipsychotics and the newer "atypical" antipsychotics. Typical antipsychotics appear to strongly block brain dopamine receptors, whereas the atypical antipsychotics less strongly and more specifically antagonize dopamine and serotonin receptors.[17] Both classes of antipsychotics have variable effects on other receptors, including adrenergic, cholinergic, or histaminergic receptors. The typical antipsychotics can be categorized in terms of their "potency," a description referring to the relative dosing of the medication and generally predictive of its side effect profile. The incidence of sedation, hypotension, and anticholinergic side effects is higher with the low-potency antipsychotics, whereas the incidence of extrapyramidal symptoms is greatest with the high-potency antipsychotics. Low-potency antipsychotics include chlorpromazine (Thorazine) and thioridazine (Mellaril), medium-potency antipsychotics include loxapine (Loxitane) and molindone (Moban), and high-potency antipsychotics include haloperidol (Haldol) and droperidol (Inapsine).

Of the older typical antipsychotics, the butyrophenones—haloperidol and droperidol—have been widely utilized in the emergency care setting. Haloperidol is the most frequently administered antipsychotic to control agitated ED patients.[17,24] It is available in oral, IM, and IV preparations, although the commonly used IV route of administration is not approved by the US Food and Drug Administration (FDA). Haloperidol is generally given in 2.5 mg to 10 mg IM doses (often 5 mg IM for the severely agitated, average sized adult), with half doses administered to elderly patients (e.g., 2.5 mg IM), followed by repeated dosing every 20 to 60 minutes as needed. Effects are usually seen within 30 minutes by the IM route, and the average patient typically requires fewer than three doses for the desired clinical effect.

Droperidol has been commonly used at doses of 2.5 to 10 mg IM or 2.5 to 5 mg IV to control the agitated or combative patient in a manner similar to haloperidol.[17,19,23] Compared with haloperidol, droperidol appears to more rapidly reduce agitation at equal IM dosing, has a shorter duration of effect, more sedation, a larger incidence of orthostatic hypotension, and a lesser incidence of extrapyramidal symptoms. When compared with midazolam 10 mg IM, droperidol 10 mg IM appears to have an equally rapid onset of action and requires fewer additional doses for sedation. The clinical use of droperidol decreased markedly after it was given a controversial black box warning in 2001 by the FDA for concern of QTc prolongation and torsades de pointes; however, subsequent studies have shown a low incidence of complications as well as superiority over other antipsychotics in its rapidity of action.[19,21] For instance, in a 2018 prehospital comparison of droperidol and midazolam, patients treated with droperidol had fewer adverse events and required fewer additional sedative doses.[20]

Haloperidol is also associated with QTc prolongation and torsades de pointes. Given the effectiveness and overall safety of these medications combined with the unclear risk association for QTc prolongation, we recommend the cautious use of both haloperidol and droperidol when administered to patients with other identified risk factors for, or the known presence of, QTc prolongation, such as in the setting of baseline antipsychotic or methadone use. We also recommend obtaining an electrocardiogram or placing the patient on a cardiac monitor before drug administration if feasible. If this is precluded by poor cooperation of a violent or agitated patient, we recommend obtaining an electrocardiogram once the patient becomes more cooperative.

Common side effects of haloperidol and droperidol include sedation, orthostatic hypotension, or extrapyramidal symptoms. Extrapyramidal symptoms are thought to be due to mesolimbic dopamine receptor blockade. They are not dose related and may occur

immediately or days following medication administration. Patients can have akathisia (extreme restlessness) or uncoordinated involuntary movements known as dystonia, including of the muscles of the mouth (buccolingual), neck (torticollis), back (opisthotonos), eyes (oculogyric crisis), or trunk (abdominopelvic). Treatment includes diphenhydramine 25 mg to 50 mg IV or IM, or benztropine 1 mg to 2 mg IV or IM, acutely and extended for 3 days to minimize symptom recurrence. Both haloperidol and droperidol have some anticholinergic properties and are often co-administered with diphenhydramine or benztropine, and thus should not be used to control agitation in a patient with known or suspected anticholinergic intoxication. Haloperidol and droperidol should also be avoided in patients with alcohol, benzodiazepine, or other sedative withdrawal syndromes, patients with known seizure disorders, patients with phencyclidine overdose, and, when possible, in pregnant or lactating females.

Neuroleptic malignant syndrome is a rare and potentially lethal idiosyncratic reaction estimated to occur in 0.01% to 0.04% of patients receiving antipsychotic medications. Characteristic symptoms include autonomic instability, hyperthermia, "lead-pipe" muscle rigidity, and altered mental status. If neuroleptic malignant syndrome is suspected, further antipsychotics should be withheld, and we recommend initiation of supportive treatment and rapid external cooling (see Chapter 150).

Chemical restraint with newer atypical antipsychotics (such as olanzapine, ziprasidone, or aripiprazole) is generally safe and effective in the treatment of agitated patients.[17,22-24] Compared with the typical antipsychotics, these medications appear to provide more tranquilization than sedation and have fewer extrapyramidal side effects. Their use in the ED is facilitated by IM or oral dissolving tablet formulations that may assist in a smoother transition to oral dosing in those patients requiring ongoing antipsychotic therapy. Although the clinical significance is uncertain, atypical antipsychotics carry a black box warning for an increased risk of death in elders with dementia-related psychosis and they also cause QTc prolongation. As a result, we recommend employing the same precautions used with the typical antipsychotics. In a 2019 study comparing agitated patients with known alcohol intoxication who were treated with droperidol, haloperidol, or olanzapine, median ED length of stay was shortest for droperidol (499 minutes), which was significantly shorter than that of haloperidol (524 minutes) and olanzapine (533 minutes). No cases of sudden cardiac death occurred.[18]

Olanzapine (Zyprexa) is readily available in IM, oral, and oral-dissolving tablet formulations; and it has a reported distinct "calming" effect in clinical practice. It has FDA-approved indications for the treatment of agitation associated with bipolar I mania and schizophrenia. IM olanzapine has an onset of action of 15 to 45 minutes after initial administration and is typically administered as an initial dose of 2.5 mg to 10 mg IM followed by one or two subsequent doses every 2 to 4 hours for a total maximum dose of 30 mg IM. Although generally well tolerated, side effects include sedation (which may be compounded in the setting of concomitant benzodiazepine use), mild hypotension, and anticholinergic properties that can exacerbate existing anticholinergic intoxication. Mild hypoxia is common but critical hypoxia or serious airway compromise remains rare.[22] Olanzapine has minimal QTc-prolonging effects and a lesser occurrence of acute dystonia and akathisia compared with haloperidol. In a 2019 study comparing the need for an additional "rescue" sedation dose, both olanzapine and droperidol required lower rates of rescue sedation at one hour and overall when compared with haloperidol. There were no significant differences in major adverse events.[21]

Ziprasidone (Geodon) is FDA approved for treatment of the agitated schizophrenic and bipolar manic patient. Typical dosing is 10 mg IM every 2 hours or 20 mg IM every 4 hours (not to exceed 40 mg/day) with an onset of action of 15 to 30 minutes. Ziprasidone is generally well tolerated, although side effects such as somnolence, dizziness, and headache are common, and it appears to have potentially notable QTc-prolonging effects.

Aripiprazole (Abilify) has FDA-approved indications for the treatment of agitation associated with the schizophrenia or bipolar disorders. Recommended doses for the acutely agitated patient are 5.25 to 15 mg IM (often 9.75 mg) every 2 hours as needed (to a maximum daily dose of 30 mg). Aripiprazole IM (9.75 and 15 mg) may have comparable efficacy to lorazepam 2 mg IM with a low risk of oversedation.

Risperidone (Risperdal) is typically used for schizophrenia and available in an oral or IM depot form with typical dosing of 1 mg to 2 mg. Given orally, risperidone appears to be as effective and tolerable as IM administration of haloperidol. The time to peak concentration is shorter than some oral second-generation antipsychotics and may be useful when rapid control of agitation by an oral medication is desired.

Combined Use of Benzodiazepines and Antipsychotics. Benzodiazepines and typical antipsychotics are commonly used in combination for chemical restraint. In a 2016 meta-analysis of chemical agents for sedation of agitated patients in the ED, combination therapy sedated a greater proportion of patients at 15 to 20 minutes than benzodiazepines alone.[17] Combination therapy was more effective and required fewer repeat doses for sedation, and the risk of adverse events was lower than for benzodiazepines alone.[17] A 2017 study of monotherapy with droperidol or olanzapine compared with combination therapy with midazolam and droperidol found significantly more patients in the midazolam-droperidol group were adequately sedated at 10 minutes.[23] The combination therapy was 6 minutes faster than either monotherapy.[23] Patients in the midazolam-droperidol group required fewer additional doses or alternative drugs to achieve adequate sedation, and the adverse event rate and length of stay did not differ between the three groups.[23] In a 2018 comparison of intramuscular midazolam, olanzapine, ziprasidone, or haloperidol for treating acute agitation in the emergency department, midazolam was found to work most rapidly and olanzapine appeared to have superior sedation without redosing, as well as less effect on QTc; however, no differences in adverse events in any treatment group were identified.[24]

Demonstrated effective combinations include midazolam (5 mg IV or IM) with droperidol (5 mg IV or IM) or lorazepam (2 mg IV or IM) with haloperidol (5 mg IV or IM). When given together, lorazepam and haloperidol appear to be more rapidly sedating than either medication alone, have fewer adverse effects, and are compatible within the same syringe. Half doses should be considered in carefully selected elders. If additional medication is immediately needed, we recommend consideration of IV midazolam every 3 to 5 minutes or IV lorazepam every 20 to 30 minutes. In summary, though antipsychotics and benzodiazepines are both safe and effective on their own, the combination is also safe, may have more rapid onset, with similar side effect profile to either medication alone.

Ketamine. Ketamine is a dissociative anesthetic with a good safety profile used to manage the violent and acutely agitated patient in the hospital or prehospital settings, including use following treatment failure with benzodiazepines or antipsychotics.[17,25-30] Although its use in agitated delirium in young adults is increasingly described, we recommend avoiding its use in elders with acute agitated delirium, patients at increased risk for heart disease, or patients with schizophrenia, given the possibility of exacerbating these conditions. For the treatment of acute violent agitation in the ED patient, we recommend an initial dose of 1 to 2 mg/kg IV or 4 to 5 mg/kg IM. The onset of drug action is typically 1 to 2 minutes after IV use and 4 minutes or longer after IM administration, with duration of action of approximately 20 minutes. It appears to be faster in onset via IM route

TABLE 185.1 Distinguishing Organic From Functional Causes of Violent Behavior

	ORGANIC		
Clinical Feature	**Delirium**	**Dementia**	**Functional**
Onset	Acute	Gradual	Gradual
Age at onset	Any	>50 years old	<40 years old
Alertness	Altered	Normal	Normal or hyperalert
Orientation	Impaired	May be normal or impaired (depending on stage of dementia)	Normal
Hallucinations	Common; can be visual, auditory, or tactile	None	Auditory in schizophrenia, otherwise uncommon
Symptom picture	Fluctuating	Stable	Stable
Abnormal vital signs	Common	Uncommon	Uncommon
Psychiatric history	No	No	Yes

than other medications; however, due to its short duration of action, it frequently requires combination therapy or repeat doses.[26,27,28,30] Notable side effects include hypertension and tachycardia (usually mild and transient), drooling, laryngospasm or other respiratory complications (uncommon), emesis, or emergence reactions. In a 2016 comparison of prehospital administration of ketamine or haloperidol for severe agitation, ketamine worked faster but was associated with greater risk of complications or intubation.[30] Overall, studies reflect that patients receiving ketamine in the prehospital setting are more likely to require intubation than when ketamine is administered in the ED, though it is unclear whether this is caused by dosing differences, unfamiliarity with side effect profile, or increased severity of illness.

Post-Restraint Medical Evaluation

Once combative patients are controlled, evaluation is necessary to screen for organic causes of agitation. Separation of functional (psychiatric) from organic (medical) disease is a challenging task complicated by the fact that many patients with psychiatric disorders also suffer from organic medical disorders that may worsen symptoms. Patients who exhibit violent behavior that is caused or exacerbated by an organic problem may rapidly deteriorate if the medical issues are not addressed in a timely fashion.

Historical features may assist in distinguishing functional from organic illness (Table 185.1). Patients aged 40 years or older who exhibit new onset of psychiatric symptoms are more likely to have an organic cause. Elders are at higher risk for organic delirium from medical illness or adverse medication reactions. Patients with a history of drug or ethanol abuse may exhibit violent behavior as a manifestation of an intoxication or withdrawal syndrome. The acute onset of agitated behavior, as well as behavior that waxes and wanes over time, suggests an organic origin. Most psychiatric patients are alert and oriented and many have known psychiatric diagnoses.

The history includes medical, psychiatric, family, and social information, including suicidal or homicidal ideation, drug and alcohol use, medication use, and any recent changes to prescribed medications or dosages. The agitated patient may be unreliable; thus family or friends may provide valuable details. When family or friends are available, interview them independently from the patient.

The violent patient should be asked for permission to perform a thorough physical examination to search for an organic cause and to evaluate for resulting injury. Restraint of the patient may be necessary to accomplish even the most rudimentary physical examination, including accurate vital signs. Patients with persistently abnormal vital signs, a clouding of consciousness, or focal neurologic findings are more likely to suffer from organic disease and require further diagnostic evaluation. A careful examination of the agitated patient includes general appearance (e.g., hygiene, nourishment, tremors), vital signs, evidence of trauma or needle tracks, characteristic odors, neurologic and mental status, or signs of a possible toxidrome (Table 185.2).

We recommend tailoring diagnostic studies to clinical findings. An initial rapid blood glucose determination and pulse oximetry are prudent when they can be performed safely. Patients younger than 40 years of age with a prior psychiatric history, normal physical examination, calm demeanor, normal orientation, and no physical complaints are unlikely to require further diagnostic testing. Additional studies that may be useful in selected patients include serum electrolyte values, blood or urine toxicology screening, serum ethanol level, thyroid function panel, cranial imaging, or lumbar puncture. Diagnostic studies should be guided by the overall clinical scenario and are not required in most patients. Specific medication levels can be determined if toxic levels would impact treatment or disposition. An electrocardiogram may be useful in elders or in the setting of a suggested intentional ingestion. In the setting of intentional toxin ingestion, serum acetaminophen, and possibly aspirin, levels may be helpful.

Although serum ethanol or toxicology screening may not significantly influence the ED course, behavioral health or other consulting specialists may utilize the results in decision making. Ideally, an agreement on a diagnostic strategy is reached with the behavioral health specialist to assist in patient disposition. Unnecessary diagnostic testing may prolong ED length of stay and delay definitive psychiatric care.

Disposition and Medical Clearance

The emergency clinician often provides "medical clearance" for the psychiatric or combative patient brought to the ED in police custody or after being placed on a psychiatric hold in the prehospital setting. "Medical clearance" is a misnomer, as a patient is not "cleared" of all possible medical conditions during the ED evaluation; additionally, standard protocols for the provision of what is more accurately termed a "focused medical assessment" remain variable. A preferred phrase in this setting is "medically stable for psychiatric evaluation." Although few patients with primary psychiatric complaints are likely to have coexisting, emergent complications of chronic disease or medical problems contributing to their violent behavior, misattribution of aberrant organic behavior remains a pitfall in the evaluation of the combative patient.

Aspects of a focused medical assessment, including recommended laboratory tests, are often influenced or dictated by local policies or procedures. When feasible, we believe that patients with known psychiatric

TABLE 185.2 Vital Signs and Toxic Syndromes

Toxin	Blood Pressure	Pulse	Respiratory Rate	Temperature	Pupil Size	Skin	Example
Sympathomimetic	↑	↑	↑	↑	↑	Wet	Cocaine
Anticholinergic	↑/↓	↑	↑/↓	↑	↑	Dry	Diphenhydramine
Cholinergic	↑/↓	↑/↓	—	—	↓	Wet	Pesticides
Opioids	↓	↓	↓	↓	↓	—	Morphine
Sedatives	↓	↓	↓	↓	↑/↓	—	Lorazepam
Withdrawal (ethanol, sedative-hypnotics)	↑	↑	↑	↑	↑	Wet	Benzodiazepine withdrawal

disease who are deemed to be at low risk for active or significant, complicating organic medical conditions can be rapidly referred for psychiatric evaluation once they are calm and cooperative. Patients at higher risk for an acute organic illness typically require further diagnostic evaluation. Potential high-risk considerations in the prehospital or ED setting include altered mental status, ingestion, hanging, sexual assault, traumatic injury, or an unrelated medical complaint.[31] The findings of a focused medical assessment should ideally be both communicated to the mental health provider and documented in the medical record, reflecting consideration of an acute medical condition as a contributor or driver of the observed behavior. When the cause of the patient's violent behavior is drug or ethanol intoxication, further observation may reasonably be achieved in the ED or another facility where the patient can be safely monitored until the effects of the intoxicants have abated and further mental health evaluation can occur, as necessary.

Assault and Hostage Situations

Interventions to prevent assault and hostage situations, such as optimization of ED security and general preparedness (see Box 185.2), remain paramount because rates of extreme hospital and ED violence have increased over time.[32] Unfortunately, physical assault may occur despite appropriate precautions or interventions. The individual who is physically assaulted or threatened with harm with a weapon can take steps to protect both themselves and others in the ED setting (Box 185.6).

The frequency of hospital-based shootings has more than doubled in the early 21st century, with deadly incidents that may involve disgruntled, angry, desperate, or mentally ill patients, visitors, or even employees.[32] Weapons may be brought in from outside or appropriated from authorized carriers, such as police. Specific scenarios that should be considered are intimate partner violence, grudges or revenge against former health care providers or employers, mental illness leading to paranoid actions or suicide attempt, and prisoners attempting escape. Violence may be related to the setting (i.e., family member angry about a previous complication, or unrelated, such as an intimate partner seeking out their significant other at work). An emerging and concerning prompt for violence is ideologically or politically motivated. Hospitals should develop an action plan for cases of extreme violence. The plan should include prevention and safety measures, a means for rapid notification of security or police personnel, evacuation routing, medical treatment strategies, and crisis intervention. Scenario-based training drills for medical personnel and dedicated multidisciplinary hospital violence management teams may help optimize readiness and management of extreme patient aggression.[33]

BOX 185.6 Protective Responses to Physical Assault or Weapon Threat

If physically assaulted:

1. Immediately summon help (via panic button if possible).
2. Maintain a sideward posture and keep arms ready for self-protection.
3. Use an arm or leg to deflect a punch or kick.
4. If choked, tuck in the chin to protect the neck, carotid circulation, and ability to breathe.
5. If bitten, do not pull away—push toward the assailant's mouth and hold the assailant's nares shut.

If threatened with a weapon:

1. Appear calm, adopt a nonthreatening posture, and avoid sudden movements.
2. Do not reach for the weapon.
3. Comply with demands and avoid arguing, despair, or whining.
4. Do not bargain, make promises, or lie.
5. Attempt to establish a human connection with the hostage taker.
6. Appear less expendable by offering to administer aid to other hostages.
7. Reassure the hostage taker that a person of authority will arrive promptly to hear their complaints or demands.
8. If a weapon is put down, do not reach for it—instead attempt verbal resolution of the crisis while awaiting security.
9. Request a hostage negotiator from legal authorities if needed.

THE DIFFICULT PATIENT

Foundations

The difficult patient is one who is perceived to interfere with the clinician's ability to establish a usual patient-clinician relationship. Difficult patients are encountered across medical specialties and may represent upwards of 15% to 30% of physician-patient encounters.[34] Difficult patients may carry a number of pejorative labels and can invoke feelings such as irritation, dread, anxiety, or dysphoria in their health care team, potentially leading to dissatisfying interactions for the patient and health care team alike. A high frequency of difficult patient encounters appears to be associated with clinician dissatisfaction and burnout.

The difficult patient-clinician relationship is a consequence of aspects of the ED environment, clinician characteristics, patient factors, and the complex dynamic interaction of these elements (Box 185.7).[33] These elements can act in concert to perpetuate a cycle of impaired patient-clinician interactions, which may dominate the clinical encounter with negative impacts on both the patient and clinician. This can be particularly problematic in the case of patients with maladaptive patterns of behavior. Clinicians may react negatively to perceived difficult or unreasonable patients, which may summon fear of abandonment in such patients. In response to this perceived threat, maladaptive responses of the patient may include an attempt to sustain the patient-clinician relationship through escalation of the actions that were originally perceived negatively by the clinician. The subsequent clinician reaction may be even greater in magnitude and result in even further escalation by the patient as the cycle continues. Ultimately,

BOX 185.7 Factors Impacting the Difficult Patient-Physician Interaction

Emergency Department Factors
Lack of patient choice of facility or physician
Time constraints, frequent interruptions, other priorities of care
Suboptimal patient privacy or comfort (e.g., hallway examinations)
Long waiting times, department crowding
Negative bias toward the patient from other members of the care team (e.g., by prehospital personnel, nursing)

Physician Factors
Poor communication
Difficulty expressing empathy or becoming easily frustrated
Personal negative bias and prejudices toward conditions and interactions
Limited knowledge of the patient's condition or psychosocial situation
Overly rigid medical agenda or interaction
Outside stressors affecting work
Emotional burnout or insecurity
Personal health issues
Situational stressors and perceived time pressure
Sleep deprivation or shift fatigue

Patient Factors
Behavioral issues (e.g., argumentative, manipulative, medical noncompliance)
Fear of abandonment
Psychiatric conditions
Low literacy
Financial constraints
Chronic pain syndromes
Multiple complaints
Beliefs or goals of care unknown to the physician
Unrealistic expectations or goals of care
Substance use disorder
Past or current physical, emotional, or mental abuse
Life stress or social disarray

Adapted from: Cannarella Lorenzetti R, Jacques CH, Donovan C, et al. Managing difficult encounters: understanding physician, patient, and situational factors. *Am Fam Physician*. 2013; 87:419-425; Breen KJ, Greenberg PB. Difficult physician-patient encounters. *Intern Med J*. 2010;40:682-688.

the patient may feel dissatisfied with care, diagnoses may be missed or made incorrectly as a consequence of the dysfunctional interaction, and discharge from the ED may occur prematurely by either the patient or provider. Following such encounters, the clinician is prone to experience frustration, exhaustion, a sense of failure or defeat, or fear of litigation. Also, nonconstructive patient stereotypes or unrecognized prejudices may develop or perpetuate.

The clinician brings personal and professional experiences, biases, individual personality traits, and interpersonal skills to every patient encounter. Some clinicians appear to have more difficult encounters than others, and similar interactions or patients may not be perceived as "difficult" by other providers. Clinicians who are more likely to have difficult patient encounters include those with fewer years of experience, who are less comfortable with diagnostic uncertainty, and may be less adaptable in communication style or acceptance of alternative lifestyle choices. Within the complex difficult patient encounter, the clinician has the greatest opportunity to positively alter aspects of their contribution to the interaction. When recognized, strategies exist to help the clinician manage negative reactions to difficult patient experiences (Box 185.8). Communication is a critical aspect of the patient

BOX 185.8 Tools for Managing Negative Reactions

Maintain Appropriate Emotional Distance
Avoid reciprocating hostile behaviors while maintaining a sense of empathy for the patient

Understand Negative Behavior as a Symptom
View the patient as a casualty of their own circumstances

Look for Cognitive Distortion
Be cautious not to overly stereotype or cloud clinical judgment and avoid perpetuating negative labels

View Negative Reactions in Context
Recognize when one feels overwhelmed by the expectations of the ED work environment to gain perspective on personal reactions

From: Cannarella Lorenzetti R, Jacques CH, Donovan C, et al. Managing difficult encounters: understanding physician, patient, and situational factors. *Am Fam Physician*. 2013;87:419-425.

encounter affecting medical care, patient satisfaction, and overall patient perception of the experience—some general concepts of communication can aid the difficult patient interaction (Table 185.3).

Specific Disorders

The primary characteristic of a difficult patient is the ability to trigger a negative emotional response or frustration in the clinician. Difficult patients are more likely to be older, widowed or divorced, and have more acute or chronic medical problems. They are more likely to have notable psychiatric, substance or alcohol use disorders, or social issues such as homelessness. Rather than a diagnosis or demographic, it is typically the behaviors of these patients and subsequent therapeutic dynamic that characterize the difficult encounter. Categorizing potentially difficult patients based on four common dominant behavior types—attention seeking, demanding, repeat visitors, self-destructive—allows a structure for the clinician to approach and manage challenges that may arise (Table 185.4).

Attention-Seeking Patients

This patient may have associated personality disorders (dependent, borderline, or histrionic), be malingering, or possess somatoform disorders or other chronic psychiatric diagnoses. The patient is characterized in part by an excessive need for attention with an initial extreme delivery of gratitude, which the clinician may welcome. However, as the amount of care that the patient receives grows, so do their needs and demands. This cycle continues to often leave the clinician frustrated and exhausted and eager to discharge or refer the patient to another health care provider.

When such patients are identified, the clinician should carefully establish reasonable expectations and limits before the "cycle of need" has set into motion. Importantly, these patients are especially likely to seek care in the ED during times of personal crisis. Structuring the encounter to be particularly attentive to the underlying crisis may provide the opportunity to address the underlying problem rather than the patient's perceived needs. This scenario is often encountered with patients exhibiting drug-seeking behavior.

Demanding Patients

Demanding patients can include very important persons (VIPs) or other well-informed successful professionals, substance abusers, or people with personality disorders, such as narcissistic or paranoid.

TABLE 185.3 Communication Strategies for the Difficult Patient Encounter

Goal	Physician Action	Example
Structure the interview	Set time limits and expectation that interruptions may occur	"Thank you for your patience. I may have to excuse myself to care for another patient, but if we are interrupted, I will return to pick up where we left off and provide you with the care you need."
Set limits	Establish ground rules for behavior	"We want to help you and your language and behavior is offending other patients—making it difficult to care for you and other patients. Please be mindful of your remarks or you may need to be escorted out."
Active listening to improve understanding	Allow the patient to talk without interruption, summarize concerns, and recognize that anger is usually a secondary emotion	"Help me to understand what is upsetting you so much right now."
Understand the patient's agenda	Nonjudgmentally inquire about the patient's primary needs, concerns, and expectations	"What is the most important thing that we can do to help you right now?"
Validate emotion and empathize	Disarm intense emotion by attempting to name the patient's emotional state and express concern and empathy	"You seem upset." "You are right. It is frustrating to wait a long time to be seen."
Redirect the interview	Avoid pursuing trivial, chronic, or tangential complaints by redirecting focus	"I think I can help you most right now if we focus on your main concern first."
Take a time out	Leaving a patient's room and returning after both parties have regained composure is prudent if unable to contain one's frustration	"Thank you for your openness. I need to step out, and I will be back to see what we can do to help you."

TABLE 185.4 Approaches to Challenging Patient Behavior Types

Patient Type	Characteristic of Physician Response	Suggested Strategies
Attention Seeking		
• Excessive need for attention and reassurance • May use helplessness and seduction • Worried about abandonment • Escalating requests and demands	• Physician may initially feel special and welcome the patient's praise • As patient demands increase and physician time and energy commitment increases, feelings of frustration, exhaustion, and resentment may dominate	• Recognize the inflated positive self-esteem feeling that is being cultivated • Maintain a professional demeanor • Establish and maintain boundaries of care early • Crisis intervention may be needed • Involve the patient in decision making including appropriate follow-up
Demanding		
• Uses intimidation, hostility, name dropping, blame, or threats • May refuse necessary steps of assessment or treatment • Behavior caused by fear of loss of power or physician abandonment	• Initial desire may be to engage in the patient's conflict • Physician may feel intimidated, inadequate, or fear litigation	• Resist urge to enter into conflict and avoid power struggles • Reinforce concept that the patient is entitled to reasonable medical care while setting limits on unreasonable demands and behavior • Allow the patient to choose between reasonable treatment options • If a specific emotion is evident, recognize and address it with the patient
Repeat Visitor		
• Excessive need for attention through multiple visits or unsolvable problems • Rejects the possibility that any treatment will help	• Physician may feel frustrated and overlook significant illness, but also may share the patient's pessimism and fear that serious illness has been missed	• Be mindful of cognitive distortions that may obscure real illness • Set limits on expectations while being supportive
Self-Destructive		
• Disregard for own health with repeated self-destructive behaviors • Feels helpless or hopeless about changing the situation	• Physician may feel frustrated, helpless, or guilty for lack of empathy • Physician may avoid being available for the patient and unconsciously provide poor care	• Be mindful of one's own feelings and keep appropriate emotional distance • Set realistic expectations and provide appropriate care • Search for signs of mental health or social needs and consider referral or consultation as needed

From: Cannarella Lorenzetti R, Jacques CH, Donovan C, et al. Managing difficult encounters: understanding physician, patient, and situational factors. *Am Fam Physician*. 2013;87:419-425, 2013; Breuner CC, Moreno MA. Approaches to the difficult patient/parent encounter. *Pediatrics*. 2011;127:163-169.

Their behavior is often hostile, intimidating, or threatening, and they may have endless needs and unreasonable demands. These patients fear being helpless in the context of their medical needs, and behaviors that have promoted success in their professional lives become maladaptive behaviors of entitlement to protect themselves from their own insecurity.

The behavior of these patients can evoke feelings of anger or antagonism and a desire to engage in debate and conflict. These power struggles are often counterproductive and only escalate the maladaptive behavior. A clinician can address the underlying insecurity and fears by maintaining a supportive relationship. Limit setting is important to curb escalation of unreasonable demands. Clinicians may preserve the patients' sense of autonomy and control in situations where they otherwise feel helpless by engaging them to participate in the selection of reasonable recommended options of care.

Repeat Visitors

This category is largely characterized by desperate and numerous repeat ED and other medical visits despite expressed certainty that past visits have been failures. Behaviors may appear entitled, manipulative, and self-defeating. These patients may have borderline or antisocial personality disorders and may be malingering. Their complaints are often vague and defy diagnosis, and clinicians may feel a sense of futility or failure. The behavior of these patients often stems from a need for connection and relationship in the setting of a fear of rejection and such patients are also at risk for unrecognized depression.

The clinician is at risk of both prematurely dismissing the patient's complaint due to a pattern of frequent visits and medical noncompliance or prematurely beginning an extensive investigation from fear that a critical diagnosis has been missed. Awareness of one's own cognitive distortions and personal biases can aid in avoiding inappropriate premature discharge, and seeking collateral information from previous medical records may reveal additional information that can help limit the evaluation and coordinate ongoing consistent medical care. Although clarifying expectations and limit setting are important, support and empathy can be particularly valuable in these encounters, as expressed lack of concern and dismissal of the patient's fears may feed an underlying sense of rejection within the patient, thus fueling the maladaptive behavior.

Self-Destructive Patients

These patients may appear hopeless, helpless, and in profound denial of their self-destructive and neglectful behaviors. These patients may be violent, chronically suicidal, suffer from substance abuse issues, or have a borderline personality disorder. Untreated anxiety or depression may be present. These patients may not personally seek help but instead are referred for care by others. ED care may result in addressing immediate needs (such as food or shelter), but despite adequate medical intervention, it is likely that the patient's often serious problems will persist.

These self-destructive patients can be challenging to treat because ED staff may feel frustration or even loathing or disgust toward the patient and minimize contact with them. Consequently, the treating clinician and others may unconsciously provide substandard care. By recognizing one's own feelings and setting realistic expectations of care, the ED care team can avoid poor medical care and may discover patient needs, including mental health conditions or crises or unrecognized social needs.

CHAPTER 185: QUESTIONS AND ANSWERS

185.1. Which of the following is a positive predictor of violent behavior in patients?

a. Age
b. Ethnicity
c. Gender
d. Level of education
e. Marital status

Answer: C. Identification of potentially violent patients is difficult, with male gender, prior history of violence, and drug or ethanol abuse the only positive predictors. Ethnicity, diagnosis, age, marital status, and education are not reliable identifiers.

185.2. Which of the following medications is associated with the highest incidence of sedation, hypotension, and anticholinergic symptoms?

a. Droperidol
b. Haloperidol
c. Loxapine
d. Molindone
e. Thioridazine

Answer: E. Antipsychotics can be divided into low potency (such as chlorpromazine and thioridazine), midrange potency (such as loxapine and molindone), and high potency (such as haloperidol and droperidol). The incidence of sedation, hypotension, and anticholinergic symptoms is highest in the low potency group.

185.3. Which of the following antipsychotic medications is associated with the highest incidence of extrapyramidal symptoms?

a. Chlorpromazine
b. Haloperidol
c. Loxapine
d. Molindone
e. Thioridazine

Answer: B. Antipsychotics can be divided into low potency (such as chlorpromazine and thioridazine), midrange potency (such as loxapine and molindone), and high potency (such as haloperidol and

CHAPTER 185: QUESTIONS AND ANSWERS—cont'd

droperidol). The incidence of extrapyramidal symptoms is greatest in the high potency group.

185.4. Which of the following disorders is best defined as a pattern of instability of interpersonal relationships, self-image, affect, and marked impulsiveness that begins by early adulthood and presents in a variety of contexts?

a. Antisocial personality disorder
b. Borderline personality disorder
c. Dependent personality disorder
d. Histrionic personality disorder
e. Paranoid personality disorder

Answer: B. Borderline personality disorder is a pattern of instability of interpersonal relationships, self-image, affect, and marked impulsiveness beginning by early adulthood and present in a variety of contexts. It may be indicated by five or more of the following:

1. Frantic efforts to avoid real or imagined abandonment
2. A pattern of unstable and intense interpersonal relationships characterized by alternating extremes of idealization and devaluation
3. Identity disturbance: Markedly and persistently unstable self-image or sense of self
4. Impulsiveness in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, or binge eating)
5. Recurrent suicidal behavior, gestures, threats, or self-mutilating behavior
6. Affective instability caused by a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate, intense anger, or difficulty controlling anger (e.g., frequent displays of temper, constant anger, or recurrent physical fights)
9. Transient, stress-related paranoid ideation or severe dissociative symptoms

185.5. A patient demonstrates inappropriate sexually seductive behavior while being interviewed by her physician. This characteristic is most consistent with which of the following personality disorders?

a. Antisocial personality disorder
b. Borderline personality disorder
c. Dependent personality disorder
d. Histrionic personality disorder
e. Paranoid personality disorder

Answer: D. Histrionic personality disorder is a pattern of excessive emotionality and attention seeking beginning by early adulthood as indicated by five or more of the following:

1. Discomfort in situations in which the center of attention is someone else
2. Interaction with others often characterized by inappropriate sexually seductive or provocative behavior
3. Displays rapidly shifting and shallow expression of emotions
4. Consistently uses physical appearance to draw attention to self
5. Has style of speech that is excessively impressionistic and lacking in detail
6. Shows self-dramatization, theatricality, and exaggerated expression of emotion
7. Is suggestible (i.e., easily influenced by others or by circumstances)
8. Considers relationships to be more intimate than they actually are

186

Multiculturalism, Diversity, and Care Delivery

Ava E. Pierce and Marquita S. Norman

KEY CONCEPTS

- Changing demography and an evolving culture in the United States are changing emergency medicine practice as disparities in health and health care delivery continue, despite efforts to improve care.
- Emergency department interventions should focus on social determinants of health, health literacy, and empowerment of patients to participate in their care.
- Treatment plans created with patients and based on what matters to them have the greatest opportunity for success.
- Emergency clinicians will improve the quality of care provided if they can meet federal standards for culturally and linguistically appropriate care, recognizing that patients with limited English proficiency have a right to medical interpretation.
- Culturally sensitive, patient-centered, and trauma-informed care will improve patient clinician communication and satisfaction, decrease medical errors, and promote patient follow-through with recommendations.

FOUNDATIONS

Background and Importance

In recent years, many high-profile incidents have put the role of multiculturalism, diversity, inclusion, and health equity in the forefront of public discourse. To obtain high-quality care, patients must first enter a health care system where many have experienced barriers to access based on race, religion, ethnicity, socioeconomic status, age, sex, disability status, language, sexual orientation, gender identity, and residential location. These issues highlight both the progress and challenges in understanding equity in society. As a microcosm of larger society within health care, the practice of emergency medicine (EM) should embrace a greater understanding and awareness of the roles of multiculturalism and diversity in the delivery of health care.

The population of the United States (US) continues to become more diverse. Women now comprise over half of the US population. By 2030, one in five Americans is projected to be aged 65 years and over. Minority groups (any group other than non-Hispanic White alone) are projected to become the collective majority as early as 2044, and almost one in five of the nation's total population is expected to be foreign-born by 2060.[1] As a specialty, EM is in a unique position to serve this diverse population. In many emergency departments (EDs), the majority of visits are with patients from minority backgrounds.[2] Emergency physicians routinely encounter patients from diverse cultural backgrounds representing various customs, practices or beliefs. All major national EM membership organizations now have policies and statements on diversity, inclusion, and equity. Policies on cultural awareness and emergency care focus on how emergency clinicians should consider the patient's culture, as it relates to history and presenting symptoms, in developing a treatment plan that is mutually agreed upon by the patient and physician. Statements also focus on beliefs and commitments to the goals of attaining equity, diversity, and inclusion in emergency medicine that reflects our multifaceted society. There is consensus around the development and promotion of education, research, and services that assist EDs in improving health for all, with a focus on eliminating health inequities.[3,4] To attain these goals, emergency clinicians must become culturally competent to meet the needs of diverse patient populations.

RATIONALE FOR CULTURAL COMPETENCE

Changing Demographics

Both the US population and the types of health problems seen by emergency clinicians are constantly changing.[5] According to US Census data from the 2018 American Community Survey, 14% of the US population identified as foreign-born.[6] Additionally, 28% of the population identified as other than "White alone" and 18% described themselves as Hispanic or Latino.[6] These changing demographics do not speak to the diversity within the various groups. The category Hispanic, for example, is an ethnic grouping counted in the race category of the census, but it fails to capture the significant range of diversity represented by Spanish speakers. Hispanics may share some cultural practices and speak similar versions of the Spanish language, but they have major differences in vocabulary and dialect, history, socioeconomic status, cultural identity, self-reference (Hispanic or Latino), levels of acculturation, health beliefs, habits, access to care, and health outcomes. The changing cultural landscape will challenge EM providers to recognize, account for, and address these differences when providing care for their patients.

Racial and Ethnic Disparities in Health Care Access and Outcomes

An overarching goal of the Healthy People 2030 Project is to "Eliminate health disparities, achieve health equity, and attain health literacy to improve the health and well-being of all."[7] Numerous studies find

that we are not meeting that goal.[5] When compared to Whites, racial and ethnic minorities have a lower likelihood of having a usual source of care, fewer physician visits, and fewer health expenditures. Hispanics and Blacks are less likely to initiate or receive mental health services when compared to Whites. Hispanics have lower health care use, including ED visits and outpatient mental health services, when compared to Whites and Blacks. Hispanic, Asian, and Black patients are less likely to have a consistent primary care provider.[8] With respect to unmet needs from ED visits, Black women fared the worst compared to men and women from White, Hispanic, and Asian backgrounds. Black patients are among the most disadvantaged of the racial/ethnic groups with a greater proportion impoverished, unemployed but looking for work, or in poor to fair health.[8]

Factors resulting in racial/ethnic disparities in health care contribute to differences in access to care. While these differences in access to care may correlate with access to financial resources or health insurance, other factors such as culture, language, and discriminatory practices may also contribute to these variations. Studies indicate that "implicit bias against Black, Hispanic/Latino/Latina, and dark-skinned individuals is present among many health care providers of varying specialties, levels of training, and levels of experience."[9] Reproductive biology and conditions specific to gender may also result in differences in health service use as it relates to gender.[8]

Tests and Treatments

Disparities in ED pain treatment persist a decade after identification of racial and ethnic differences in analgesic administration.[10,11] Studies indicate that provider bias may contribute to a skewed assessment of pain and therefore inadequate treatment.[12] Lee et al. reviewed studies from 1990 to 2018 comparing racial and ethnic differences in the administration of analgesia for acute pain and found that Black and Hispanic patients were less likely than White patients to receive analgesia for acute pain.[13] Goyal et al. found that Black children with appendicitis are less likely to receive any pain medication for moderate pain and less likely to receive opioids for severe pain, suggesting a different threshold for treatment.[14]

Racial and ethnic differences in provision of medically appropriate procedures and therapies have been documented. Wilder et al. found that Blacks and Hispanics were significantly less likely to receive any antidote when presenting to the ED for acute drug overdose.[15] Miller et al. found that a protocol-driven care pathway eliminates the racial disparity among Black and White participants with chest pain in the acquisition of index-visit cardiovascular testing.[16] Despite decades-old identification of these differences and regardless of the setting, health care disparities remain a real and pervasive threat to patient care, but studies indicate that protocol-driven pathways may help to decrease racial disparities.

Health Outcomes

Even perceived discrimination has a significant effect on health.[17,18] Thames et al. performed a cross-sectional bioinformatic analysis relating perceived discrimination (measured by the Perceived Ethnic Discrimination Questionnaire [PED-Q]) to the activity of proinflammatory, neuroendocrine, and antiviral transcription control pathways relevant to the conserved transcriptional response to adversity (CTRA) in peripheral blood leukocytes. They found that differential exposure to racial discrimination may contribute to racial disparities in health outcomes in part by activating threat-related molecular programs that stimulate inflammation and contribute to increased risk of chronic illnesses.[19]

Lee et al. evaluated the association between discrimination and leukocyte telomere length (LTL), a biologic marker of systemic aging. High discrimination was associated with shorter LTL after controlling for sociodemographic factors, health factors, depressive symptoms, and stress. Results suggest that discrimination experiences accelerate biologic aging in older African American males and females alike. This finding helps advance our understanding of how discrimination generates greater disease vulnerability and premature death in African Americans.[20]

Failure of Trust

Patients from minority communities have reason to be skeptical about the validity of medical research and appropriateness of medical recommendations. The legacy of Tuskegee, for example, has long been seen as the etiology of mistrust in the African American (AA) community. Lack of trust can result in failure to follow medical advice, arrange follow-up appointments, and obtain prescriptions.[21]

Higher levels of acculturation and lower levels of perceived discrimination are associated with higher levels of trust in health care providers. Patients often rate their physician interactions as longer, more participatory, and having more positive effects when their physician is of the same race.[22] For immigrants, shorter lengths of time spent in the United States and increased experiences with discrimination predicted increased distrust in the health care system. In one study, interventions aimed at the reduction of perceived discrimination reduced health care disparities in Korean Americans.[23]

SPECIFIC ISSUES

Communication and Use of Interpreters

Effective communication between patients and physicians is essential for improved health outcomes. There are over 300 languages other than English spoken in the United States. According to US Census data released in 2015, over 60 million Americans over the age of 5 years speak a language other than English at home, and 25 million speak English less than very well.[24] Patients with limited English proficiency are more likely to defer needed health services, leave against medical advice, miss appointments, fail to adhere to treatment regimens, lack a regular provider, and report poor health status.[25] Additional challenges faced by this diverse population with limited English proficiency include risk of increased medication errors, decreases in understanding medical conditions, and misdiagnosis resulting from the lack of physician understanding of complaints or patients' ability to effectively convey their symptoms.[26] The use of untrained nonprofessional interpreters (employees, family, friends, etc.) can result in patient confidentiality concerns and miscommunication due to oversimplification of medical problems or other interpretation errors, which potentially compromises quality, safety, and patient satisfaction.[27,28]

The National Standards for Culturally and Linguistically Appropriate Services in Health and Health Care (The National CLAS Standards), last modified in October 2018 and published by the US Department of Health and Human Services Office of Minority Health, aim to improve health care quality and advance health equity by establishing a framework for organizations to serve the nation's increasingly diverse communities. Institutions and practitioners are required to provide for medical needs in a patient's primary language and in a manner compatible with the patient's health beliefs and practices. The overarching goal of the CLAS standards is to "provide effective, equitable, understandable and respectful quality care and services that are responsive to diverse cultural health beliefs and practices, preferred languages, health literacy and other communication needs."[29] Health care institutions and providers are asked to collect data stratified by race, ethnicity, and language, and to institute quality improvement efforts when cross-cultural differences in outcomes of care, process indicators, or

BOX 186.1 Pitfalls in Language Communication Standards

- Use of family members, friends, or children
- Failure to translate documents such as consent forms and discharge instructions
- Lack of documentation of a patient's need for an interpreter or English language limitations
- Lack of documentation of the use of an interpreter and background and qualifications of the interpreter

patient satisfaction are detected. They are asked to develop culturally competent systems of care based on an assessment of the organization's mission, goals, policies, practices and services, staff training needs, and current diversity of the staff. After the assessment process, health care organizations must identify opportunities to improve the cultural competence of the organization and its delivery of health care services to a diverse population. At the top of the list is the improvement of interpreter services. Hospitals are asked to establish minimum performance standards for interpreters, which includes training in the culturally specific medical language and code of ethics.[29,30]

Standards and certification for medical interpreters are necessary to ensure consistency and quality.[31,32] As of 2019, every state and the District of Columbia had enacted multiple laws addressing language access.[33] The Joint Commission requires hospitals to provide professional interpretation services to every patient who needs it. The International Medical Interpreters Association recommends that standards cover interpretation, cultural interface, and ethical behavior.[34] Because the meaning inherent in the message is rooted in culturally specific beliefs, values, assumptions, customs, and norms, and language is itself an expression of culture, it may be necessary for a medical interpreter to go beyond a literal interpretation to explain unstated assumptions and find new ways of communicating untranslatable words or concepts. In addition to maintaining confidentiality, the medical interpreter has an ethical burden to uphold the trust of both parties and to assure them that the considerable power associated with the interpreter's role will not be abused, and that information will be faithfully conveyed without interjection of the subjective opinions and thoughts of the interpreter. Even with such qualified interpreters, the emergency clinician still needs to monitor the flow of the interview and, from time to time, clarify meaning and ensure understanding. This can be done by having the interpreter repeat what he or she thought the patient meant and asking the patient to repeat what the interpreter said. It is important to observe the interaction for phrase length as an indication of material not translated or added by the translator.

Finally, failure to meet language and communication standards in clinical scenarios can have financial implications. Professional interpreter usage has been demonstrated to have cost lowering effects resulting from decreased administration of intravenous fluids, unnecessary laboratory and radiologic testing, and admissions as a precaution.[27] In addition, the use of nonprofessional interpreters can yield medical malpractice claims resulting from harm caused because of language barriers. In a study of medical malpractice claims of a malpractice carrier that insures providers in four US states, researchers found that 2.5% of the carrier's total claims reviewed were related to language barriers resulting in patient death or irreparable harm. The study reported that the carrier paid $2.3 million in damages or settlements and $2.8 million in legal fees between 2005 and 2009. In 32 of the 35 cases, the health care providers did not use competent interpreters.[35] Box 186.1 lists common pitfalls in meeting language communication standards.

Disability and Accommodations

Overview

According to the World Health Organization (WHO), roughly 15% of the world's population (over a billion people) live with some form of a disability. Disability is defined as impairments, activity limitations, and participation restrictions of individuals with a health-related condition and their personal and environmental factors.[36,37] Increasing rates of disability are related to an aging population and increase in chronic conditions. All people with disabilities have basic health care needs requiring access to the mainstream health care services despite the diversity and complexities of the disability. According to the WHO, people with disabilities search for more health care options than people without disabilities and have greater unmet needs.[38] People with disabilities can be subject to prejudice and the resulting health disparities and poorer health care outcomes, similar to people from other stigmatized groups. They can experience many barriers in accessing health care, including factors such as prohibitive costs, limited availability of services, physical barriers to access facilities or treatment, and lack of knowledge and skills of health care workers.[38]

Patients living with disabilities present for a variety of reasons that may or may not result from their disability. The ED may be the first point of contact with the health care system and the visit may be the first presentation of a condition that could result in a disability or a complication arising from it.

The Hearing Impaired

Deaf and hard-of-hearing individuals over the age of 12 comprise 23% of the US population.[39] This group encompasses varying skills with spoken language, lip-reading, sign language, and written language. The level and type of skill usually depends on when in life the impairment occurred. For example, an individual with congenital hearing loss may be proficient in sign language, while someone with acquired deafness may be more proficient with written notes and may be less able to lip read.[40] Individuals whose language is American Sign Language (ASL) or another sign language face significant barriers to access to the health care system due to lack of health care sign language interpreters.[41] Although antidiscrimination legislation exists to protect the deaf community, persistent gaps in support and resources still exist that impacts accessibility for the hearing impaired. Communication barriers prevent deaf patients from being able to maintain strong patient-provider relationships with primary care. This can lead to overutilization of the ED and urgent care for routine health concerns.[41] Inadequate provision for sign language interpretive services can have legal, financial, and ethical implications. These consequences can include discrimination suits based on the American with Disabilities Act, breach of duty concerns in regard to patients' informed consent and their ability to participate in their health care, as well as professional conduct of health care providers as it relates to equitable patient-centered care.[40] The National Association of the Deaf (NAD) has outlined guidelines for health care providers to provide effective communication to deaf patients who communicate with sign language[41] (Box 186.2).

The Homeless

The homeless often encounter multiple barriers to accessing health care, yet they experience high levels of both chronic and acute medical problems. They are also disproportionately vulnerable to violence and injury and are at increased risk of premature death and disability.[42] Homeless individuals use the ED at higher rates, are more likely to have repeat ED visits, and are more likely to present via ambulance because of their lack of transportation than non-homeless persons.[43] Homeless individuals often use the ED for nonemergent medical needs because demands and costs for food, shelter, and safety supersede obtaining

BOX 186.2 National Association of the Deaf Communication Guidelines for Health Care Providers

- Clearly identify at-risk individuals for poor communication.
- Provide visual medical aids.
- Providers who know basic sign language can be beneficial but be aware of limitations.
- Establish an effective communication policy for the office or institution.
- Provide qualified sign language interpreters.
- Ineffective methods of communication are discouraged, including lip-reading or written notes.
- Be aware of effective communication approaches and resources.
- Make health care providers and staff aware of relevant laws and mandates that provide equal access and communication for deaf patients.

primary care. The high prevalence of concomitant substance abuse and psychiatric illness can make treating the homeless population more challenging. Homeless individuals have a significantly higher risk of opioid overdose and opioid-related ED visits and hospitalizations compared to low-income housed individuals.[44] This finding highlights the importance of recognizing the homeless population as high-risk for opioid overdose. Comprehensive discharge planning is required for homeless patients due to their comorbid psychiatric and substance abuse issues combined with their lack of consistent and safe shelter.

The ED presents a window of opportunity where early intervention strategies may be implemented to improve the health status of homeless patients. Intensive case management has been shown to reduce ED use and result in better health outcomes by connecting homeless patients with available community resources. Greater attention must be given to the hospital services that are provided to the homeless so that behavioral, environmental, and psychosocial needs are also addressed effectively and efficiently. Improved integration of health care facilities and shelters as overlapping systems of care may improve the quality of transitions of care and health care outcomes for homeless patients.[27] Caring for homeless patients in the ED requires attention to the social determinants of health[42] (see Chapter 189).

Prisoners

Prisoners have a higher incidence of physical and psychiatric disorders compared to the general population. The health disparity between prisoners and the general population has been attributed to socioeconomic and behavioral factors including increased rates of intravenous drug use, infectious diseases, alcohol abuse, and smoking, which have increased the risk of cardiovascular disease and some cancers. Approximately one in seven prisoners has a mental illness. Mental illness has been shown to increase the risk of crime and repeat offending. The disproportionate degree of physical and psychiatric disease in prisoners presents both unique public health challenges and opportunities for public health intervention. For many underserved individuals, prison provides an opportunity for diagnosis, disease management education, counseling, and treatment that they would not otherwise receive. Treating mental and physical illnesses of prisoners can improve public health.

Unfortunately, prisoners often have limited access to health care after release from prison.[27] Upon release from prison, the previously incarcerated return to their communities with their physical and psychiatric morbidity, occasionally untreated and sometimes worsened, creating additional societal burden within their communities. Psychiatric morbidity leads to increased suicide rates and contributes to repeat offending.

The Undocumented

Undocumented patients rely on the ED for a disproportionate degree of care due to barriers to health care access. For example, reliance on the ED for routine dialysis occurs because of ineligibility for Medicare and Medicaid, leading to increased mortality.[45-47]

Emergency clinicians should become familiar with strategies and resources that will impact the ED care of undocumented individuals. Also, strengthening ties with community-based organizations and medical legal partnerships can facilitate linking undocumented patients to social services and may help to facilitate successful discharge planning and follow up.

Understanding immigration status as a modifiable social determinant of health is a first step in improving the care and health of undocumented populations (see Chapter 189).

CULTURAL COMPETENCE

Appreciation of Different Beliefs, Values, and Experiences

The encounter between a clinician and patient is guided by perspectives dictated by cultural differences or similarities. Knowledge and awareness of those differences or similarities can often enhance satisfaction and health outcomes. A patient-centered approach to the clinical encounter requires the clinician to be carefully observant to sufficiently assess or even inquire about a patient's preexisting assumptions in order to provide culturally sensitive care.

Diagnosis of specific diseases can be interpreted differently depending upon differing cultural perspectives. For example, in African American and Puerto Rican communities, a cancer diagnosis may be perceived as fatal even if diagnosed at an early stage with a more favorable prognosis. As a result, patients may be more likely to avoid initial evaluation or choose no treatment when initially diagnosed. A health care provider who understands these health beliefs and concerns can work collaboratively with patients to provide health information in a format that the patient can accept.

Alternative healing systems have strong cultural roots. In the 2007 National Health Interview Survey (NHIS), approximately 38% of adults reported using complementary and alternative medicine (CAM) in the previous 12 months, with approximately 354 million visits to CAM practitioners and approximately 835 million purchases.[48] The National Center for Complementary and Integrated Health maintains an extensive database of literature on alternative healing methodologies in the United States.[49-52]

Folk medicine is too diverse for providers to know all possible practices, but emergency clinicians need to be aware of the more common folk therapies. For example, more than a few physicians have called social workers to investigate children with apparent bruises caused by coining, which involves vigorous rubbing of the skin with coins and warm oil (tiger balm) to release "bad wind" (reduce fever). These parents, who have attempted to help their children by using health care practices that are widely accepted in their communities of origin, feel accused, and the trust between the physician and family may be irrevocably lost. Similarly, herbal remedies can be effective or at least harmless, but they can occasionally be toxic, as in the case of clay ingestion by pregnant women, marijuana tea to treat asthma, and powders containing high concentrations of lead oxide to treat *empacho,* a condition in which it is believed that a substance (usually food or saliva) gets stuck to the walls of the stomach or intestines, causing an obstruction. Specific uses of folk medicine need to be elicited respectfully in a careful history and evaluated. Recommendations can then be presented nonjudgmentally, and alternative folk remedies that are benign can be prescribed along with needed allopathic medications.

The practitioner and patient will inevitably bring different beliefs and values to the medical encounter; the key to cultural competence is respectful negotiation of these differences without imposing the power of the physician's expertise, thereby protecting the patient's autonomy. If patients are satisfied, they will carry out follow-up recommendations and return to the ED in the future when they need emergency care.

Interpreting the Culture of Medicine for Patients From Diverse Backgrounds

There are inherent conflicts between the culture of western medical practice and the cultures of many patients. Physicians are experts in diagnosis and treatment of *disease*, the abnormal structures or functions of the human body (the pathophysiology of disease states). Patients, on the other hand, experience *illness*, a subjective feeling state that is interpreted through the lens of culture and has a personal and social meaning. The patient is an expert on his or her own illness and its effects on daily living, whereas a physician is expert on the effects of diseases on organ systems. Both ways of looking at the world have validity and a culturally competent approach recognizes both and works to integrate both perspectives for the best possible outcomes.

If patients with true disease remain asymptomatic or experience no alteration in functioning, they may be reluctant to accept a physician's diagnosis. On the other hand, a patient may be significantly, subjectively symptomatic in the absence of medical diagnosis, despite a thorough investigation. Concepts such as *susto* (fright), *coraje* (anger), and *fatalismo* (fatalism) are common cultural beliefs that manifest in physical symptoms. For example, *susto,* an illness recognized by Mexican Americans, causes listlessness, insomnia, depression, and anorexia, and is believed to be caused by exposure to a frightening experience. Treatment requires the patient to speak openly about the events that led to the susto, followed by bed rest and a ritual that includes prayers, incantations, and *barridas*—sweeping of the body with an egg, candle, or herbal tea. If these beliefs are not well understood by the health care provider, recommendations for treatment are likely to be discarded. As a result, the health care provider must develop trust with the patient. One useful approach is to engage a family member or *promotora* or *promotor* (community health worker) in the conversation.[53]

To be most effective, physicians need to investigate how patients view the causality of their illnesses and how they experience them to negotiate a therapeutic intervention. Exploration might take the form of comments and questions, such as, "Help me see through your eyes how you understand this problem," or "Have you or someone you know experienced it before?" The role of the physician is to accept the patient's experience as uniquely his or hers or, when possible, to reframe it in terms of medical knowledge. Then both physician and patient will be satisfied with the outcome of the encounter.

Every medical encounter is potentially a cross-cultural experience within this context and negotiation of the divide can be challenging for both patients and providers. Cultural competence involves reframing many of these unstated rules so that underlying circumstances and problems can be recognized and addressed. Circumstances may exist where patients may not feel comfortable sharing information with clinicians because of cultural, racial, sexual orientation, or language barriers. Vague complaints may be a sign of social stressors that result in mental health–related symptoms. These presentations may be further complicated by negative stimuli related to racial and ethnic discrimination.[54] People from minority cultures often experience significantly higher levels of daily stressors and there is mounting evidence that these types of negative encounters engender clinical depression and anxiety and contribute to hypertension and other medical sequelae.

Minority populations consume ED care at higher rates and are more likely to use the ED as a usual source of care.[55] Emergency clinicians must appreciate the context of their practice settings; recognize how rules, language, hierarchy and bias can potentially interfere with effective patient care; and work to provide care that is patient-centered and culturally sensitive. These actions can help create a safe environment for practitioners and patients who will experience higher levels of satisfaction with the care experience.

Combining Cultural Competence and Patient-Centered Care

Models for cultural competence and patient-centered care have evolved separately yet are closely aligned. The goal of both models is to improve the quality of the health care experience in a multicultural setting. Cultural competence involves providing equitable, evidence-based, high-quality care for diverse patient populations.[56] It requires the clinician to recognize and respect individual differences and the impact of individual interpretation on health, illness, and health care delivery. Patient and family–centered care is an approach to health care delivery that is a mutually beneficial partnership among the patient, family, and the health care team to address the planning, development, and assessment of the medical care.

Ideal health care systems incorporate the principles of both cultural competence and patient centeredness. A health care system built on patient-centered principles represents the heart of cultural competence—seeing the problem and solution from the point of view of the patient.[56] In 2015, the American Association of Pediatrics published a technical report which stated that "commitment to patient and family centered care ensures that the experiences and perspectives of patients and families guide the practice of coordinated and culturally sensitive care that promotes patient dignity, comfort, and autonomy."[57]

Medical education at the undergraduate, graduate, and professional levels about the impact of culture on health care encounters is a key component for the development of culturally appropriate health care and is a requirement for organizational accreditation. Students and residents in training consistently express greater levels of comfort in multicultural environments when they have had preparatory training. Training also helps students and residents understand that their own culture also affects clinical encounters and is equally participatory.

The Accreditation Council of Graduate Medicine Education (ACGME) and the Liaison Committee on Medical Education (LCME) have provided guidelines that graduate training programs and medical schools use to teach cultural competency through communication skills and professionalism.[27,58-59] The American Association of Medical Colleges (AAMC) also provides the Tool for Assessing Cultural Competency Training (TACCT) to assess cultural competency training in medical schools and provide medical schools and graduate medical education programs with a suggested rubric.[60]

According to the Emergency Medicine Milestones Project, patient-centered communication and professional values are assessed for every emergency medicine resident. This particular area addresses the learner's ability to elicit presenting symptoms from a diverse population of emergency department patients. Additionally, it assesses the learner's ability to communicate effectively with vulnerable populations. The professional values milestone requires learners to demonstrate cultural humility by providing compassion, integrity, and respect during patient care.[61]

RECOMMENDATIONS

Diversity among the ED patient population poses a challenge to emergency clinicians. Recognition of cultural differences, knowledge about diverse cultures, awareness of the health impact of cultural beliefs and practices, and sensitivity to patients' needs can reduce access barriers

BOX 186.3 Six Principles for Cultural Competence Standards and Expectations

1. Community representation and feedback at all stages of implementation
2. Cultural competency integrated into all systems of the health care organization, particularly quality improvement efforts
3. Ensuring that changes made are manageable, measurable, and sustainable
4. Making the business case for implementation of cultural competency policies
5. Commitment from leadership
6. Staff training on an ongoing basis

and improve clinical outcomes and hospital-community relationships while reducing the number of repeated visits and costs of health care. Diversity, inclusion, and health equity education also creates a rich environment for conceptualizing and researching health problems.

There are many opportunities for EDs and their institutions to improve their care of multicultural communities. These include plans to address problems related to lack of protocols for patient care and lack of resources for translation and cross-cultural interpretation. Cross-culture teaching guidelines and standards in medical education can correct false perceptions of culturally competent care such as negative impacts on flow and efficiency in the ED. Opportunities also exist to develop, recruit, and retain residents, faculty, and practitioners who are underrepresented in medicine in order to enhance multicultural patient care, opening the doors to community engagement.

Specific recommendations, based on the National Standards for Culturally and Linguistically Appropriate Services in Health and Health Care, have been proposed for pediatric emergency settings that can be applied universally. Institutions should use trained medical interpreters and should have a goal of employing a diverse workforce. Pharmacies are encouraged to label prescriptions and provide medical instructions in the patient's primary language. Administrators should post multilingual signs and ensure that handouts and forms are translated. Quality improvement programs should collect and analyze data and provide information to monitor outcomes based on race and ethnicity. Efforts should be made to expand minority enrollment in research studies and clinical trials to improve the validity and applicability of discoveries and new therapies.

The process of change for the development of culturally competent medical systems has been slow, but progress is occurring. Evolution of culturally appropriate environments for patients and their families has begun on all levels and, with the development of new standards and performance monitoring systems, assurance of established culturally competent systems will be an expectation. These expectations are important and tightly linked to safety and quality. The linkage of cultural competence to social justice broadens the depth of comprehension for the learner and provides opportunities for enhanced engagement with consumers and greater quality of care.

The process of creating a successful plan to move cultural competency from a theoretical model to one of action and implementation has been outlined in six principles that incorporate key points recommended by the IOM report of 2003 for systems aligned with new cultural competence standards and expectations (Box 186.3).

Essential cultural competence tools for providers include recognition of cultural differences, respect for individual opinions and perspectives about health and illness and, most importantly, ability and willingness to negotiate differences to offer the best opportunity for good health care outcomes. Culturally appropriate health care systems should be incorporated into EDs, which serve as the gateway to our health care institutions.

CHAPTER 186: QUESTIONS AND ANSWERS

1. Which of the following factors has not been identified as a health care disparity for minorities?
- **a.** High rates of no insurance or underinsurance
- **b.** Lack of prenatal care
- **c.** Likelihood of living in an area with adequate physician concentration
- **d.** Lower life expectancy when compared to white populations
- **e.** Relatively low number of minority providers

Answer: C. Minority patients are likely to live in impoverished areas with limited access to both primary and specialty medical care. As a result, they may present to the ED with previously undiagnosed medical problems underlying their symptoms.

2. Patients' cultural perceptions can have a significant impact on how they perceive their provider and the care they are receiving. Which of the following methods can be used by providers to approach different cultural perceptions so as to enhance the provider-patient relationship?
- **a.** Being aware of one's own cultural values
- **b.** Developing assumptions of cultural perceptions base on patients' ethnicity or race
- **c.** Limiting participation of alternative therapies and folk medicine in the patient's care plan
- **d.** Maintaining the role of the physician as the decision maker, even when it may conflict with the patient's autonomy

Answer: A. Being aware of one's own preconceived notions and biases is the first step a health care provider can take on the path toward developing cultural sensitivity toward patients from minority groups.

3. Which method of communicating is adequate to utilize with a deaf or hard-of-hearing patient?
- **a.** Certified interpreter
- **b.** Family member
- **c.** Lip reading
- **d.** Written communication on notepad

Answer: A. Using a certified interpreter for the hard-of-hearing is the only reliable way of communicating with such patients.

4. A helpful language translator can be essential in communication with a patient who is facing a language barrier. Which of the below methods are recommended for using an interpreter during a medical examination?
- **a.** Asking the patient to have friends or family translate discharge instructions for them
- **b.** Only obtaining an interpreter if the patient requests one
- **c.** Using a family member is appropriate as long as they are older than 18 years
- **d.** Using a trained medical interpreter
- **e.** Using health care staff members who are fluent in the patient's language

Answer: D. Using a certified interpreter is the only consistently reliable way of communicating with patients with language barriers.

5. Which of the following organizations have suggested guidelines to address cultural competence in educational standards?
- **a.** American Association of Medical Colleges
- **b.** Liaison Committee on Medical Education
- **c.** Accreditation Council on Graduate Education
- **d.** All of the above

Answer: D. These are just some of the medical organizations that have developed guidelines to assist medical schools and residency programs in teaching physicians-in-training to become culturally competent in their approach to patients from minority groups.

Human Trafficking

Wendy Macias-Konstantopoulos and Hanni Stoklosa

KEY CONCEPTS

- Labor and sex trafficking involve the exploitation of a person for labor or commercial sex, respectively, affecting up to 25 million persons worldwide.
- Human smuggling, a crime in which a person contracts a smuggler to facilitate their illegal entry into a country, can evolve into trafficking during transit or at the destination and under such circumstances the person is considered a victim of human trafficking.
- Child victims of sex trafficking are considered victims of child abuse and neglect under the law and thereby call into relevance state mandated reporting statutes.
- Populations at greater risk for trafficking include persons with histories of child abuse, family dysfunction, diverse sexual orientation or gender identity, intellectual disability, homelessness, financial insecurity, and migration.
- Human trafficking often involves the use of abusive and violent tactics, including forced substance use and psychological coercion to entrap and exert control over trafficked persons, with profound implications for survivors' physical, reproductive, and mental health.
- Trafficked persons seek health care services during their exploitation for a wide range of health conditions and the emergency department (ED) is the most common access point for this patient population where indicators of abuse, control, and the physical and psychosocial red flags of trafficking can assist in the recognition of trafficked victims.
- Inquiry about forms of interpersonal violence, including trafficking, is fundamentally different from screening for medical issues with the goal of providing a safe environment in which patients feel empowered to share as much or as little as they choose, and where strengths and resilience are recognized.
- Trafficked people may return to exploitative situations repeatedly before exiting permanently; therefore, safety planning is critical for the discharged trafficked patient.
- Trauma due to trafficking results in neurobiologic changes such that commonly occurring smells, sounds, sights, and procedures of the ED environment may be perceived as threats by those with trauma histories.
- The six principles of trauma-informed care include physical and psychological safety; trustworthiness and transparency; peer support; collaboration and mutuality; empowerment, voice, and choice; and cultural, historical, and gender acknowledgment.
- Law enforcement involvement should be limited to patient request, in state-specific mandated reporting scenarios, or when clinicians suspect imminent danger to staff or the patient.

FOUNDATIONS

Background and Importance

Human trafficking is an abusive and exploitative form of interpersonal violence. It is a global public health problem associated with a multitude of health problems. The United States (US) recognizes both labor trafficking and sex trafficking as "severe forms of trafficking in persons" punishable under federal and state laws. Under the US Trafficking Victims Protection Act (TVPA) of 2000 and its subsequent reauthorization acts, as amended (22 USC § 7102):

- *Labor trafficking* is "the recruitment, harboring, transportation, provision, or obtaining of a person for labor or services, through the use of force, fraud, or coercion for the purposes of subjection to involuntary servitude, peonage, debt bondage, or slavery," and
- *Sex trafficking* is "the recruitment, harboring, transportation, provision, obtaining, patronizing, or soliciting of a person for the purposes of a *commercial sex act*, in which the commercial sex act is induced by force, fraud, or coercion, or in which the person induced to perform such an act has not attained 18 years of age."[1,2]

Federal law assumes that persons under the age of 18 years performing commercial sex acts have been induced to engage in commercial sex and does not require that force, fraud, or coercion be proven for minors to be considered victims of sex trafficking. (Pursuant to Pub. L. 106-386, 114 Stat 1469 (2000), a commercial sex act refers to "any sex act on account of which anything of value is given to or received by any person.") Antitrafficking legislation since the TVPA of 2000 has focused further attention on prosecution, protection, and prevention of child trafficking. The Justice for Victims of Trafficking Act of 2015 authorized a range of provisions for combating trafficking and assisting victims, including an amendment to the Child Abuse Prevention and Treatment Act of 1988 by which the legal definition of *child abuse and neglect* was expanded to incorporate "sex trafficking" and "severe forms of trafficking in persons" involving minors.[3] Although mandated reporting statutes vary across jurisdictions, all states, the District of Columbia, and US territories mandate the report of suspected child abuse and neglect to the proper authorities.[4]

Finally, it is important for providers to understand that the law differentiates between human trafficking and human smuggling. Whereas human trafficking involves the exploitation of a victim for compelled labor or commercial sex, *human smuggling* involves a person contracting a smuggler to facilitate their voluntary and illegal entry into a country. Although human smuggling is a crime of migration committed against the state (not against a person), persons smuggled across international borders may be subjected to labor or sex trafficking during transit or upon arrival at their destination. Under these circumstances, their voluntary consent to smuggling does not render legal their subsequent entrapment in forced labor or commercial sex and such individuals are considered victims of the crime of human trafficking under federal law.[5] Understanding this distinction is important to educating victims about their legal rights and linking them to services where they can access the legal protections and redress to which they are entitled.

EPIDEMIOLOGY

Trafficking Typologies

The US Department of State has determined that human trafficking is an umbrella term that comprises a number of different forms of compelled service including forced labor, bonded labor (debt bondage), domestic servitude, sex trafficking, child sex trafficking, forced child labor, and child soldiering.[6] Exploitation of adults and children in the United States has been reported in typically formal labor markets (e.g., restaurant and hospitality, construction, agriculture, farming), informal labor sectors (e.g., domestic work, landscaping, traveling sales crew, peddling rings), and commercial sex industries.[7] In the United States, the illegal commercial sex economy may involve street-based commercial sex, brothels and cantinas, technology-facilitated rendezvousing, escort services, adult entertainment venues, child sex tourism abroad, live-streaming of child sexual abuse, and child and adult pornography.[7,8,9] Additionally, nail salons, massage parlors, health spas, and other unregulated bodywork businesses can serve as storefronts for both labor and sex trafficking.[7,9]

Global and US Prevalence

Prevalence estimates of human trafficking are historically wide-ranging and influenced by multiple factors. Data integrity and reliability are challenged by the clandestine nature of human trafficking, the failure to use a standardized definition of trafficking across organizations and countries, the focus of the data collecting agency (i.e., law enforcement versus social service agency, labor versus sex trafficking, adults versus minors), and the lack of centralization or even compatibility across databases. In 2016, the United Nation's International Labor Organization in collaboration with the Walk Free Foundation and International Organization for Migration (IOM) estimated that 24.9 million persons around the globe are trapped in forced labor, including sexual exploitation.[10] According to this study, women and girls account for 71% and children account for 25% of victims, and nonsexual forced labor comprises the majority of cases.[10] Centralized, reliable, high-quality data are needed to enhance our understanding of the scope of the problem globally and within individual countries.

Polaris, a US nongovernmental organization (NGO), has been monitoring human trafficking and operating the National Human Trafficking Hotline (NHTH) in the United States since 2000. Although reporting hotlines fail to capture all cases of trafficking, statistics from the national trafficking hotline offer relevant proxy data regarding the extent of the problem. According to published hotline statistics, nearly 52,000 *situations* of human trafficking involving one or more victims were identified across the US and US territories between December 2007 and December 2018.[11] In 2018 alone, the NHTH identified over 23,000 individual survivors of human trafficking, 64% of whom were survivors of sex trafficking, 24% labor trafficking, and 6% both forms of trafficking.[12]

Demographics of Trafficked Persons

Within the subset of tip calls received by the national hotline for which survivor demographic data are available, the majority of survivors are adults (≥18 years), female, and Latinx. Extrapolation from the limited data suggests that the average age (mode age range) at the onset of trafficking was 25 (15–17) years old for labor trafficking and 18 (15–17) years old for sex trafficking.[12,13] Given the challenges in collecting comprehensive and accurate information, demographic data from identified and reported cases in any local or national database may not accurately reflect the overall demographics of US trafficked persons.

Although human trafficking can affect persons of any age, gender identity, sexual orientation, ethnicity, race, citizenship, socioeconomic standing, religion, and physical or intellectual ability, certain populations are at greater risk for trafficking. Circumstances that place individuals at risk for trafficking are those that increase their dependence on others to meet their basic needs or obtain something of value. Box 187.1 lists factors associated with increased vulnerability to human trafficking.[12,14-29]

BOX 187.1 Factors Associated With Increased Vulnerability to Human Trafficking

- Child abuse and neglect, particularly sexual abuse
- High levels of adverse childhood experiences
- Caregiver strain and conflict or family dysfunction related to a wide range of potential factors:
  - Domestic violence
  - Family sex work
  - Parental substance use
  - Mental health problems
  - Sexual or gender identity diversity
- Use of children for forced labor
- Exposure to criminality and transactional sex
- Involvement with child protective services and/or law enforcement
- Substance use
- Teen pregnancy
- Intellectual disabilities
- Running away or being thrown out of the home
- Homelessness (particularly relevant to sexual or gender identity diverse youth)
- Financial insecurity or poverty
- Migration

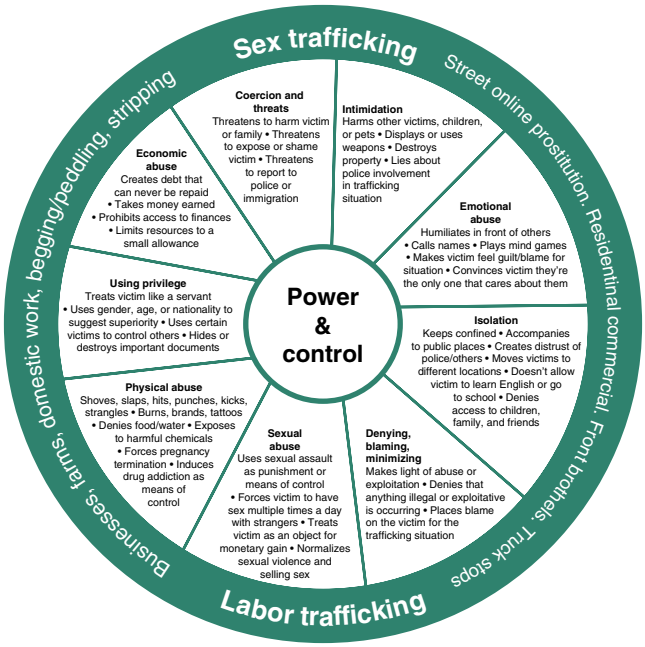

Fig. 187.1 Polaris Human Trafficking Power and Control Wheel. (Adapted from Polaris and available for download at https://humantraffickinghotline.org/resources/human-trafficking-power-and-control-wheel.)

Recruitment and Control Tactics

Traffickers entrap and maintain control over victims of human trafficking in multiple ways. Figure 187.1 summarizes the constellation of methods used, which often extends to financial disempowerment,

debt bondage, coerced involvement in illegal activities, blackmail, and a host of other criminal tactics.[14,15,30]

According to 2018 NHTH data, the top *labor trafficking* recruitment methods used, in order of reported frequency, included false job offers or advertisements, false promises/fraud, smuggling-related initiation, coercion, and familial inducement.[12]

In nearly 12,000 cases of *child trafficking*, data from the Counter-Trafficking Data Collaborative suggest that children are most commonly trafficked by family members (41%), intimate partners (14%), and friends (11%) by means of psychological abuse (24%), physical force (16%), sexual violence (10%), and substance-related coercion (9%).[31]

IMPACT ON HEALTH

Traffickers often employ abusive and violent tactics to exert and maintain control over victims in order to effectuate the crime of human trafficking. These tactics have profound implications for the health of trafficked individuals, leading to physical, reproductive, and mental health problems. Accidental (occupational) and intentional (violence-related) traumatic injuries occur during trafficking as a result of the physical demands of manual labor, lack of personal protective equipment, hazardous working conditions, and physical and sexual violence.[17,32] Sex trafficking survivors and labor trafficking survivors experiencing sexual violence are at elevated risk for sexually transmitted infections (STIs) including human immunodeficiency virus (HIV) infection, pregnancies, and terminations.[17,33-36] In addition, trafficked persons may experience control through induced debilitation, specifically food and sleep deprivation, coerced substance use, and confiscation of needed medications or medical supplies.[30] The abuse and violence endured while trafficked can result in depression, anxiety, posttraumatic stress disorder (PTSD), dissociative states, psychosomatic pain syndromes, substance use, self-injurious behavior, and suicide attempts.[17,25,33-42]

Substance use, mental illness, and pregnancy merit special consideration given the unique degree of vulnerability conferred on victims. These health conditions can create or exacerbate relational imbalances of need and dependency that traffickers can exploit to subvert victims. When caring for patients with these conditions, providers must consider the possibility of the trafficker being a family member, intimate partner, or friend.

Substance Use

Research has established a correlation between substance use and human trafficking. A retrospective chart review of 12- to 18-year-old victims of sexual violence found that drug use rates were significantly higher among commercially sexually exploited and trafficked youth compared to sexually abused and assaulted youth.[19]

The complex relationship between substance use and human trafficking has been increasingly recognized and understood. Substances can play a key role throughout the various stages of trafficking, including in the recruitment, entrapment, and exploitation of victims. Highly addictive substances (e.g., opioids, stimulants) provide a relatively easy opportunity for traffickers to entrap experimenting adolescents and young adults by exploiting newly evolving addictions. In cases where the trafficker is someone close or known to the individual being targeted for recruitment, the trafficker may be the person who introduces the addictive substance and encourages its use with the intent of creating a vulnerability to exploit. Similarly, previously formed addictions offer traffickers a mechanism through which they can entrap individuals with addiction for the purpose of exploiting them.

In addition to facilitating recruitment and entrapment, victim accounts suggest substances may play a central role in maintaining control over trafficked persons. In some cases, traffickers force drug-naïve victims, particularly adolescents, to use substances as a means of weakening their defenses and creating an addiction that can be leveraged to exert control over them during their exploitation.[43] In other cases, the trafficker may simply ensure substances are available and trafficked persons may initiate use on their own as a way to cope with the physical and emotional trauma of their trafficking situation. Victims' reliance on substances to numb their pain and cope with the anxiety, depression, and PTSD related to their everyday experiences while trafficked creates high levels of dependence on the trafficker for access to the drug.[44] Traffickers are thus able to exert and maintain control over trafficked individuals by regulating the type (drug class), manner (route of administration), and extent (dosage and frequency) to which the substance is available to them.

Mental Illness

In addition to mental health disorders potentially heightening risk for trafficking, the traumatic experiences endured by victims while being trafficked may induce or unmask mental health disorders. Trafficking may exacerbate preexisting mental health disorders and lead to increased frequency or severity of psychiatric manifestations.[45] In a historical cohort study of trafficking survivors receiving mental health services in the United Kingdom, the most commonly encountered diagnoses in the adult sample included 34% affective disorders; 28% PTSD, severe stress, or adjustment disorder; 15% schizophrenia and related disorders; and 22% intentional self-injurious behaviors.[45] Similarly, 27% of the youth in the study were diagnosed with affective disorders and another 27% with PTSD, severe stress, or adjustment disorder. Among youth, 27% exhibited intentional self-harm while in care.[45] In a US study among court-involved commercially sexually exploited female youth, 88% endorsed substance use, 76% identified with having a mental health problem, 43% reported previous psychiatric admissions, and 14% reported suicidal ideation.[46]

Anecdotally, traffickers can use a victim's mental illness to remain undetected. A trafficked person who presents to an ED providing accounts of seemingly unrealistic events may be erroneously assumed to be suffering from acute paranoid delusions, persecutory delusions, or hallucinations. Any inconsistencies in their accounts might even raise suspicion among providers of malingering for secondary gain rather than memory gaps related to trauma.[47] Subsequent attempts to obtain assistance in the ED may be misdiagnosed as episodes of acutely decompensated psychiatric illness rather than real life events related to being trafficked. In this manner, traffickers can continue their abuse and control with less concern that the veracity of a victim's report will be investigated.

Pregnancy

Trafficked adolescent and adult women often experience decreased ability to negotiate condom use during transactional sexual encounters,[33,44] as well as decreased access to family planning services and prenatal care.[39,48] Decreased reproductive control and diminished access to family planning services theoretically increases the likelihood that trafficked women may present to an ED for such services (e.g., counseling about alternative discrete forms of contraception, STI screening and treatment, HIV counseling and testing, and emergency contraception). Moreover, lack of access to prenatal care is associated with adverse pregnancy outcomes, including insufficient gestational weight gain, premature rupture of membranes, and precipitous labor,[49] and these outcomes may be at play among trafficked women who present to the ED in the later stages of pregnancy seeking to either initiate prenatal care or deliver.

For trafficked adolescent and adult women, desires to carry or terminate a pregnancy are influenced by the circumstances of their trafficking situation, but such decisions may be unduly influenced by traffickers. As in intimate partner violence, pregnancy also carries an increased risk of trafficker-perpetrated abuse and violence,[44] which in turn is related to increased risk of preterm labor, small-for-gestational-age infants, postpartum depression, and decreased likelihood of breastfeeding.[50,51] Pregnant and postpartum women who present to an ED for violence-related injuries should be queried about other potentially exposed children. Limited evidence suggests that traffickers may use pregnancy and children (e.g., threats of forced abortion, threats to take away children, threats to cut off financial support) to exert and maintain control over their mothers.[14,18,48,52]

Little is known about the experiences of trafficked women's children in the United States. An exploratory study in 2016 found that children of sex workers or trafficked mothers experience significant health risks and outcomes, including behavioral and mental health problems, physical and sexual abuse, the use of cough medicine, alcohol, and other sedating substances to induce sleep, death from a wide range of causes including neglect (e.g., exposure after being left in a car, house fire after being left home), untreated HIV, poisoning, overdose, lethal physical abuse (e.g., abusive head trauma, previously *shaken baby syndrome*), and gang-related murder.[48]

SPECIFIC ISSUES

Recognition and Assessment

Indicators and Red Flags

While indicators and red flags of trafficking can assist in the recognition of possible trafficking, there is no single characteristic that is pathognomonic of human trafficking. Although there are certain segments of the population at higher risk for trafficking, the overall sociodemographic characteristics of trafficked persons are wide-ranging, and no two experiences of trafficking are exactly alike.

Currently there is no defined set of signs and symptoms that cuts across all forms of human trafficking with any sufficient degree of sensitivity and specificity to employ for the identification of victims in the ED. Familiarity with general indicators of abuse and control and the red flags of human trafficking can help elevate a suspicious situation into the level of awareness (Table 187.1).

Indicators of abuse and control can include the presence of an accompanying person who is reluctant to leave the examination room, insists on answering questions or providing language interpretation, and attempts to control the encounter; combined with a patient who appears fearful or anxious, defers information sharing to the person accompanying them, and frequently glances at the accompanying person for evidence of approval after speaking.[35,36,53] Other potential indicators include patient communications that seem rehearsed or scripted, patient reluctance or inability to answer simple questions about their living or working situation, conflicting information, reported mechanism of injury inconsistent with the physical evidence, and evidence of psychological distress (e.g., limited eye contact, low trigger threshold, hypervigilance, hyperstartle reflex).[36,53]

Physical red flags of human trafficking include delayed presentation for care of injuries or infections; signs of abuse or neglect (e.g., malnourishment, poor oral health); work injuries or exposures that would be easily prevented by personal protective equipment (PPE); intravaginal foreign material to interrupt menstrual flow; delayed presentations for prenatal care; distinctive tattoos or other forms of branding; and multiple STIs, pregnancies, or abortions.[35,36]

Psychosocial red flags of human trafficking include a reluctance to expose or explain a tattoo or marking; unusually high numbers of sexual partners at an early age; truancy and absenteeism from school at certain hours of the day; chronic running away from home; multiple fake forms of identification; lack of identification or immigration documents; long work hours without breaks; limited access to PPE; living in overcrowded quarters; and weather-inappropriate clothing.[36,53]

Trafficking Inquiry

While it is routine in medical care for multiple providers to ask a patient their history, retelling of a traumatic event can be inherently retraumatizing. Concerted efforts to minimize the number of times a patient recounts their history can be conducive towards a feeling of safety. Furthermore, when there is concern for trafficking, the goal of a clinical encounter is not for the patient to disclose victimization, but for providers to treat, educate, and empower the patient.

Inquiry around forms of interpersonal violence, including trafficking, is fundamentally different from screening for medical issues. Rather than disclosure, the goal of inquiry is to provide a safe environment in which patients feel empowered to share as much or as little as they choose, and where their strengths and resilience are recognized. Inquiry-based assessment is an active process that includes open-ended questions and dialogue.[54] The context around which questions are asked, especially for issues where a trafficked patient may feel emotionally and physically unsafe (due to shame, judgment, threats of deportation, etc.) modulate how much a patient may feel comfortable

TABLE 187.1 Potential Trafficking Indicators and Red Flags

Physical	Relational	Other
• Delayed presentations to care • Signs of physical, sexual, or dental trauma • Signs of neglect • Signs of malnourishment • Substance use • Multiple recurrent STIs • Foreign bodies to stop menstrual flow • Multiple previous pregnancies • Work injuries preventable with training and/or personal protective equipment • Tattoos or branding indicating ownership	• Accompanied by a person who attempts to control the encounter • Accompanied by a person who insists on translating • Scripted or restricted patient communications • Patient frequently glances to the accompanying person for approval after speaking • Patient avoids eye contact with accompanying person and/or provider • Other signs of submission, fear, or hypervigilance • Distrust of authority	• Difficulty answering simple questions (e.g., name, age, home address, work, current location) • Apparent vs. reported age discrepancy • Discrepancy between history and clinical presentation • Possession of multiple fake IDs or numerous hotel keys • Inappropriate clothing for weather • Truancy or absenteeism from school at certain times of day • Not in possession of identification or immigration documents • Excessive work hours • Possession of large sums of cash or payment in cash

Revised/adapted from Macias-Konstantopoulos W. Human trafficking: the role of medicine in interrupting the cycle of abuse and violence. *Annals of Internal Medicine*. 2016;165(8):582-8.

disclosing at a given point in time.[55] In contrast to inquiry, screening is a "process for evaluating the possible presence of a particular problem" and "the outcome is normally a simple yes or no."[56] Screening for trafficking through a checklist approach may unintentionally retraumatize the patient by triggering the patient's traumatic memories.[57] The only trafficking screening tool that has been validated for use in the pediatric ED is limited to English-speaking 13- to 17-year-olds who have been sex trafficked.[58] The Rapid Appraisal for Trafficking (RAFT) is a validated 4-item trafficking screening tool for labor and sex trafficking of adults in the ED.[58a]

Although evidence exists to support universal inquiry in domestic violence, the extant trafficking literature offers no evidence in support of this. Based on current evidence, trafficking inquiry may be focused on high-risk populations and patients exhibiting red flags. That inquiry may follow trauma-informed frameworks, such as the Privacy, Educate, Ask, Respect, Respond (PEARR) tool.[54] It should be noted that perception of red flags may be influenced by a provider's unconscious and conscious bias.[59] For example, if a clinician views trafficked persons as Caucasian, cis-gendered, and sex trafficked, they may miss an obvious case involving a labor trafficked Black transgender male patient who presents to their ED.[59a]

Use of Professional Interpreters

If the patient speaks a foreign language, emergency providers should use professional interpreter services. Accompanying persons (e.g., friends, relatives including children, or others) may unintentionally compromise confidentiality and even be a trafficker or trafficker's associate. Remote telephone interpretation services may be preferred in certain circumstances including if a potential trafficked person is from a small ethnic group where the interpreter's ties to the local community could pose a risk for a trafficked person.[60]

Evaluation and Treatment

The ED care of a trafficked person involves providing appropriate emergency medical care for the chief complaint, while respecting the patient's goals for the encounter. ED evaluation may include addressing acute medical issues, evaluation of possible untreated chronic medical problems, documentation of acute and remote injuries, STI testing and treatment, and consideration of a sexual assault medical forensic examination and evidence collection. For both labor and sex trafficking, empirical STI treatment and emergency contraception may be indicated.[60]

When a case of suspected human trafficking has been identified, a sexual assault medical forensic examination may be clinically appropriate. Research shows that the use of sexual assault or forensic nurse examiners results in better patient outcomes in legal and emotional support. To the extent that the resource is available, EDs may preferentially offer this service or consider transfer to a crisis center.[60]

Trauma-Informed Approach to Care

Studies of trafficked persons have demonstrated the critical importance of using trauma-informed approaches to care.[59,61] The Substance Abuse and Mental Health Services Administration (SAMHSA) defines trauma as "an event, series of events, or set of circumstances that is experienced by an individual as physically or emotionally harmful or life threatening and has lasting adverse effects on the individual's functioning and mental, physical, social, emotional, or spiritual well-being."[62] Trauma results in neurobiologic changes such that commonly occurring smells, sounds, sights, and procedures of the ED environment may be perceived as threats by those with trauma histories, including trafficked persons. For example, a patient who appears to be uncooperative, avoidant, jumpy, or agitated, may instead be manifesting a natural "fight," "flight," or "freeze" stress reaction.[63]

Sincere, empathetic, nonjudgmental communication is the foundation of trauma-informed care. This includes clinician awareness and mitigation of conscious and unconscious biases, including their manifestation in body language and word choice, in order to prevent retraumatization of trafficked persons.[59,63,64] Loss of control is a major part of the trafficking experience and the medical environment can exacerbate those feelings. Therefore, emergency clinicians should look for and offer choices when possible, helping the patient regain a sense of autonomy. Clear communication about the clinical team composition, the care plan, events to expect, and possible timeline, allows a trafficked patient to feel a sense of control.[59,63,64]

Helping a traumatized patient to feel safe and calm includes a mindfulness of a patient's stress reactions, including demeanor, speech, and even pulse rate. When these reactions are observed, clinicians may respond using psychological first-aid techniques of connectedness, calmness, safety, structure, self-efficacy, and hope (Fig. 187.2).[63] Potentially triggering environmental factors could include the visibility of security guards who may remind the patient of prior traumatizing law enforcement experiences. Trauma-informed approaches are especially important for the agitated patient with an experience of trauma. Beginning with de-escalation and psychological first-aid techniques can mitigate retraumatization and should be balanced with staff safety concerns. If restraints are necessary for the safety of the patient and staff, use of the least restrictive measures possible is recommended.[63]

The Privacy, Educate, Ask, Respect, and Respond (PEARR) tool provides a trauma-informed framework for the clinician assessing any form of interpersonal violence, including human trafficking.[54] The first step of the PEARR tool is to find a place to speak to a patient alone, explaining any limits to confidentiality with the patient before beginning this sensitive discussion. The clinician attempts to educate the patient regarding abuse, neglect, or violence in a nonjudgmental and normalized manner, and then asks about the patient's personal experience. The patient may or may not disclose their exploitation experience at this point in time. The final step involves ongoing respect of the patient's wishes and responding according to their goals. It is common for patients experiencing interpersonal violence, including trafficking, to choose to return to their exploiter. If a patient denies victimization or declines assistance, and there are persistent concerns about abuse, neglect, or violence, then the clinician may offer the patient information about resources that can assist in the event of an emergency (e.g., local service providers, crisis hotlines).

Multidisciplinary Response

Establishing multidisciplinary protocols inclusive of labor and sex trafficking and involving internal and external resources allows clinicians to respond to a trafficking disclosure in a safe, trauma-informed manner. In addition to a myriad of acute and chronic medical and mental health needs, trafficked persons may also require assistance with substance use treatment, housing, vocational, and legal needs. Response protocols will vary considerably based on a clinical practice setting. The majority of health care institutions already have protocols in place that address various forms of violence including intimate partner violence, child abuse, elder abuse, and sexual assault. Human trafficking responses may be incorporated into existing interpersonal violence protocols to streamline training, treatment, and referral processes.[60,65,66]

Breaches of privacy may harm the provider-patient relationship, compromise patient autonomy, and produce distrust among other trafficked persons. Therefore, EDs and health care institutions may consider establishing memorandums of understanding with external partners, including limitations of HIPAA, and need for patient consent for information sharing. If case management is not available, the patient may

Goals	Useful statements or actions
Connectedness	Assign a single team member to be the primary source of communication with the patient: "I am going to stay and help you with everything you go through here." For pediatric patients, if feasible, allow parental presence and support.
Calmness	Minimize presence of non-participatory members of the care team. Avoid excess noise/chatter. Encourage the patient to perform slow breathing exercises.
Safety	Provide patient a simple reminder that he or she has been removed from the site of injury: "You are in the safest place you could be right now."
Self-efficacy	Discuss care plan with patient to diminish sense of loss of control. Use language that acknowledges rather than undermines the patient's defense mechanisms; for example, "You are going through a tough situation" rather than "Tough it out." If feasible, allow patients to provide input into decisions about care. Identify resources (e.g., case management, community organizations) that can facilitate
Hope	Avoid statements that may exacerbate patient feelings of self-blame. Provide realistic statements of expected positive outcomes: "It will not be easy or fast, but I expect you will recover from your injuries."

Fig. 187.2 Statement or action examples grounded in psychological first-aid principles. (Adapted from: Fischer KR, Bakes KM, Corbin TJ, Fein JA, Harris EJ, James TL, Melzer-Lange MD. Trauma-informed care for violently injured patients in the emergency department. *Annals Emerg Med*. 2019 Feb 1;73(2):193-202.)

be encouraged to contact a local or statewide hotline or the National Human Trafficking Hotline to learn more about available resources.[60]

DISPOSITION

Admission versus Discharge

As with all admissions, the decision to admit a trafficked person should be made in a clinically grounded, patient-centered manner. The reason for admission may be medical; in some cases, health facilities may permit a "social" observation admission in order to carry out complex case management to facilitate a trafficked person's exit from exploitation. As with intimate partner violence, not all trafficked persons recognize or are ready to leave their exploitative situation. This happens for a variety of reasons, including fear of retribution, fear of endangering loved ones, threats of police or immigration involvement, blackmail, as well as trauma bonds. Clinicians may consider utilizing motivational interviewing techniques based on the Stages of Change model to engage the patient and provide support in the decision-making process (Box 187.2). Ultimately, trafficked persons are most knowledgeable about the potential risks involved with seeking help or beginning the process of leaving the trafficking situation and respecting their wishes aligns with trauma-informed care principles.[60]

Safety Planning

Trafficked persons may return to exploitative situations repeatedly before exiting permanently. Involving social workers, case managers, and advocates early in suspected cases of human trafficking helps facilitate safety planning for a patient who is not ready to commit to leaving. Safety planning involves assessing for potential future health risks and identifying strategies for avoiding or reducing the threat of harm when safety is threatened. Safety planning facilitates a sense of trust and safety with the health system and encourages patients to return when ready to access services or for further medical care.

Safety planning varies greatly depending on how the patient views their trafficking situation and whether the patient wants to stay in the situation, is in the process of leaving, or has left.

BOX 187.2 Stages of Change

Stage 1: Precontemplation—Feeling there is no control of your situation
Stage 2: Contemplation—Wondering if there might be a way of managing your situation
Stage 3: Preparation—Researching and planning ways to manage your situation
Stage 4: Action—Taking steps to manage your situation
Stage 5: Maintenance—Continuing positive steps and learning new strategies to maintain your new situation

Important determinants in assessing risk include the patient's level of fear and his or her own appraisal of both immediate and future safety needs. The following indicators of escalating lethality risk may be explored with the patient: an increase in the frequency or severity of threats or assaults; increasing or new threats of homicide or suicide by the trafficker if the patient discloses; the presence or availability of a firearm or other lethal weapon; and new or increasingly violent behavior by the perpetrator, including strangulation.[68]

Resources

A follow-up appointment can be a helpful component of safety planning for trafficked persons. This can take a variety of forms, depending on institutional resources, including arranging for an outreach worker (public health nurse or community health worker) to make a follow-up visit or returning to see the ED social worker. The means of conveying post-discharge resources will vary based on the patient's situation; clinicians may consider providing resources verbally to patients or through discrete messaging, while the patient is alone. Examples of discrete resource sharing include writing the human trafficking hotline number on a business card or on a sanitary napkin. Many patients will not be able to leave with written information because their belongings are monitored.

Resources to consider sharing with potential victims of trafficking include information about the National Human Trafficking Hotline which can be accessed 24/7 by texting "INFO" or "HELP" to BEFREE

(233733) or calling 1-888-373-7888 for information or help, though patients should be reminded that smartphones provided to them by the exploiter may be monitored. Other potentially helpful resources include a health system contact number to call or text if the patient wants further assistance; a referral and resource list from community partners for such needs as food, clothing, shelter, housing, social services, and legal services; and an address of local police departments should patients find themselves in imminent danger. Confirming with patients that it is safe for them to take such material with them can signal to patients that the clinician understands the potential gravity of their circumstances. The clinician may discuss with the patient the safest way to communicate with them and carefully consider whether it is safe to contact the patient for follow-up.

Some patients may be unwilling or unable to return for ongoing or follow-up care. For this reason, on discharge the clinician could consider explicitly reassuring patients that they deserve to be safe and free from abuse, that they are not to blame for their circumstance, and that the health care system is "always open" as a source of safe, confidential, and supportive care.[60]

SPECIAL CONSIDERATIONS

Mandatory Reporting

Notably, many human trafficking situations do not fall under mandated reporting requirements. Depending on the state, there may be components of a trafficked person's experience that fall under mandatory reporting laws for abuse of children, disabled adults, and elders; injuries resulting from burns, firearms, or knives; or threats of imminent harm to oneself or another. In certain states, mandatory reporting of sexual assault, domestic violence, or strangulation may come into play. These reporting requirements should be built into institutional human trafficking protocols. Mandated reporting can be executed in a trauma-informed manner, including explaining limits of confidentiality prior to a patient's disclosure, and if a disclosure is made, explaining why reporting is necessary, soliciting patient input into what information will be given to authorities and offering to have the patient present for the conveying of information.[60]

Medical Record Documentation

Because of the complexity of medical-legal issues around human trafficking cases, and great variation in state and local laws, institutions may consider consulting with local prosecutors, defense attorneys, and advocates, particularly those with expertise in privacy and rape shield laws when establishing documentation guidelines.

Depending on the legal climate, entering more or less information in the patient's chart can either be helpful or harmful. In some cases, accurate documentation can potentially substitute for, or supplement, the clinician's personal testimony in court. Alternatively, information in the medical record can potentially be harmful to the patient when the case goes to trial (e.g., if a trafficked person contracts HIV, in some states they could be criminalized for the transmission of HIV). In many jurisdictions, crimes committed by trafficked persons while under the control of their trafficker will be prosecuted (e.g., a patient coerced to sell sex may still be charged with prostitution). Sensitive information in the medical record may or may not be redacted during a court hearing or trial depending on whether the state has a rape shield law, and if that state has determined that the rape shield law applies to trafficking victims. It may be difficult to balance the need for inclusive information with medico-legal discretion. For example, obtaining information about prior injuries, consensual sex, number of partners, and STIs may influence the clinician's work-up, examination, and the anticipatory guidance, but documentation of these data may be used against the patient in certain legal circumstances.[60]

Inclusion of victim quotes in the medical record is often advised in cases of injury or sexual assault, but such details about a victim's story may not be helpful should they change their account later, which is a common phenomenon when someone has experienced trauma. Keeping the documentation of history simple can prevent insignificant points from becoming a disputed fact in a legal case. Similar to cases of sexual assault, careful documentation of the physical examination includes signs of abuse such as old scars, surgical incisions, birthmarks, skin lesions, tattoos, and piercings.[60]

Diagnostic Codification

The International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10-CM) released the first ever trafficking-specific abuse codes in October 2018 developed through a partnership between the American Hospital Association, Catholic Health Initiatives, and Massachusetts General Hospital.[69] Inclusion of one of these 29 ICD-10 abuse codes for forced labor and sexual exploitation, when appropriate and relevant as a finding, diagnosis, or problem, may help strengthen data collection on human trafficking in the health care system and inform the allocation of resources and future development of services equipped to respond to the needs of trafficking victims and survivors. Care must be taken to ensure that the use of these codes does not stigmatize or cause harm to already traumatized survivors.[69a]

Law Enforcement Considerations

Many trafficked persons have a negative or fearful perception of law enforcement (LE) officials because of previous arrests, fear of arrest or deportation, or abuses imposed by authority figures, so a thoughtful approach to law enforcement engagement with suspected human trafficking cases is advised. Law enforcement involvement should be limited to patient request, in state-specific mandated reporting scenarios that require LE involvement, or when clinicians appreciate imminent danger to staff or the patient.[60] In cases where LE involvement is mandated by law, trust and rapport can be safeguarded by ensuring a transparent, predictable, and non-retraumatizing process. It is not advisable, however, for providers to promise safety.

Barriers to Identification and Care

Trafficked persons generally do not self-identify as victims of human trafficking. In some cases, trafficked persons may not recognize their victimization, especially when cultural practices or beliefs cast a sense of normalcy on their circumstances (e.g., gender inequality, domestic violence, sex work).[14,25,70] In other cases, the victim narrative may not resonate with trafficked persons due to its failure to accurately capture their experience of and relationship to their trafficker, particularly when emotional or romantic bonds exist (e.g., parent, family member, boyfriend).[70] Still, in other cases, a trafficked person may outright reject the label of victim, opting instead for more empowering interpretations of their trafficking experiences.[70] Nevertheless, even when the trafficked person is acutely aware of their victimization and desires assistance, disclosure and engagement in care is hampered by shame, fear of physical retaliation, fear of harm to loved ones, fear of immigration authorities, and fear of police if compelled to commit crimes as part of their exploitation (e.g., shoplifting, drug selling, peer recruitment into trafficking).[14,17,53,71]

A recent systematic review on health care access barriers found that extrinsic, intrinsic, and structural barriers contribute to the reluctance among trafficked youth to access care.[72] Barriers identified included trafficker control, physical confinement, diminished trust in health care providers, concerns over discrimination, lack of confidentiality, language barriers, and complex registration process.[72] Similarly, a mixed-methods study identified three distinct profiles of survivor

Key element	Preparedness actions
Multidisciplinary teams	Identify champions among the key stakeholders whose discipline, expertise, local knowledge of the problem, and community partnership will enhance preparedness and response (e.g., medical, nursing, mental health, social work, child protection, forensic examiners, legal counsel, security, risk management).
Institutional policy	Adopt an institutional policy that is survivor-centered, based on available evidence or "promising practices," and in accordance with applicable state mandatory reporting laws.
Resources compendium	Create and maintain an up-to-date database of hospital and community resources available to address the varying needs of trafficking survivors.
Network partnerships	Partner with law enforcement, government agencies, social service organizations, hospital-based services, and other community stakeholders to determine best practices for collaboration and referrals, and more effectively serve survivors.
Response protocol	Develop a stepwise algorithm that leverages interdisciplinary teams, promotes a trauma-informed care approach, and accounts for the unique needs of adults and children when responding to the disclosure or identification of a trafficked patient.
Knowledge, training, and quality & safety	Establish mechanisms for knowledge dissemination (i.e., human trafficking and trauma-informed care education), response protocol implementation training, monitoring and evaluation of response incidents, evaluation of quality and safety gaps and opportunities, and protocol revisions when needed and appropriate.

Fig. 187.3 Health care preparedness: framework for developing human trafficking response protocols. (Adapted from: Macias-Konstantopoulos W. Human trafficking: the role of medicine in interrupting the cycle of abuse and violence. *Annals Internal Med.* 2016;165(8):582-588.)

experiences and engagement with health care: avoidant, distrustful, and constrained. Common across the three profiles was a feeling of disenfranchisement that contributed to decreased care access behaviors.[73] Trauma-informed, culturally sensitive, and survivor-centered care practices may mitigate this sense of disenfranchisement by minimizing retraumatization, fostering psycho emotional safety and well-being, and empowering survivors in their recovery.[73]

Studies have established that the ED is a significant health care access point for trafficked persons.[74] Identification is central to a more comprehensive and effective health care response for this patient population. One of the most consequential barriers to identification and care is the lack of formal human trafficking curricula in education and training which reinforces an underappreciation of its relevance to clinical practice, perpetuates a gap in knowledge and skill, and leads to preconceived biases about who victims are and what they look like. Other barriers include failure to establish trust, interview the patient alone, use professional interpreters, recognize red flags, and carry out more in-depth assessments.[17,53] This gap in knowledge and skill not only places the emergency practitioner at a disadvantage in caring for trafficking survivors, but also may place the trafficked patient at greater risk of harm if the provider proceeds with the evaluation and response in a manner that is unsafe, no matter how well-intentioned. A focus on education and training has been growing in the last decade.[36,75-80]

Similarly, there has been increased advocacy for clinical guidelines and protocols that guide a safe, effective, and comprehensive response, including the need for trauma-informed care, patient privacy, professional interpreters, mandatory reporting when appropriate (e.g., children), and referrals to national and local community resources for unmet needs.[53,80] Existing protocols for identifying and assisting trafficking patients in hospitals across the United States vary widely.[62] A "health care preparedness" framework for the development of response protocols proposes six main elements: interdisciplinary teams, survivor-centered institutional policy based on evidence or promising practices, collaborations and partnerships with community resources and cross-sector agencies, a stepwise trauma-informed response algorithm, and a plan for provider education/training and quality assurance of response protocols (Fig. 187.3).[53]

The ED visit represents a critical opportunity for trafficked persons to receive assistance and a potentially life-altering intervention. Through universal adoption of trauma-informed principles, labor and sex trafficking education, and development of multidisciplinary policies and procedures, emergency clinicians can positively impact the lives and health of trafficked patients.

CHAPTER 187: QUESTIONS AND ANSWERS

1. Which of the following statements regarding human trafficking inquiry is true?
   - **a.** It is imperative that trafficked victims recount their history as often as possible to ensure consistency and to support law enforcement in the investigation of trafficking networks.
   - **b.** The primary goal of inquiry is disclosure.
   - **c.** Inquiry is a series of protocol-based standard questions designed to efficiently obtain information from traumatized victims.
   - **d.** The goal of inquiry is to provide a safe environment for patients to share as much or as little as they choose.

Answer: D. Rather than disclosure, the goal of inquiry is to provide a safe environment in which patients feel empowered to share as much or as little as they choose where strengths and resilience are recognized. Inquiry-based assessment is an active process that includes open-ended questions and dialogue.

2. Which of the following statements regarding health impacts on trafficked victims is false?
   - **a.** Traffickers employ abusive tactics that can cause physical, reproductive, and mental health problems.
   - **b.** Schizophrenia is not a diagnosis commonly associated with the psychological and psychiatric sequelae of victims of trafficking.
   - **c.** Commonly occurring smells, sounds, sights, and procedures in the emergency department may be perceived as threats by trafficking victims who have experienced trauma but is not caused by neurobiologic changes.
   - **d.** Substance abuse and drug use rates are common in trafficked victims under 18 years of age.

Answer : C. Trauma due to trafficking results in neurobiologic changes such that commonly occurring smells, sounds, sights, and procedures of the emergency department environment may be perceived as threats by those with trauma histories.

3. Which of the following statements regarding the indicators and red flags used to identify victims of trafficking in the ED are true?
   - **a.** Hypervigilance and hyperstartle reflexes are pathognomonic of human trafficking.
   - **b.** Accompanying individuals who are reluctant to leave the room, insist on answering questions or attempting to control encounters, or communications that may seem rehearsed may all be indicators that a victim is being trafficked.
   - **c.** Physical red flags of human trafficking often include immediate presentation for care for easily preventable injuries.
   - **d.** Evidence of psychological distress including limited eye contact, low trigger threshold, hypervigilance, and hyperstartle reflex are uncommon presenting characteristics of trafficked victims and are not reliable enough indicators in emergency departments to raise suspicion.

Answer: B. There is no single characteristic that is pathognomonic of human trafficking. Physical red flags of human trafficking include delayed presentation for care of injuries or infections; signs of abuse or neglect (e.g., malnourishment, poor oral health); work injuries or exposures that would be easily prevented by personal protective equipment (PPE). Other potential indicators include patient communications that seem rehearsed or scripted, patient reluctance or inability to answer simple questions about their living or working situation, conflicting information, reported mechanism of injury inconsistent with the physical evidence, and evidence of psychological distress (e.g., limited eye contact, low trigger threshold, hypervigilance, hyperstartle reflex).

4. Which of the following statements regarding the evaluation and treatment of trafficked victims is true?
   - **a.** Empiric STI treatment and emergency contraception is indicated only for sex trafficked victims and not labor trafficked victims.
   - **b.** Emergency department evaluation should include addressing acute medical issues and focus on forensic examination but should exclude the evaluation of chronic medical conditions.
   - **c.** Law enforcement involvement should be limited to patient request or when clinicians appreciate imminent danger to staff or patients.
   - **d.** When a suspected human trafficking case is identified, forensic examination should be performed by the original provider because including a sexual assault examination by forensic nurse examiners can worsen victim traumatization.

Answer: C. For both labor and sex trafficking, empirical STI treatment and emergency contraception may be indicated. ED evaluation may include addressing acute medical issues, evaluation of possible untreated chronic medical problems, documentation of acute and remote injuries, and STI testing and treatment, and consideration of a sexual assault medical forensic examination and evidence collection. Research shows that the use of sexual assault/forensics nurse examiners results in better patient outcomes in legal and emotional support.

5. Which of the following statements regarding the trauma-informed care of trafficking victims is false?
   - **a.** Mitigation of conscious and unconscious biases is important in contributing to the traumatization of trafficked victims.
   - **b.** Preventing retraumatization is an essential feature of trauma-informed care in the emergency department.
   - **c.** The PEARR Tool provides a trauma-informed framework for emergency clinician assessment but is only validated for victims of human trafficking.
   - **d.** If a patient denies victimization or declines assistance, the clinician may offer information about resources that can assist in the event of an emergency.

Answer: C. The Privacy, Educate, Ask, Respect, and Respond (PEARR) tool provides a trauma-informed framework for the emergency clinician assessing for any form of interpersonal violence, including human trafficking.

Sexual Minority Populations (LGBTQ)

Joel Moll and Carolyn Kluwe Holland

KEY CONCEPTS

- Sexual orientation, gender identity, and gender expression occur along a continuum and may be completely separate and discordant from one another.
- Multiple health disparities exist in sexual minority populations, but many of the contributing factors are likely unknown due to lack of studies.
- ED provider education about sexual minorities is often inadequate, limited, or absent.
- Transgender individuals may utilize a variety of medical and surgical interventions in their transition to affirm their gender identity. Emergency clinicians should be aware of complications related to these practices that may require treatment in the ED.
- Sexual minority patients at extremes of age, or who share another minority identity, have additional disparities that require consideration to deliver equitable and safe care.
- Open, inclusive, and nonjudgmental patient-centered communication using appropriate terminology is fundamental to fostering provider trust and minimizing health disparities in sexual minorities.

FOUNDATIONS

Background and Importance

Sexual minority individuals cross every demographic, and multiple cultural and societal influences can affect their visibility and disclosure of sexual and gender identity. They represent a diverse continuum of individuals without a strict heterosexual identity (lesbian, gay, bisexual. queer, or questioning [LGBTQ]) and include those whose gender identity is different or fluid from their sex-based gender assigned at birth. Although sexual minorities share many similarities, there are also key differences. There is a wide range of perceptions on the prevalence of sexual minorities in the United States (US). This reflects societal bias, lack of research, and barriers to disclosing or collecting data regarding an individual's sexual and gender identities. One recent estimate is that 4.5% or 11 million Americans identify as a sexual minority,[1] and at least 0.6% or 1.4 million identify as transgender.[2,3] Importantly, sexual and gender identities should be considered separate from sexual behavior. It is estimated that 8.7% of women and 8.2% of men have had same-sex sexual behavior.[4]

Terminology and Concepts

To create a welcome and inclusive environment for sexual minorities, health care providers should be familiar with culturally competent terminology to better communicate and avoid unintentional offense (Table 188.1). Providers should avoid terms associated with bias or prejudice. Terms like "homosexual" or "sexual preference" may be common in language, but have stigma when used in the sexual minority community. The use of the word "homosexual" is associated with past bias and discrimination; therefore preferred terms include lesbian, gay, or bisexual. Similarly, because there is no legitimate evidence that sexual orientation is a choice, the term "sexual preference" should not be used. Patients should be asked about their partner(s) in gender neutral terms without assuming that they are in a heterosexual relationship. Asking open-ended questions will signal being receptive to patients not in traditional heterosexual relationships or gender identities. When in doubt, ask the patient for their preferred terms, or allow them to define their relationships.

Historical Context

Same-sex relationships and transgender identity have existed throughout recorded history, although societal acceptance and tolerance has varied over time. Laws and attitudes against same-sex sexual behavior were common in the United States, which adversely influenced attitudes of health care providers and isolated sexual minorities from medical care. Despite recent increased acceptance of sexual minorities, past actions and discrimination can still be a powerful barrier to equitable care. Although the majority of Americans support sexual minority rights,[5] it is far from universal, and continued implicit and explicit bias along with outright discrimination and refusal of care still exist. Basic health care rights and choices assumed by the majority are often not afforded to sexual minorities, or are incomplete. Some forms of discrimination, including employment discrimination, are still legal in many states, making patient-provider trust and confidentiality of substantial importance to the sexual minority patient. Emergency care providers should be prepared to assure LGBTQ patients of laws protecting their medical records from disclosure.

Identity

Sexual minorities undergo a deeply personal process of accepting their sexual orientation or gender identity and then disclosing it to the outside world, known as "coming out." This process should occur on the patient's own terms and timeline. Since many individuals who engage in same-sex behaviors may never identify themselves as a sexual minority for a variety of reasons, clinicians should inquire about specific sexual activity and not just sexual orientation or identity when it is pertinent to their clinical presentation.

Legal identity and the patient's gender identity may be discordant for transgender patients, leading to confusion and discomfort. If the patient's insurance uses their gender assigned at birth, their preferred name and gender may not appear in many electronic health records (EHRs), and services and prescriptions using their preferred name and gender may not be covered. Few transgender people have all of their identification materials with their preferred name and gender, and for 68% none of their identification reflects their preferred name and gender, financial costs being one of the largest barriers to acquiring updated identification.[6] Creating an inclusive environment

TABLE 188.1 Terms and Definitions for Sexual Minorities

	Term	Definition
General Terms	Sexual Minority	Term for the diverse group of people whose sexual orientation and gender identity fall on a spectrum outside of strictly heterosexual and/or their gender identity of sex at birth
	Sex	Biologically male or female
	Gender	Psychological, behavioral, and cultural characteristics of being male or female
	Queer	Overarching term for sexual minorities
	Questioning	Person unsure of sexual and/or gender identities
Sexual Attraction	Gay	Man or woman who identifies as someone with sexual attraction to the same sex
	Lesbian	Woman who identifies as someone with sexual attraction to the same sex
	Bisexual	Man or woman who identifies as someone with sexual attraction to both men and women. This attraction may be more female or male.
	Sexually Fluid	Identity is not fixed as purely opposite or same-sex attraction
Gender	Gender Identity	Identity along a spectrum from female to male
	Gender Expression	Expressions and behavior of traits traditionally associated with women or men
	Cisgender	Gender identity is similar to identity associated with sex at birth
	Transgender, Trans, or Gender Nonconforming	Gender identity is different or opposite of identity associated with sex at birth
	Gender Affirming	Behaviors or interventions to affirm gender identity
	Transitioning	Undergoing interventions to affirm gender identity different from gender associated with sex at birth

without assumptions or judgment about identity will best promote an honest and trusting dialogue that will enhance health decisions and care.

SPECIFIC ISSUES

Factors Affecting Equitable Care

Legal Barriers

Legal issues can affect sexual minority patients' care in unique ways. Prior to marriage equality, many same-sex couples completed legal documents to provide some of the rights automatically provided by marriage. These issues include medical decision making and hospital visitation rights. Despite these documents, the wishes of patients were not always respected by hospitals, courts, or families. In 2010, the Department of Health and Human Services prohibited hospitals that participate in Medicare or Medicaid from denying visitation on the basis of race, color, national origin, religion, sex, sexual orientation, gender identity, or disability.[7] Marriage equality in 2015 provided the opportunity for stronger and automatic protections previously denied to same-sex couples; however, only 50% of same-sex couples' households are legally married compared to over 90% of heterosexual households[8,9] Same-sex spouses in the ED should be given the same level of access to health care information, decision making, and visitation as married heterosexual couples without having to provide a marriage certificate to prove their relationship status. Additionally, unmarried same-sex couples who have completed legally structured powers-of-attorney for health care and finance should have those documents respected and followed to the fullest extent of local and state laws.

Sexual Minority Parental Barriers

Up to 3.7 million children under 18 years old have an LGBTQ parent, with 200,000 being raised by same-sex couples. This represents approximately 16% of all same-sex couples (8% of male and 24% of female same-sex couples), while almost 40% of heterosexual coupled households have children.[10] These same-sex couples with children are far more likely to have an adopted child (20%) or foster child (3%) than majority couples (3%, 0.4% respectively).[8]

Legal recognition of parenthood is currently derived from marriage, adoption, or biology. Even with marriage equality, not all states recognize the same rights of parenthood to nonbiological parents. The legal recognition of nonbiological married same-sex parents varies state by state, and there are no requirements for a different state to recognize a legal tie between parent and child granted elsewhere. Additionally, some states will allow a single LGBTQ person to adopt a child, but will not allow the second parent to also be named as a legal guardian. This can leave same-sex parents in a precarious position when trying to access health care for their children.[11] Until there are consistent standards that provide clear legal status to nonbiological same-sex parents, health care providers need to be aware of and follow their local laws as they relate to consent for procedures and treatments.

In additional to lack of standardized legal recognition of nonbiological parents of children born to same-sex couples, there are other barriers to obtaining health care for these families. On arrival to the emergency department (ED), registration forms and the EHR often are not structured to accommodate same-sex couples. Typically, there are data fields to document a mother or father, but not two mothers or two fathers. This may keep providers from having accurate information about a child's family structure, and may put one parent in the position of not having decision-making authority concerning the child's medical care.[12] Heteronormative assumptions about adults accompanying a child in the ED may cause a provider to not recognize that a full family is present by assuming that the second adult is a nonparent relative or family friend.[12] Nonbiological parents may fear their lack of genetic ties to the child could cause them to be inappropriately ineligible to make health decisions for their child.[13] By focusing on a child's genetic parentage and not the legal and emotional relationships that make a family, nonbiological parents from same-sex couples feel a lack of respect for their family which can act as a barrier to full and candid communication between providers and parents.

Remedies to these described barriers include the development of cultural competency in the health care team and adaptation of the EHR and paper forms to accommodate all family structures and parent roles. Cuing from the EHR about unique family structures can alert providers to be mindful of how and to whom questions are asked about

the child, and assist in the collection of relevant information without inadvertently offending parents.

Barriers to Health Care Access

Sexual minority patients have less access to health care than their majority counterparts. They are less likely to have health insurance and more likely to live in poverty. Patients may fear sensitive information being disclosed to their employer, and if they have insurance, it may not cover gender affirming treatment. These factors can lead to delays in medical diagnosis and treatment. A quarter of transgender patients experience health insurance–related problems, including being denied coverage for nonemergent care due to their transgender status.[6] One in ten transgender people report having access to a bathroom denied to them, and may experience verbal harassment and even physical or sexual assault when accessing a restroom.[6] A third of transgender people have limited their fluid intake to avoid public restrooms, resulting in 8% reporting urinary tract infections due to avoidance and holding urine.[6]

Health Care Experience

Many sexual minorities report negative experiences in navigating the health care system, especially among the transgender population, leading to avoidance and delay of care.[14,15] In a small survey of transgender individuals in Ontario, Canada, half felt that presenting as their stated gender had prompted negative experiences in the ED, leading 21% to avoid visiting an ED in the future.[15] This was also demonstrated in the 2015 US Transgender Survey where 33% had at least one negative experience related to their transgender status, and 23% reported avoiding needed health care.[6,16] Issues include: being "misgendered" even after disclosing their gender identity; lack of provider knowledge about transgender health, including hormone effects; unnecessary questions about gender-related surgeries for unrelated chief complaints; and a persistent focus on genital examinations.[17,18] In the San Francisco area, where LGBTQ individuals are more visible than in many other regions, most practicing nurses had very little understanding of gender-related terminology, and many health care organizations did not have inclusive forms or standard language to discuss transgender patient issues.[2] However, despite these experiences, for some sexual minorities the anonymity of the ED may be preferred over their primary care physician, who may not be aware of their sexual behaviors or gender identity. Limited research suggests increased ED utilization among some sexual minorities compared to their majority counterparts.[19,20] Because the majority of these patients are in relationships, partners should be included in health discussions if desired by the patient.

Provider Education

A significant number of sexual minority patients do not disclose their sexual orientation, same-sex sexual behavior, or gender identity to their physician. A mix of societal, patient, and provider factors account for this nondisclosure. Prior to 2019, the Model of the Clinical Practice of Emergency Medicine (EM) jointly developed by the major EM organizations and published by the American Board of Emergency Medicine did not specifically include sexual minority health, and medical school and EM residency training often offers limited, if any, sexual minority education. Recent initiatives have been undertaken to determine needs and knowledge gaps. One study of EM residents found that 43% felt obtaining history and physical examinations from transgender patients was more challenging, and 25% felt similarly about LGB patients.[21] Most EM residents did not ask patients about sexual orientation or sexual behaviors even when pertinent to the chief complaint (e.g., abdominal or genitourinary concerns). Another survey of emergency physicians found that although most cared for transgender patients, few had formal training regarding their health needs or care. More than half asked patients about gender affirming surgeries, regardless of the chief complaint. Only 9% could identify the most commonly used nonhormonal medication used by female transgender patients (spironolactone), and only 26% could identify the most commonly used surgery by male transgender patients (mastectomy with thoracoplasty).[22] One should take an organ and hormone inventory only when relevant to the complaint. Similarly, when related to the presenting condition, one should inquire about sexual partners, specific sexual practices, and sexually transmitted infections (STIs; past diagnoses, use of protection) to improve health care to sexual minority patients.[23]

All emergency health care providers should receive training on LGBTQ inclusion and cultural competency. Education on terminology, sex differentiation, hormone therapy, mitigation of personal bias, and creating a safe environment has been shown to improve knowledge of, comfort with, and attitudes toward sexual minorities.[24,25] Creating an atmosphere of inclusion is fundamental to candid health care conversations and providing equitable and competent care.[26]

Health Disparities

Sexual minorities have the same basic health care requirements as others, but also have specific health needs intrinsic to their sexual orientation, gender identity, and behavior. Obstacles to equitable health can lead to health care disparities. The Minority Stress Model, described by Meyer, explains that minority groups, including sexual minorities, experience chronically high levels of stress from societal stigmatization. Sexual minority health disparities adversely affect both physical and mental health (Table 188.2). Higher prevalence of mood and substance abuse disorders result from increased stress caused by discrimination, rejection, and the adoption of societies' negative attitudes toward oneself. Research on disparities is limited, due in part to infrequent collection of sexual orientation or gender identity data, so many disparities are likely currently unidentified.

When considering health disparities among sexual minorities, HIV infection is often the focus despite the fact that the vast majority are HIV negative. However, in 2017, 70% of new cases of HIV were among men who have sex with men (MSM), making treatment and prevention important considerations.[27] One in six MSM who are HIV positive are unaware of their status.[27] Intimate partner violence among MSM has been associated with riskier sexual practices and increased risk of sexually transmitted infections, including HIV.[28] Men who have receptive anal sex are 13 times more at risk for HIV transmission than those who have insertive anal sex.[27] Sexually active MSM should be tested for HIV at least annually, or more frequently based on individual risk.[29] HIV treatment is paramount since an undetectable viral load markedly decreases the risk of transmission to seronegative partners, and treatment can significantly prolong life. Unfortunately, only 62% of HIV-positive MSM are receiving treatment, and only 52% have achieved viral suppression at levels that decrease transmission.[30] ED HIV testing and referral can provide an impactful opportunity on sexual minority health care. Additionally, pre and postexposure prophylaxis against HIV can provide further risk reduction, and has been shown to be effective and well tolerated.[31] Tenofovir disoproxil fumarate and emtricitabine (Truvada) is the only FDA-approved regimen for preexposure prophylaxis (PrEP).[32] Emergency care providers should be trained and prepared to prescribe these treatments for at-risk individuals.

Transgender Health

Health care delivery to a transgender patient can be challenging for providers due to lack of education and familiarity with transgender health (Table 188.3). Transgender individuals who are "out" or are

TABLE 188.3 Best Practices in Caring for Transgender Patients

Area	Best Practice
Registration	Collect sexual orientation and gender identity so health needs can be identified early. Include preferred pronouns and name to be utilized during their ED visit.[17]
Identification	Call for patients by their last name only without the use of gender prefixes when in group settings such as waiting rooms.[17]
Scripting	Use standardized scripts to facilitate cultural sensitivity for sexual and gender minorities.[78]
Health Records	EHRs should have the ability to record and display preferred name and pronouns of patients for all users in all views. Once a patient has legal documents that reflect their gender identity and chosen name, indicators of transgender status should be removed from the view of casual users.
Organ and Hormone Inventory	Information about a patient's transition history, including an inventory of organs and hormone use information, are best stored in the medical/surgical history of the EHR.[79,34]
Accommodation	Restrooms should be defined as gender-neutral, or have specific signage and policies that patients may choose either the women's or men's room based on their own preference and identity. If patients have to choose a gendered bathroom, making at least one gender-neutral/all-gendered bathroom available will be helpful and supportive to nonbinary patients as well as those patients who are in transition.[34,17]
Patient Room	Patients should have single-occupancy rooms.

perceived as transgender experience verbal harassment (54%), physical assault (24%), and sexual assault (13%) because of their gender identity. Forty percent of transgender individuals have attempted suicide, almost nine times the rate of the general population.[6] Many transgender people have challenges with their families or religious communities and experience psychological stress due to rejection from previous sources of nurturing and support. Ten percent of transgender people report violence from an immediate family member, 8% have been kicked out of their homes, and 20% leave their spiritual or religious community due to rejection based on their gender identity.[6] Nearly a third of transgender people live in poverty, compared to 12% of the general US population.

Medical Gender Affirming Therapy and Complications

Transgender Female. For the transgender female, medical gender affirmation therapy commonly includes hormone supplementation with androgen blocking medication, in conjunction with estrogen in physiologic doses. The most commonly used androgen blocker in the United States is spironolactone, with alternative androgen blocking medications including 5-alpha reductase inhibitors (finasteride, dutasteride). Outside the United States, cyproterone acetate, a synthetic progestogen commonly used in the treatment for prostate cancer, is used as an androgen blocker. Options for estradiol administration include daily oral or sublingual, weekly transdermal, or biweekly intramuscular (IM) dosing. Use of feminizing hormone therapy for transgender women is considered off-label, and may need to be administered in higher doses than normally used in postmenopausal cisgender women.[33] Additionally, some transgender women may also take progestogens to enhance breast development, mood, or libido. Common changes seen with the implementation of hormone therapy include breast development, facial and body subcutaneous fat redistribution, muscle mass reduction, body hair reduction, and slowing or reversal of scalp hair loss. Erectile dysfunction, decreased or absent sperm count, and reduced testicular size also occur.[33] Some transgender women still produce sperm even in the setting of androgen blockade and estrogen use, and are at risk for causing an unplanned pregnancy if they are engaging in sexual activity that could cause fertilization.[33] Transgender women who went through puberty and had exposure to testosterone will not have complete elimination of male patterned facial or body hair, change in skeletal bone structure, or change in pitch of their voice with hormone therapy alone. These individuals require specific interventions such as plastic surgery, laser hair removal or electrolysis, and voice therapy.

Although the use of estrogen and progesterone are associated with mental health conditions among cisgender women, such as premenstrual dysphoric disorder, this does not appear to occur in transgender women. The use of feminizing hormones does likely lead to increased risk for cardiovascular disease and diabetes when other risk factors are present. Additionally, venous thromboembolism (VTE), gall stones, elevated liver enzymes, and weight gain are exacerbated in individuals taking supraphysiologic doses of estrogen feminizing hormones. Estrogen should be discontinued during the acute treatment of VTE.[34] While the use of progestogens in combination with estrogens is associated with increased cardiovascular events and breast cancer in postmenopausal cisgender women, there are no specific studies defining this risk in transgender women.[33] There is also no conclusive increased risk for breast cancer.[33,35] There is a theoretical pro-growth impact of estrogen on human testicular cells; however, there is no specific link between exogenous estrogen and testicular cancer risk.[36]

"Tucking" of testicles and the penis provides a more feminine appearing contour of the genital area and involves manually displacing the testes into the inguinal canal followed by positioning of the penis and scrotal skin between the legs directed rearward toward the anus. The position is maintained with tight underwear, tape, or a special garment known as a gaff, with some transgender women staying "tucked" up to 24 hours per day. Prolonged tucking is associated with increased risk of urinary tract infections.[34]

Injection of very small amounts of medical-grade free silicone with the intent of causing local reaction of fibroblasts and collagen growth is often used in the management of HIV-related lipodystrophy. In the transgender community, "silicone injections" may involve the injection of up to 3 liters of a variety of non–medical grade substances such as aircraft lubricant, tire sealant, window caulk, mineral oil, methyl acrylates, or petroleum jelly.[37] An estimated 20% to 50% of transgender women may have received these injections from nonmedical providers in their efforts to relieve their gender dysphoria and have immediate body changes that conform to their gender identity. Unfortunately, this practice often leads to significant immediate, early, and late-term health consequences (Table 188.4). Patients may not be forthcoming with information about having received filler injections in a nonmedical setting, so health care providers must be diligent in determining if injections might be a possible cause of patients' symptoms.

Transgender Male. The most common gender affirming medical treatment utilized by transgender men is testosterone. It can be administered IM, subcutaneously, or topically. With topical use, there is a modest risk of exposure to other people from skin to skin contact, and caution should be taken around patients with more sensitivity to testosterone such as pregnant women and small children.[38] Adjuvant therapies include progestogens, 5-alpha reductase inhibitors, aromatase inhibitors, gonadotropin-releasing hormone antagonists, and direct application of topical testosterone to the clitoris.[38] Use of hormone replacement therapy mimics male puberty, taking 4 to 5 years for full

TABLE 188.4 Silicone Injection Adverse Effects and Complications

Immediate	• Bleeding, pain, focal tissue necrosis, hypersensitivity reactions • Silicone embolization causing ARDS, multisystem organ failure, or loss of limbs
Early Onset *days to weeks*	All of the immediate adverse events, PLUS • Infected inflammatory nodules that may be fluctuant • Angioedema • Non-inflamed nodules that are painful, pruritic, and cause hypopigmentation
Long Term *weeks to years*	All of the immediate and early adverse events, PLUS • Nodules (inflamed and non-inflamed) may form sterile abscesses or fistulae • Migration of silicone causing pain or deformity • Silicone granulomas • Hypercalcemia • Sepsis, hypersensitivity pneumonitis, immune reconstitution inflammatory syndrome (IRIS) • Organ failure from direct mass effects

effect. Clitoral growth starts in as soon as 3 months and peaks at 1 to 2 years. Some may also try off label use of dihydrotesterone (DHT) to enhance clitoromegaly. Menses usually stop after 3 to 6 months of testosterone treatment, but this is dose dependent.

Transmen who were amenorrhoeic from testosterone may also present with new vaginal bleeding. This may be due to inadequate suppression of menses by the testosterone, but evaluation for pregnancy, infection, or malignancy, and gynecologic consultation may be necessary.[38] Testosterone provides ineffective birth control. In transgender men who became pregnant, 60% used testosterone prior to pregnancy, 20% conceived while amenorrhoeic from testosterone, and 32% of the pregnancies were unplanned.[39] If transgender men engage in vaginal receptive intercourse, they should use contraception such as condoms, progesterone-only birth control, or a hormonal IUD.[38] Testosterone is contraindicated in pregnancy and should be discontinued immediately if the pregnancy is desired.

Transgender men may also experience vaginal atrophy similar to that which occurs in postmenopausal women.[38] Atrophic vaginal tissue with decreased tissue resiliency and an altered microbial environment can be present due to relative estrogen deficiency. This can lead to bacterial vaginosis, cystitis, or cervicitis. Treatment with vaginal estrogen for symptom relief and comfort is appropriate, and should be accompanied by reassurance that the minimal systemic absorption of estrogen should not interfere with masculinization effects of testosterone. If patients are uncomfortable with intravaginal administration, they can just apply the estrogen cream on their external genitalia.

Transgender men on masculinizing hormones should have their labs interpreted based on standard male values, except for hemoglobin values. If the patient is still having menses, their hemoglobin should be interpreted relative to female values. Use of masculinizing hormones leads to an increased risk for polycythemia, weight gain, acne, androgenic alopecia, and sleep apnea. Additionally, there are possible increased risks for elevated liver enzymes, hypercholesterolemia, cardiovascular disease, hypertension, and diabetes if additional factors are present. Psychiatric disorders that include manic or psychotic symptoms may have an increased risk of destabilization from masculinizing hormones. There is no conclusive increased risk for bone density loss, breast cancer, cervical cancer, ovarian cancer, or uterine cancer.[35,38]

Masculinizing hormone treatment may not shrink breasts, and thus transmen may bind their breasts with tight-fitting sports bras, shirts, ace bandages or specially made binders to flatten the contour of the chest. Larger-breasted people may use multiple garments at the same time, which can lead to pain, diminished respiratory capacity, skin breakdown, or fungal infections.[40] Sensitive and appropriate history taking and physical examination of patients who may be reluctant to remove bindings is key to providing culturally competent care and allowing a discussion about safe binding.[34]

Surgical Gender Affirming Therapy and Complications

Transgender Women. Gender affirming surgeries for transgender women included genital procedures such as orchiectomy, vaginoplasty involving the creation of a neovagina, clitoris, urethral rerouting, and labiaplasty, most commonly using the penile inversion technique. Nongenital procedures commonly seen include breast augmentation, facial feminization with plastic surgery, and reduction thyroid chondroplasty to decrease prominence of the "Adam's apple."[33] Of note, the prostate is generally not removed with any of these procedures, so health maintenance including screening for prostate cancer is still required.

Transgender Men. Mastectomy is one of the most commonly requested surgery by transgender men. They experience the same rate and type of complications as cisgender women who have mastectomies.[41] Genital surgical procedures include metoidioplasty (movement of the hypertrophied clitoris anteriorly to a normal penile position) and phalloplasty (construction of a neophallus using free and/or pedicled flaps). Complications of both procedures include spraying or dribbling of urine, urethral strictures or fistulas, and, with phalloplasty, the additional risk of vascular compromise of the flap and necrosis.[38]

Physical Examination

Examination of a neovagina in a transgender woman involves looking at a blind cuff that lacks a cervix or surrounding fornices. It may be more posteriorly oriented than expected. Using an anoscope instead of a vaginal speculum may provide a more anatomic approach. Once inserted, the trocar can be removed from the anoscope, and direct visualization of the walls of the neovagina can occur as it is withdrawn and the walls collapse around the end of the anoscope.[34]

Physicians evaluating transgender men who present with complaints of pelvic pain should take the same general anatomic based approach as a non-transgender woman, considering urologic, gynecologic, gastrointestinal, musculoskeletal, and psychiatric causes. Recognizing that transgender men may engage in receptive vaginal sex, a comprehensive sexual history including specific behaviors (vaginal-vaginal contact, vaginal or anal or receptive penile sex) should be collected.[42] Pregnancy should also be considered in any patient who still has a uterus and ovaries. Explaining that pregnancy testing is part of a standard protocol may ameliorate any offense taken by patients who deny any sexual activity with a partner capable of insemination.[34]

Even when medically necessary, having a pelvic examination can be traumatic and anxiety provoking for transgender men. It may have been a long time since their last exam, and they may not be up to date on screening for cervical cancer or STIs. Techniques for decreasing discomfort with pelvic exam include: discussing the procedure beforehand; allowing the patient to have a support person in the room; directly explaining each step before performing it; using the patient's terms for their body parts instead of medical terms. Some transgender men may decline speculum exam, transvaginal ultrasound, or bimanual exams as it may exacerbate their gender dysphoria. If the patient requires a transvaginal ultrasound, a low-dose benzodiazepine may be considered in conjunction with the application of lidocaine ointment to the vulva and vagina prior to the procedure. Having the patient insert the intravaginal ultrasound themselves may also facilitate a transvaginal ultrasound.[34]

Special Populations

Youth

Sexual minority youth have similar health disparities as adults; however, they also face challenges unique to their developmental stage and vulnerable position. In addition to typical formative milestones, LGBTQ adolescents are challenged by the realization that their sexual attraction and/or gender identity may be different than what is expected of them by their parents, peers, or society. Parents, peers, and medical providers may lack insight or knowledge into the complexities of their situation, and heteronormative assumptions may cause unintended harm. Youth can become disconnected from support and social networks by self-isolation or rejection. In 2017, the Youth Risk Behavior Surveillance study found that sexual minority youth reported much higher rates of mistreatment than their heterosexual counterparts.[43] One-third of LGBTQ teens were bullied at school, 27% were bullied electronically, 30% were victims of physical violence, and 22% experienced sexual violence.[43] Ten percent of LGBTQ students had missed school due to safety concerns.[43] Sexual minority adolescents also have an increased rate of mental health disorders, substance abuse, STIs, and self-harm or risky behaviors compared to majority adolescents.[44]

While 13% of heterosexual students contemplate suicide, the number rises to 48% of sexual minority youth.[43] Up to 40% of homeless youth identify as LGBTQ.[44]

For transgender youth, puberty-suppressing medications may be prescribed. The purpose is to allow more time to explore their gender identity and other developmental issues, and potentially facilitate future transition by preventing the development of secondary sex characteristics, such as facial hair, breasts, or deepened voice. These secondary sex characteristics are otherwise difficult to impossible to reverse if the person later chooses to pursue gender confirming procedures. Adolescent patients with male genitalia may be taking gonadotropin-releasing hormone analogues to stop luteinizing hormone secretion, or medications that block secretion or action of testosterone, such as progestins. Adolescent patients with female genitalia may also be treated with gonadotropin-releasing hormone analogues to stop production of estrogen and progesterone. Surgical interventions should not be carried out until the patients reach the legal age to consent for medical procedures and have met other criteria for gender affirming surgeries.[35]

Elders

There are approximately 3 million Americans over the age of 55 years who identify as LGBTQ, and by 2030 it is estimated there will be 6 million.[45] Significant health disparities also disproportionately affect older sexual minorities (see Table 188.2). Physical disparities may result in significant disability later in life. Mental health concerns are staggering with over half of sexual minority individuals over age 65 experiencing depression, almost 40% have contemplated suicide, and over 50% feel isolated.[46] Like other sexual minorities, they are less likely to have medical insurance and more likely to live in poverty.[46]

Although LGBTQ individuals and couples are increasingly parents through surrogacy, adoption, or other means, most do not have children who may assist them in advanced age compared to heterosexuals. Elder sexual minorities are twice as likely to live alone and may be estranged from biological family.[46] Sexual minorities commonly rely more on friends and community, but may become separated from social support by declining independence and health.[47] As a result, sexual minority individuals anticipate more use of institutional long-term care.[48] Among elder transgender individuals, 35% are concerned about being judged by their health care providers and believe that their health care will be limited (65%) or denied (55%) as they age.[49] Sexual minorities dependent on others have a high rate of abuse from caregivers. In one study, 22% of sexual minorities over 60 years of age reported that they had been harmed or neglected by a caregiver, and 26% reported knowing someone else who had been mistreated.[50] These factors are essential in consideration of a safe discharge from the ED.

People of Color

Although sexual minorities face many barriers in the obtainment of equitable health care, those of color have additional burdens. African American and Latino sexual minorities experience greater stigma relative to white counterparts.[51] Even within the sexual minority community, African Americans have the highest levels of racial/ethnic stigma, Caucasians the least, and Latinos and Asians in between.[52] Being LGBTQ and an underrepresented minority due to race, creed, ethnicity, or religion can potentially cause direct conflict with strongly held community values. As a cohort, African Americans and Hispanics have higher spirituality,[53] and religious institutions can therefore have an important role in helping or exacerbating their double minority stress.[54] Providers should be aware of how different cultural expectations that form identity can conflict and have an impact on the overall mental and physical health of these patients, and potentially magnify preexisting disparities.

African American and Latino sexual minorities are disproportionately affected by HIV compared to other racial groups, accounting for 37% and 29% respectively of new HIV infections among MSM.[27] Black MSM have a one in two chance of acquiring HIV during their lifetime,[55] and Latino MSM have a one in four lifetime risk.[30] Both are also are less likely to use PrEP, but this alone does not account for the difference between racial groups.[56] Although overall rates of HIV have been stable in the last decade, rates rose 52% among Asian and 18% among Latino MSM.[27] The HIV infection rate was stable among Black MSM, and the rate among white MSM rate decreased by 16%.[27] Intimate partner violence has been shown to be independently associated with HIV risk in Latino MSM.[57]

CHAPTER 188: QUESTIONS AND ANSWERS

1. Which of the following statements regarding sexual minority populations is true?
   - **a.** Sexual orientation, gender identity, and gender expression define psychological, cultural, and behavioral characteristics of either being male or female.
   - **b.** Lesbian, gay, bisexual, and homosexual are all acceptable terms when addressing the sexual minority community.
   - **c.** The demographics of sexual minority populations indicate that a majority of vast transgender individuals were born after 1994 (Generation Z).
   - **d.** In sexual minority populations, it is important to separate sexual and gender identities from sexual behavior.

Answer: D. Sexual orientation, gender identity, and gender expression occur along a continuum and may be completely separate and discordant from one another whereas gender refers to the psychological, behavioral, and cultural characteristics of being either male or female. The term *homosexuality* is associated with past bias and discrimination and is not a preferred term when addressing sexual minority populations. Sexual minority individuals cross every demographic, and multiple cultural and societal influences can affect their visibility and disclosure of sexual and gender identity.

2. Which of the following factors does not affect equitable care in sexual minority populations?
   - **a.** Parental barriers
   - **b.** Same-sex marriage
   - **c.** Access to care
   - **d.** Provider education and knowledge
   - **e.** None of the above

Answer: E. Same-sex couples with adopted children can face difficulty in legal recognition of parenthood, resulting in barriers in medical decision making and obtaining appropriate health care. Although marriage equality provided the opportunity for stronger and automatic protections previously denied to same-sex couples, only 51% of same-sex couples' households are legally married compared to over 90% of heterosexual households. Sexual minority patients have less access to health care and are less likely to have health insurance compared to majority counterparts. ED provider education about sexual minorities is often inadequate, limited or absent, leading to lack of understanding and poorly informed decision making or advocacy on behalf of sexual minority populations.

3. Which of the following statements regarding medical gender affirming therapy is true?
   - **a.** Commonly used medications include hormone supplementation with androgen blocking medications in conjunction with estrogen.
   - **b.** The most common gender affirming medical treatment for the transgender male is spironolactone in addition to 5-alpha reductase inhibitors and aromatase inhibitors.
   - **c.** Transgender women who went through puberty and had exposure to testosterone will usually have complete elimination of male patterned facial or body hair and change in pitch in voice although little change in skeletal bone structure would occur with hormone therapy alone.
   - **d.** Finasteride is a 5-alpha reductase inhibitor used only in transgender males for gender affirming therapy.
   - **e.** Both A and B are true.

Answer: A. The most common gender affirming medical treatment utilized by transgender men is testosterone. The most commonly used androgen blocker in the United States is spironolactone. 5-Alpha reductase inhibitors (finasteride, dutasteride) are alternative androgen blocking medications. Transgender women who went through puberty and had exposure to testosterone will not have complete elimination of male patterned facial or body hair, change in skeletal bone structure, or change in pitch of their voice with just hormone therapy. These require specific interventions such as plastic surgery, laser hair removal or electrolysis, and voice therapy.

4. Which of the following statements regarding surgical gender affirming therapy is false?
   - **a.** Genital procedures in gender affirming surgeries for transgender women also include the removal of the prostate gland as well as orchiectomy and vaginoplasty.
   - **b.** Complications of metoidioplasty and phalloplasty include spraying or dribbling of urine and the development of urethral strictures and fistulas.
   - **c.** In transgender males, pregnancy is not a consideration.
   - **d.** Both a and c are false.
   - **e.** None of the above are true.

Answer: D. Genital procedures in gender affirming surgeries for transgender women do not include the removal of the prostate gland, so the risk for prostate cancer persists necessitating screening. Pregnancy should always be considered in any patient who still has a uterus and ovaries.

5. Which of the following statements is false?
   - **a.** There is an increased risk for mental health disorders among the sexual minority population.
   - **b.** The population of older Americans who identify as LGBTQ is likely to shrink by the year 2030 and experience less depression.
   - **c.** African American and Latino sexual minorities experience greater stigma relative to white counterparts.
   - **d.** Rates of HIV have risen among the Asian and Latino males who have sex with males over the last decade.

Answer: B. There are approximately 3 million Americans who identify as LGBTQ over the age of 55, and by 2030 it is estimated there will be 6 million, with increasing burdens of mental health and lifetime physical disabilities. Although overall rates of HIV have been stable in the last decade, rates rose 52% among Asian and 18% among Latino MSM. The HIV infection rate among Black MSM was stable and the infection rate among white MSM decreased 16%.

189

Social Determinants

Dennis Hsieh

KEY CONCEPTS

- Challenges with food, housing, transportation, and other social determinants of health account for approximately 50% of poor health outcomes in the United States.
- Emergency providers can connect patients to resources that can help address challenges with different social determinants of health.
- Legal services attorneys provide low-cost or free services that can assist with a number of health-harming legal needs.
- Health care providers and systems need to work with nonprofits, community groups, community members, and community leaders to expand the capacity to address social determinants of health.

FOUNDATIONS

The emergency department (ED) serves as the interface between health care and the community in a nexus where health care delivery can become a complex integration of significant physical and mental health crises intertwined with other life emergencies such as homelessness, poverty, and hunger.[1] These social and economic factors are collectively known as the social determinants of health (SDOH).

SDOH create barriers to health care access and result in nonadherence to medical interventions. It is estimated that 20% of a patient's health outcome is influenced by medical care, whereas social and economic factors account for 50% of such outcomes, highlighting the importance of concurrent medical and social interventions to advance patient health outcomes.[2]

Furthermore, left unaddressed, SDOH drive both health care cost and utilization. Even for those with access to care, many competing social needs impede the ability of the individual to adhere to treatment plans. These factors have a significant effect on health. For many of these concerns, providers can connect patients to concrete resources regardless of whether or not social work is available.

SPECIFIC ISSUES

Patient and Provider Factors

A large number of patient and provider factors affect the care of patients (Table 189.1).[2a]

Language

Many ED patients do not speak English as a first language. Title VI of the Civil Rights Law requires all recipients of federal funding to provide interpretation for patients with limited English proficiency. With time pressure in the emergency department and lack of proper training, providers do not always use a certified interpreter and instead use their limited knowledge of a second language or a patient family member. Failure to use a certified interpreter leads to poorer health outcomes and persistent health disparities.[3] Given this, emergency clinicians should use certified interpreters for patients with limited English proficiency.

TABLE 189.1 Patient and Provider Factors

Patient and Provider Factors	Rosen's Chapter
Race, ethnicity, and diversity	Chapter 186
Cultural humility	Chapter 186
Implicit bias	Chapter 186
Sexual orientation and gender identity	Chapter 188
Mental health	Chapters 96-101
Disability	N/A
Language and literacy	Chapter 189 (this chapter)

Health Literacy

Even patients who speak English as a first language may have limited health literacy, which is defined as limited capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions. Those who have low health literacy may have trouble with tasks including reading appointment slips, understanding medication labels, and comprehending information from their providers, all of which are associated with poorer adherence to care plans and poorer health outcomes.[4] To address this, ED providers can use techniques such as "teach back" by providers and engaging with family members and friends to support patients.

Insurance and Access to Care

Uninsured and underinsured patients are often unable to access care prior to an ED visit.[5] This leads to delayed presentations of serious health conditions, poor health outcomes, and higher mortality.[6] For those who have poor access to care, two of the main drivers are the lack of ability to afford care and low health literacy regarding how to utilize care once coverage is obtained.[7]

For emergency clinicians, insurance and access to care are crucial to ensure proper follow up for patients. Rapid follow up reduces both return ED visits[8] and avoidable hospital admissions.[9] Thus, making sure patients have a practical and accessible follow-up plan is key. For those patients who have trouble navigating the system, case management can reduce ED recidivism.[10]

Employment, Income, and Financial Strain

The United States (US) has an extremely high rate of income inequality that has continued to grow in recent years.[11,12] As income inequality has grown, so have health care disparities: lower-income Americans have higher rates of chronic disease, anxiety, and depression, as well as lower life expectancy.[13,14] Low income, financial strain, and resulting

poverty lead to increased stress, poor access to healthy foods, unsafe housing, and challenges with other SDOH.

Medical debt is related to income, employment, and financial security and is estimated to contribute to 67.5% of all bankruptcies, even after passage of the Affordable Care Act.[15] Hospitalization itself leads to decreased employment and income with a rise in out-of-pocket spending on medical care.[16] This highlights the importance of ensuring patients are connected to health care coverage and other programs to minimize the impact that an ED visit and/or hospitalization has on their lives.

Food Insecurity

Food insecurity, defined as a condition in which individuals do not have access to nutritionally adequate and safe food because of limited financial or other resources, is a leading health issue in the United States.[17] Lack of access to healthy foods leads to increased rates of low birth weight, hypertension, diabetes, and mental health disorders, particularly depression.[18] Not surprisingly, this is associated with increased emergency department visits and acute care utilization[19] and therefore increased costs within the health care system. Food insecurity led to an estimated $53 billion dollars of excess health care spending in the United States in 2016.[20]

Food insecurity leads to poor health by forcing individuals to choose between eating and medications, medical care, housing, education, utilities, and transportation.[21] Furthermore, food insecurity makes it difficult for individuals to follow a healthy diet and reduces the cognitive bandwidth available to manage chronic illnesses.[21]

Poverty, lack of education, and unemployment lead to individuals and households not having enough to eat and substituting cheaper, less nutritious items for healthy foods[22] or choosing not to eat to meet other basic needs. Low-income individuals often live in areas that have been historically underdeveloped with poor public transit and lack access to healthy foods. These areas, known as food deserts, lead to poor outcomes for those with chronic disease, including cardiovascular disease[23] and diabetes.[24]

Homelessness and Housing

Lack of access to safe, habitable housing is an important social determinant of health for many patients. These individuals have worse health outcomes and mortality compared with those who are housed.[25] Unhoused individuals may be unable to properly store certain medications, which can affect their efficacy (e.g., refrigeration of insulin or other antidiabetic agents may not be possible). Additionally, patients with housing insecurity may take irregularly or avoid taking certain medications based on expected side effects and potential legal implications. An example includes the use of diuretics, which cause increased need for urination; due to lack of access to bathroom, patients may be unable to reliably relieve themselves or be charged with indecent exposure or public urination. Housing First programs that provide housing and supportive case management decrease the use of nonroutine health care services, including ED visits, while improving self-perceived health.[26,27] However, compared to other federal, state, and local means-tested programs such as Medicaid and SNAP, housing programs have a limited supply and long waitlists.

For those with housing, utility payments can be challenging. Utility assistance programs are available for low-income patients and have been shown to improve health.[28,29]

Transportation

Lack of access to transportation leads to missed appointments, poor adherence to medications, and delayed access to care, resulting in increased costs and poorer health outcomes.[30] Lack of transportation also impacts access to services, healthy foods, jobs, and other social determinants of health. Barriers to transportation include poor infrastructure, costs, lack of access to vehicles, distance and time burden, and policy-related issues.[31]

Elders, veterans, children, women, minorities, and those with lower incomes and chronic conditions face more transportation barriers.[32] Rural settings are especially challenging, given the great distances and lack of public transportation.[33] Providing transportation improves adherence to care, thereby decreasing costs and improving outcomes.[34]

Immigration Status

The immigration experience has profound effects on individuals and their health.[35] Immigration status is linked to ability to work and access public benefits, including health care.[36] The lack of proper immigrant status causes stress and poorer health.[37] Immigration law and policy are complicated and continuously changing. Important interventions that can be initiated in the ED include identifying vulnerable patients and educating them about potential opportunities to adjust their immigration status through mechanisms such as the T-Visa, U-Visa, and Violence Against Women Act (VAWA), as well as providing education and dispelling fear regarding accessing medical and social services.

Education

Youth behavioral issues in school can be related to mental health or developmental delay, resulting in the youth being brought to the ED. Parents or guardians may express concerns regarding the issues of truancy, suspension, expulsion, and reasonable accommodation, challenges that appropriate social services can help them address. For adults, educational needs are more subtle and tied to employment opportunities and income. Lower educational attainment is correlated with lower health literacy and poor health outcomes. More years of education are directly linked to a lower risk of mortality, a lower risk of obesity, and a lower risk of smoking.[38]

Legal Concerns

Health-harming legal needs is a term used to describe the legal avenues that exist to address many SDOH. For example, if an individual has mold, pests, or other housing issues that a landlord refuses to address, or an individual is improperly denied Medicaid coverage for durable medical equipment, a lawyer can help advocate and enforce housing and Medicaid regulations, respectively. Addressing SDOH through the law diminishes stress, decreases ED visits, and improves adherence to care and health outcomes.[39]

Justice Involvement

The United States has the largest population of incarcerated individuals in the world.[40] Individuals in custody or otherwise justice-involved are often seen in the ED. Many of these individuals experience comorbid psychiatric and substance use disorders, chronic health conditions, or homelessness, making these populations extremely vulnerable.[41] Furthermore, individuals in custody lose their rights and privacy. Being justice-involved is associated with higher mortality, morbidity, and poorer health outcomes.[42]

The Built Environment

Emergency clinicians must view and treat patients within the context of their lives and their communities. As such, the built environment, the surrounding physical environment, and conditions that are constructed by human activity affect patients' ability to follow up for care, exercise, access transportation, eat healthy food, and address other social determinants of health.[43] Improvement in the built environment is associated with better health outcomes in areas such as increased physical activity, better mental health, and improved dietary behaviors.[44] Emergency clinicians often see patients who reside in poorer

areas, where following common preventative measures such as healthy eating and exercise is often challenging. Providers can address specific barriers, such as food insecurity and challenges with transportation, as previously discussed. Beyond this, however, changing the built environment requires gathering evidence from the bedside and engaging with health systems, local and state government, and the community to help bring about systematic change.

MANAGEMENT

Overview

Most EDs do not currently screen for social needs. Instead, social needs arise during the course of the patient encounter. Options for systematic screening exist but require implementing a framework for both identifying and addressing social needs.[45] After identifying concerns with the social determinants of health, patients can be linked to resources. Social workers or ED staff can help assess and provide emotional support prior to providing patients with a list of resources. Some systems have adopted electronic platforms such as One Degree (www.1deg.org), 211 (www.211.org), or Aunt Bertha (www.findhelp.org), which are accessible for patients to use themselves.[46] Some systems also use patient navigators to help more actively connect patients to resources.[47,48]

EDs, hospitals, and health systems cannot address SDOH and poverty alone. In addition to working across specialties, health systems must look outside of health care to meet patients' social needs. There are many community groups, nonprofit organizations, and government agencies working on factors affecting SDOH. Together, these partnerships not only provide an opportunity to invite service organizations into the health care setting to connect with patients, but also ensure closed-loop communication that ensures that patients actually receive help.

Apart from connecting patients to resources, community engagement can lead to building capacity within the community through infrastructure changes such as offering low-cost day care and early childhood education opportunities, introducing violence prevention programs in schools, increasing the number of parks and green spaces, reducing unhealthy food options, creating bike lanes, or introducing farmer's markets to combat food deserts. Even with these types of changes, other challenges such as the lack of affordable housing and low wages require further advocacy in partnership with the community at the local, state, and federal levels.

Health Care Access and Literacy

Even for those who have health care coverage, access to follow-up care from the ED can be challenging. There are no federal standards requiring that appointments be available within a certain number of days, or how many providers there must be for a certain number of enrollees. However, most states do require that Medicaid and managed care plans provide adequate networks and timely access.[49] Patients having trouble accessing care can call their insurance plan to find out who their doctor is, what specialists are available, and how quickly they should be able to get an appointment. If, despite contacting their doctor and their insurance plan, they are still unable to access care in a timely manner, patients can contact their state's department of insurance for further assistance.

Health Care Coverage

When a patient does not have health care coverage, there are a number of options to consider.

Medicaid was created by the Title XIX of the Social Security Act in 1965 and is a means-tested program, meaning that eligibility depends in part on income. The program is administered by states and jointly funded by federal and state dollars. At a minimum, coverage must be provided to individuals who are pregnant, blind, disabled, over 65 years of age, and parents or caretakers of a dependent child whose household income falls below a certain amount. Beyond this, states have the option to cover additional populations. Income levels are set by the state.[50] Patients can look to their state government website for more information and to sign up for Medicaid.

Medicare was established in 1965 under Title XVIII of the Social Security Act for individuals age 65 (currently) and older, those less than 65 who receive Social Security Disability Insurance, and those who suffer from end-stage renal disease. People who fall into one of these three categories must have worked or be linked to an individual who has worked at least 40 quarters (10 years) during their lifetime. Medicare is administered and funded by the federal government and contains several parts including inpatient hospital coverage (Part A), outpatient medical coverage (Part B), and alternative coverage options—Medicare Advantage (Part C), and prescription drug coverage (Part D). To sign up for Medicare, one must go through the Social Security Administration by either visiting a Social Security Office or registering online: https://www.ssa.gov/benefits/medicare/.

In addition, all states have a health care marketplace (healthcare.gov) under the Affordable Care Act (ACA) where individuals can see plan options and sign up for health care. Generally, the exchanges have a period of open enrollment during which an individual must sign up for insurance. However, instances such as a job loss or relocation will permit signing up for insurance outside of open enrollment periods. If an individual is not eligible for Medicaid or Medicare, signing up for insurance via the exchanges is the most appropriate option.

There are specific programs focused on providing access to care for children under the age of 18, including the Children's Health Insurance Program (CHIP). However, transitional age youth between the ages of 18 to 25 years face special challenges because they become ineligible for many benefits, including health care, during this age range and can also lose access to their pediatrician. The Affordable Care Act requires plans and issuers that offer dependent child coverage to make coverage available until the child reaches the age of 26.

Individuals who are not eligible for these options will receive a bill of charges that is higher than the negotiated rates that insurance companies pay. These individuals should be advised to call the health care provider or hospital to discuss options that include free care, a reduced rate, or a payment plan. A reduced rate or free care (collectively also known as charity care) is available at the discretion of the provider and is generally based on income. A payment plan is a plan where the amount due after negotiations can be paid in installments, much like credit card payments. Note that facilities built with assistance from the Hill-Burton Act of 1946 (usually hospitals) have legally mandated charity care obligations.

Patients who have trouble navigating these options, feel that they have been wrongly denied benefits, or have been sent to collections can contact the patient advocate at the hospital and a local free legal services organization for assistance. Those sent to collections can call the original provider to ask that the bill be taken back from collections to work out a payment plan as the provider receives substantially less reimbursement when a medical bill is sold to a collection agency. Additionally, patients may be unable to afford some or all of their medications, leading to repeated presentations to the ED. Determining alternative strategies from different medication options (e.g., transitioning from SGLT-2 inhibitor or GLP-1 inhibitor for treatment of diabetes mellitus to a sulfonylurea) or different mechanisms for payment may be crucial to prevent additional visits.

Disability and Loss of Employment

Emergency clinicians often care for individuals who have suffered an injury that affects their ability to work. Depending on the nature of the injury, the patient may qualify for either short-term or long-term disability insurance that will pay them a portion of their wages while they are unable to work. States administer short-term disability, which is anticipated to last less than one year. For long-term or permanent disability, people must apply through the Social Security Administration for either Social Security Disability Insurance (SSDI) or Supplemental Security Insurance (SSI).

The Family and Medical Leave Act of 1983 (FMLA) protects individuals who have to take leave from their jobs due to the birth of a new child, caring for a sick family member, or recovering from a serious illness, allowing for unpaid leave for up to one year without the risk of job loss. Those taking time off for pregnancy and childbirth also qualify for short-term disability insurance.

Challenges with Employers

Clinicians will also encounter patients who feel that they have been wronged by their employer. Complaints may include employment discrimination, denial of meals and breaks, improper termination, unpaid overtime, and unpaid wages. For these concerns, referral to a legal services attorney or an employment law attorney is the appropriate next step.

Finding Employment

Patients who need assistance in finding employment can contact local workforce development agencies and nonprofits that help individuals find and retain employment. For those who have misdemeanors or felonies on their records, referral to legal services for record expungement may help these individuals obtain jobs.

Income Support

Patients who are employed but earn very little may qualify for earned income tax credit (EITC). Those who are able to work but have lost their jobs can apply for unemployment insurance, which is administered on a state-by-state basis. Those who have minor children may qualify for Temporary Assistance for Needy Families (TANF), which is funded by the federal government and administered by states. For those without minor children, local jurisdictions may have limited cash aid, such as General Assistance or General Relief. These programs are generally administered by the local department of social services. Those who are older may also qualify for Social Security retirement benefits, which is administered by the Social Security Agency. Individuals who have a history of military service may be eligible for income assistance from the Department of Veterans Affairs. Providers should also make sure that these patients are linked with other programs that assist with basic needs, such as programs that help with food and housing.

Management of Food Insecurity

Health Care Based Resources

Some hospitals and health systems have partnered with local food recovery organizations, food banks, and farmers to set up food pharmacies that provide healthy produce for free to patients who are food insecure and/or have chronic disease.[51] These food pharmacies are often supplemented with cooking classes and nutrition education for patients. Many hospitals and health systems also partner with local growers to host on-site farmers markets to make healthy food accessible to patients and some institute a 1-to-1 match for supplemental nutrition assistance program (SNAP match) purchasers.[52]

Community-Based Resources

Patients can also be referred to community resources that provide food ready for consumption, such as churches, soup kitchens, and shelters, as well as those that provide groceries, such as food banks and pantries.[53] Other sources include farmers markets that provide a SNAP match, food delivery services such as Meals on Wheels, and medically tailored meals, such as those provided by Project Open Hand in the San Francisco Bay Area.

Public Programs

Public programs are generally limited to those who have legal status in the country. The supplemental nutrition assistance program (SNAP), formerly known as food stamps, is a federally funded program through the United States Department of Agriculture (USDA) that is based on financial need. Local offices can be found on the USDA website.[54]

The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) is a program open to postpartum women and children up to the age of five. This program is also administered by the USDA and local offices can be found on the USDA website.[55]

Housing and Homelessness

Clinicians also care for many patients who are experiencing challenges with housing, including the imminent risk of homelessness. Given already substantial challenges in obtain housing, any pending eviction or loss of a Section 8 voucher should be treated as a legal emergency with an immediate referral to a legal services provider given often strict timelines (days) to respond to any pending legal action.

For those who have concerns with the habitability of their housing due to pests, mold, rodents or other health hazards, or have nonfunctioning heating or appliances, a request can be made of the landlord to adhere to codes of habitability to resolve the concerns. Patients may also require reasonable accommodation because of a disability or feel that they have been discriminated against in violation of the Fair Housing Act. For patients who own their homes and are at risk of foreclosure, working with a lawyer who specializes in housing may allow individuals to negotiate a modification on their mortgage or a payment plan in order to keep their housing. All of these patients can be connected to their local legal services organizations for additional support.

Challenges may also exist with utilities. Many regions or states have heating assistance programs for low-income individuals. There are also other utility assistance programs for electricity, gas, telephone, and even internet services. Patients with limited income should inquire with their utility companies about any available assistance.

Those experiencing homelessness can apply for Section 8, the federal housing assistance voucher program that pays a portion of an individual's rent. Section 8 is extremely limited in supply, and in many jurisdictions the waitlist for Section 8 is only open a few days each year for new individuals to sign up. Once an individual registers, the wait can be as long as 5 to 10 years.

Health care organizations may support funding for housing through a Housing First model, which has been shown to improve health while reducing costs.[55a] For those with medical needs and insurance, skilled nursing facilities, congregate living, medical respite, and recuperative care are options. For those with limited income, board and care facilities or renting a room may be an option. Individuals with immediate housing needs can access available shelter systems. Shelters often offer little privacy, do not allow individuals to stay during the day, and require people to line up for a bed on a daily basis. Shelters often also have restrictions based on age and gender, making it challenging for families or couples to stay together. Given these restrictions and limited availability, many individuals opt to live under less stable conditions—in their vehicles, with friends or family, or on the streets.

Transportation Challenges

Most EDs offer a range of transportation options for patients at the time of discharge, including public transit assistance, taxi, rideshare, shuttle service, and medical transportation. This is the perfect time to make sure that patients understand their transportation options to obtain follow-up appointments.

Health plans often have transportation benefits included. Medicaid is legally required to provide nonemergency transportation for patients. Ensuring patients understand how to use this service can decrease barriers to transportation, improve adherence to follow-up, result in improved health outcomes, and lead to significant savings.[56] Those who are having trouble accessing required benefits should contact legal services.

Health facilities either provide patients with transportation vouchers in partnership with local providers or let providers know that the patient would benefit from transportation assistance. The vouchers can be for public transportation, taxis, or rideshare programs such as Lyft. Some health facilities have taken on this approach[57] while others have created shuttle services or used volunteer drivers to address the challenge of transportation.[58]

Immigration Status

Adjustment of Status

For those who are without legal status, there are several options for adjusting status. A family-based petition process is available if there is a family member who is a US citizen to adjust their status and become a legal permanent resident (green card holder). However, initial entry to the United States without permission may require the petitioner to leave the United States for up to 10 years prior to reentering even if they qualify for a green card. Petitioning for and support by an employer for a green card is also an option.[59] A number of other special categories that qualify a petitioner for legal status can be found on the US Citizenship and Immigration Services (USCIS) website (https://www.uscis.gov/citizenship). Immigration is a complex issue, and individuals with immigration questions should be connected to the local bar association to work with a qualified attorney.

Victims of Violence and Crime

Interpersonal violence is an important cause of morbidity and mortality. For further discussion of this issue, please see the chapters on community violence and intimate partner violence and abuse (see Chapters 190 and 192). Clinicians can work with social services to help victims in reporting their crime to law enforcement and to ensure a safe ED discharge plan. Furthermore, victims of interpersonal violence may be eligible for a temporary or permanent restraining order as part of their safety plan. Courthouse self-help centers and legal aid organizations can help victims apply for a restraining order. Regarding financial assistance for victims of violence, any victim (and their families) are eligible for the Crime Victims Fund established by the Victims of Crime Act of 1984. This fund is managed by the Office for Victims of Crime and administered by each state.[60] For those victims who are without legal status, cooperating with law enforcement to investigate and/or prosecute the crime may allow the individual to apply for a special visa or to become a legal permanent resident (green card holder)

Victims of violence and crime are especially vulnerable when they are without legal immigration status because their abusers may threaten to report them to immigration officials as a deterrent to reporting the crime and seeking help. Victims of intimate partner violence can adjust their status and apply to become legal permanent residents (green card holder) through either the federal Violence Against Women Act (VAWA)[61] or the Victims of Criminal Activity U Nonimmigrant Status (U Visa),[62] as long as the victims make a police report and cooperate with law enforcement to investigate and prosecute the crime. Those who are the victims or witness to other crimes, including but not limited to assault, rape, kidnapping, and blackmail, are also eligible for the U Visa.[63]

Those who are victims of sex or labor trafficking and/or who are certain family members of these victims are eligible to apply for the T nonimmigrant status as long as they cooperate with law enforcement to investigate and/or prosecute the crime[64] (see Chapter 187).

Although complicated, a path to legalization and citizenship for these vulnerable patients is possible. Ensuring appropriate documentation such as police reports, discussing options with social work, and ensuring connection to a local legal services provider are all important next steps of which the emergency clinician should be aware.

Refugees and Asylees

Refugees are individuals who have been persecuted or fear that they will be persecuted based on their race, religion, nationality, political opinions, or membership in a particular social group who seek refugee status from outside of the United States. Asylees are individuals who are already in the United States, or those who are actively seeking to enter the United States and meet the definition of a refugee. If asylees do not have legal status, they can apply for adjustment of status through USCIS (recommended to do so with an attorney's help).[65]

Asylees under 21 years of age who are seen in the ED may qualify for Special Immigrant Juvenile Status. To qualify to apply through USCIS (recommended to do so with an attorney's help), the individual must be currently unmarried, cannot be reunited with parents because of abuse, abandonment, neglect or other similar reasons, and cannot in their best interest return to the country of nationality.[66]

Hospital Safe Spaces Initiatives

Immigrants often fear seeking medical care because of confusion caused by complicated and ever-changing immigration policies.[67] Educating patients that the ED and hospital are safe spaces where providers are focused on treating health and will not report patients to the USCIS is crucial to ensuring that patients seek care in a timely manner. Providers should respect patient privacy and not disclose patient information unless served with a valid warrant. Any questions that arise should be deferred to the hospital's legal counsel and the administrator on duty.

Immigration Status and Public Charge

The idea of becoming a "public charge" or one who is reliant on public benefits, has caused fear and hesitation among immigrant communities to seek care.[68] Although applying for and receiving certain public benefit programs *may* make one a public charge, seeking and receiving health care services never does. However, for the undocumented individual, eligibility to receive public benefits is impermissible unless the specific exceptions are met. Individuals should be reassured that obtaining health care never makes them a public charge and providers should refer them to a legal services attorney to evaluate their individual case and public benefits.

Education-Related Challenges

For youth with school-related concerns regarding truancy, suspension and expulsion, or with respect to reasonable accommodation with an Individualized Education Plan (IEP), clinicians can connect the youth and their parents or guardians to an attorney specializing in education law. Connecting with the local bar association is one way to find low-cost or no-cost attorneys who specialize in education law.

For adults, connection to the local community college or other special adult education programs allows for exploration of affordable educational options.

TABLE 189.2 Health Harming Legal Needs

Health Harming Legal Needs Categories	Specific Needs
Housing	Eviction, Section 8 voucher termination/denial, habitability, discrimination, reasonable accommodation
Employment	Improper termination, discrimination, unpaid wages, unpaid overtime, lack of breaks/meals/accommodation
Family	Divorce, custody, child support, restraining orders, guardianship, adoption
Immigration	Adjustment of status (family-based, employment based, U-Visa, T-Visa, VAWA, SJIS, asylee/refugee), naturalization, deportation defense
Healthcare Benefits	Denial/termination of coverage (Medicaid, Medicare, other insurance), denial of specific benefits, lack of timely access, medical debt/charity care/negotiating a payment plan
Other Public Benefits	Denial/termination of TANF, VA benefits, SSI, SSDI, SNAP, IHS, unemployment, short term disability, other cash aid; overpayments; improper amount of benefit
Consumer	Debt, fraud
Elder	Advanced directives, conservatorship, wills and trusts
Justice-Involved	Expungement, tickets, warrants,
Miscellaneous	Name change, gender change

Domestic Concerns and Social Isolation

Troubled family dynamics and relationships can be a source of stress and lead to ED visits and poor health.[69] In most jurisdictions, emergency providers are required to report cases of suspected child or elder abuse. Patients may face challenges with marriage and children. If there is no intimate partner violence, then a referral to the local legal services agency, courthouse, and/or bar association can help patients access resources to resolve these concerns.

Patients are sometimes dropped off in the ED because family members are unable to care for them. Medicaid offers in-home support services (IHSS) as part of its benefit to help individuals remain in the least restrictive environment. This is often an option for elders or disabled patients. The local social service agency may provide some assistance with childcare as part of its Temporary Assistance for Needy Families (TANF) benefit.

Elders and their families may request assistance with creating an advanced directive. In addition to assisting patients and their families fill out the portable medical order (POLST) form, caregivers can refer patients to the local bar association for assistance. Providers may see patients who feel socially isolated. Working with social work and local agencies can provide options such as day programs for elders and support groups for individuals with special needs.

Legal Concerns

Legal Assistance

Reduced cost or free legal services are available to help low-income individuals with issues such as public benefits, housing, and family law (Table 189.2). Many of the nonprofit legal services providers who offer low-cost or free legal services programs are federally funded.[70] For issues that legal aid providers do not assist with, clinicians can refer patients to the local bar association for help.

Medical legal partnerships are arrangements that place attorneys into the health care setting to work as part of the health care team.[71] These attorneys can be hired by the health care team directly or come from local nonprofit legal services organizations. They work with the health care team to address health-harming legal needs. The co-location and communication allows the provider to make the legal team part of the treatment plan while the legal team works with the provider to demonstrate the health harm that patients are suffering.

Patients in Police Custody

Clinicians often care for patients who are in police custody, where there is a significant power imbalance between the patient and law enforcement. It is often difficult for patients in custody to obtain health care, so providers should ensure thorough medical assessments are performed in this vulnerable patient population where routine care is limited.[72] Best practices support patient interviews in private, clear communication of results, and follow-up instructions clearly documented in discharge instructions confidentially communicated to the correctional facility's health care staff. Any physical or medical limitations for the patient should be communicated to accompanying officers.

To avoid conflict between the emergency clinician and law enforcement officials when the question of blood draws for legal purposes arises, policies should be in place to allow providers to respect patient autonomy. This will help the clinician avoid the difficult legal circumstance of having to choose between either defying a request from law enforcement or being potentially liable for assault.

Tickets and Outstanding Warrants

Patients who are not in custody may have concerns about unpaid tickets and outstanding warrants. These public records may make it difficult for them to access housing or jobs. Such concerns are becoming more prevalent as jurisdictions criminalize homelessness and poverty with laws such as the sit-lie laws that prohibit sitting or lying on the sidewalk or in other public spaces. Referral to local legal services providers can allow patients to receive an evaluation and potentially address these concerns.

CHAPTER 189: QUESTIONS AND ANSWERS

1. Which of the following statements regarding social determinants of health (SDOH) is true?
   - **a.** Less than 20% of health outcomes can be attributed to SDOH.
   - **b.** SDOH equally impacts all segments of the US population regardless of income.
   - **c.** Immigration status is not considered a SDOH.
   - **d.** Health literacy is one of the most significant aspects of SDOH.

Answer: D. Patients may have limited health literacy, which is defined as limited capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions may have poorer adherence to care plans and poorer health outcomes. An estimated 20% of a patient's health outcome is influenced by medical care, whereas social and economic factors account for 50% of such outcomes. Social concerns disproportionately affect the poor and impede health. Immigration as an experience has profound effects on individuals and their health. Immigration status has an important effect on patients for two reasons—immigration status is linked to ability to work and to access public benefits, including health care.

2. Which of the following factors impact health outcomes?
   - **a.** Access to transportation
   - **b.** Homelessness and housing
   - **c.** Food insecurity
   - **d.** Income and insurance
   - **e.** All of the above

Answer: E. Access to transportation affects an individual's ability to access care, adhere to appointments, and carry out treatment plans, having a direct impact on health. These individuals have worse health outcomes and mortality compared with those who are housed. Delayed care is a common issue that arises in the ED as uninsured and underinsured patients often are unable to access care prior to an ED visit. Lack of access to healthy foods leads to increased rates of mental health problems, low birth weight, depression, hypertension, diabetes, and hyperlipidemia.

3. Which of the following ED-based strategies can counteract SDOH?
   - **a.** Systematic screening in the emergency department can be a significant step in recognizing patients with significant SDOH.
   - **b.** Addressing SDOH must occur only within the health care system for the strategy to be successful.
   - **c.** Addressing concerns of health literacy first will substantively impact health outcomes by improving patients' failure to comply with follow-up care instructions and access to community resources.
   - **d.** Violence prevention is not a reasonable strategy in combating poor outcomes due to SDOH.

Answer: A. Most departments do not currently screen for social needs. Instead, social needs arise during the course of the patient encounter. Options for systematic screening exist but require implementing a framework to address social needs.

4. Which of following health-related benefits available in the United States can impact access to care and health outcomes?
   - **a.** Children's Health Insurance Program (CHIP) is a specific program focused on providing access to care for children up to age 26.
   - **b.** The Affordable Care Act requires plans and issuers that offer dependent child coverage to make coverage available until the child reaches the age of 21.
   - **c.** The Hill-Burton Act of 1946 mandates charity care obligations for facilities that benefited from the funding.
   - **d.** Part A Medicare benefits are essential to supporting prescription drug coverage.

Answer: C. Facilities built with assistance from the Hill-Burton Act of 1946 have legally mandated charity care obligations. There are specific programs focused on providing access to care for children under the age of 18, including the Children's Health Insurance Program (CHIP). The Affordable Care Act requires plans and issuers that offer dependent child coverage to make coverage available until the child reaches the age of 26. Medicare is administered and funded by the federal government and contains several parts including inpatient hospital coverage (Part A), outpatient medical coverage (Part B), alternative coverage options including Medicare Advantage (Part C), and prescription drug coverage (Part D).

5. Which of the following statements regarding legal services available to ED patients is true?
   - **a.** Legal services are typically unhelpful in increasing access to health care coverage but are invaluable in supporting immigration status adjustments.
   - **b.** A public charge applies to anyone seeking health care services, so referral to legal services is essential to evaluate individual cases and public benefits.
   - **c.** In managing family and domestic concerns, referral to legal services should only occur if there is evidence of intimate partner violence or elder abuse.
   - **d.** Heath-harming legal needs are defined as a group of legal factors that can adversely impact health outcomes.

Answer: D. Legal services are typically helpful in a wide variety of circumstances and address what may be considered health-harming legal needs. The idea of becoming a "public charge," or one who is reliant on public benefits, has caused fear and hesitation among immigrant communities to seek care. While applying for and receiving certain public benefit programs *may* make one a public charge, seeking and receiving health care services never does. However, for the undocumented individual, eligibility to receive public benefits is impermissible unless the specific exceptions are met. Family dynamics and relationships can be a source of stress and lead to emergency department visits and poor health. Addressing challenges can improve health for patients. Patients may face challenges with marriage and children. If there is no intimate partner violence, then a referral to the local legal services agency, courthouse, and/or bar association can help patients access resources to resolve these concerns.

Community Violence

Theodore Corbin and Thea James

KEY CONCEPTS

- It is important for prevention efforts, including those in hospitals and emergency departments, to consider unjust social conditions disproportionately experienced by minority communities, and especially by African Americans; these include generational poverty, residential segregation, and other forms of racism that limit opportunities to grow up in healthy and violence-free environments.
- Interventions should focus on altering the quality of life course for survivors of violence through targeting their total wellness and thriving through employment, education, financial stability and economic mobility, independence, and stable emotional health.
- Hospital based violence intervention programs (HVIPs) that incorporate at least some brief intervention and case management demonstrate HVIP cost-effectiveness with decreases in injury recidivism.

FOUNDATIONS

Population Characteristics and Violence

Young adults and adolescents in the United States (US) are exposed to crime and violence at much higher rates than those in other developed nations.[1] Rates of violence in the United States also vary by location, with higher homicide rates in metropolitan communities compared to suburban or rural areas.[2] Over 80% of the 12,979 firearm homicides in the United States in 2015 occurred in urban areas,[3] and disparities are larger in certain areas of large cities (e.g., racially and ethnically diverse neighborhoods). For instance, in Philadelphia's safest police district, which is approximately 85% white, there were no reports of anyone being killed by gun violence. Conversely, the most violent district, with a roughly 90% African American population, had over 180 shooting victims and 40 deaths.[4] African American youth in the United States disproportionately carry the largest burden of violent experiences. The homicide rate for African Americans in the United States is eight times higher than that of their white counterparts,[3] and African Americans are 500 times more likely to die this way.[5] While African American young adults and adolescents only make up about 2.4% of the US population, they are disproportionately victims of injuries from assault (26%) and homicide (20.7%).[3,6]

Contributing factors to these differences in rates of violence by location are rooted in historical, present day, and persistent structural racism (e.g., racial segregation), inequality, and poverty.[7] Structural barriers that impact present day rates of violence were established decades ago.[8-11] In the 1930s, President Franklin D. Roosevelt (FDR) created opportunities for wealth-building to help Americans recover from their financial losses in the 1929 Great Depression, securing home ownership through access to guaranteed financial services. In the same decade, FDR's administration established redlining, a practice with long-lasting effects that segregated America both racially and socioeconomically. Redlining policies drew red lines through cities across America, and residents living behind red lines were denied access to financial services (i.e., mortgages, loans, insurance companies) needed for wealth-building through home ownership and the benefits of home equity. A majority of people living behind red lines were people of color and low income. Redlining policies established two distinct socioeconomic populations that still exist today.[8-11] Communities located behind historic red lines have lower rates of education attainment, income, and life expectancy, and higher rates of homicide.[9,12,13] In general, populations in these communities have lower rates of health, as do their children[12] as beneficiaries of their parents' limited resources.[14]

Community Violence

Community violence is a complex and persistent health issue that disproportionately affects low-income neighborhoods and communities of color in the United States. Community violence occurs primarily in public settings, occurs between individuals or groups who may or may not know each other, and is often an impulsive or loosely planned act.[15] The effects of community violence are severe and often result in injuries or death. Both those who contribute to and are survivors of community violence are disproportionately young men and adolescent males from historically disadvantaged backgrounds and communities.[15] Analysis of 2017 data from the National Vital Statistics System, National Crime Victimization Survey, and the Youth Risk Behavior Surveillance System concluded that African American young adults and adolescents are at a much greater risk of violence (e.g., homicides, fights with injuries, aggravated assaults) compared to their white counterparts.[16] Furthermore, the frequency of exposure to community violence is higher in large urban cities and within impoverished communities. There is an overrepresentation of racial minorities, especially African American males, among youth who live in these communities and are disproportionately exposed to violence.[17]

Further exacerbating community violence is the lack of economic growth in an area, further contributing to the cycle of urban flight. For instance, there is slower growth in businesses, new retail, and a depreciation of home values in communities with higher rates of violence.[18] Families of victims and survivors of gun violence often experience financial stress, such as having challenges in paying rent, bills, and phone services because of the loss in earnings from employment and medical costs.[19] Exposure to community violence can be very traumatic for individuals and contributes to poor health among African American young adults and adolescents. Community violence exposure has been found to be associated with an increase in psychological health problems, including posttraumatic stress disorder, depression or anxiety, and aggression.[17] Alarmingly, the disproportionate impact of violence on young African Americans comes from forms of violence

having the greatest immediate negative consequences on physical and mental health, such as aggravated assault and homicide.

SPECIFIC ISSUES

Root Causes of Community Violence

Since the first Africans were brought to the United States, African Americans were forced to live in poor physical and social conditions. For over 250 years, enslaved African Americans suffered social, physical, and mental abuse and brutalization. Although slavery has ended, African Americans still live in a country that is unjust, and one that has systemically discriminated against and oppressed them. Slavery and present day structural and institutionalized racism have contributed to the poor health among African Americans.[20] African Americans in the United States are exposed to constant racism that is systemic (organized socially and culturally) through exclusion, prejudice, and discrimination.[21] Racism is also correlated with second-rate employment, housing, education, income, and access to health services. Racism is a factor in health disparities and inequities that is not explained by other demographic factors such as age, gender, and educational attainment.[21] Due to their lower socioeconomic status, racial or ethnic minorities suffer disproportionate risks for poor health outcomes: occupational hazards, exposures to toxic substances and allergens in the home, low-quality schooling, and lack of availability of healthy foods.[20] While these risk factors are not clinical in nature, they make up the social determinants of health which includes factors such as race/racism, poverty, education, housing, access to healthy food, environmental exposures, violence, and gender. Compared to their white counterparts, proportionately fewer African Americans in the United States graduate from high school or earn a college degree,[22] and they are more than two times as likely to be unemployed.[23,24] The social determinants of health predict the health needs of a population, and the health risks, much more than clinical care.[20]

African Americans, through poverty and residential segregation, live in some of the poorest neighborhoods throughout the United States, areas with high rates of homicide.[20] Violence influences health greatly and can cause injury, disability, and preventable death. African American youth are more than four times more likely to die from a gunshot wound than their white counterparts.[20] African American children are much more likely to witness violence and 20 times more likely to witness a murder than their white counterparts.[25]

Race or ethnicity alone are not risk factors for violence, but rather are associated with socioeconomic risk factors for violence.[26] Therefore, it is important for prevention efforts, including those in hospitals and emergency departments, to consider unjust social conditions that are disproportionately experienced by minorities, and especially African Americans, including generational poverty, residential segregation, and other forms of racism that limit opportunities to grow up in healthy and violence-free environments. Addressing these conditions is critical to lessening and eliminating violence exposure among African American and other minority and vulnerable communities.[16]

Psychological and Mental Health

Trauma has been defined as an emotional response to a distressing event, such as an accident, rape, violent attack, or natural disaster.[27] Trauma can invoke long-term reactions and adverse effects such as flashbacks to the traumatic event, unpredictable emotions, poor mental, physical, social, emotional, or spiritual well-being.[27,28] Experiencing traumatic events or chronic traumatic events, such as exposure to community violence, is also associated with traumatic stress reactions that include fear, anger, sadness, shame, guilt, aggression, and behavioral health issues.[29-33]

The physical and mental health consequences of experiencing violence over time can lead to the development of preventable chronic conditions and can result in considerable health burdens and costs, lower quality of life, and lost productivity.[34] Racial and ethnic minorities, particularly African American young adults and adolescents in urban areas, are experiencing trauma from community violence at levels that impede their ability to cope in healthful ways.[35] The stressful and traumatic events from community violence contribute negatively to mental health and overall quality of life through emotional changes, and this is also passed on through generations. With poverty and high exposure to racism and discrimination, African Americans suffer from more frequent and intense poor mental and behavioral health compared to their white counterparts.[36]

Disparities in Access to Mental Health Care Services and Treatment

Community violence disproportionately persists in communities of color. Also disproportionately impacting African American young men and adolescents, exposure to community violence is negatively associated with psychological and behavioral health issues. Disparities in access to and utilization of mental health care services among African Americans and Latinos stem from limited access, mistrust, stigma, misdiagnosis, little understanding about mental illness, and feeling culturally misunderstood.[37-38] Shame, ridicule from peers, mistrust of health care service providers, and mental health stigma can deter African American young men and adolescents from receiving mental health treatment.[39] One study observed that African American parents were much less likely to seek mental health care services for their children if they themselves held high levels of stigma towards mental health.[40] Furthermore, uninsured African Americans with depression are less likely to be prescribed antidepressants compared to those who are insured, and those who are insured are still less likely to be prescribed medications compared to their white counterparts.[41]

PHYSICAL TRAUMA FROM VIOLENT INJURY AND THE ROLE OF HOSPITALS, EMERGENCY DEPARTMENTS, AND TRAUMA CENTERS

Victims of interpersonal violence may experience traumatic physical injuries and seek treatment from hospitals, emergency departments (EDs), and trauma centers. The vast majority of these centers focus almost exclusively on stabilizing patients, and clinicians in these settings may not recognize the importance of assessing psychological and mental health issues that victims may experience post-injury. Most trauma centers are not equipped with the resources, staff, and systematic approach to identify and address the social factors that contribute to persistent community violence among the patient populations they serve.[42] Individuals who are victims of interpersonal violence and have exposure to community violence are more at risk for recurrent trauma.[43] Health care providers that care for victims of physical injury have an opportunity to incorporate violence prevention into their care. With emerging acceptance that violence is structural in the United States, emergency and trauma physicians have been inspired to participate in the reduction of violence through prevention and intervention efforts.[44-47]

Hospital-Based Violence Intervention Programs

The first hospital-based violence intervention programs (HVIPs) in the United States were developed in the 1990s: the "Caught in the Crossfire" program in Oakland, California, and Project Ujima in Milwaukee, Wisconsin.[42] Since then, several HVIPs have been developed and implemented in the United States with the National Network of Hospital-Based

Violence Intervention Programs, now known as the Health Alliance for Violence Intervention (HAVI).[48] According to Rosenblatt et al., several fundamental principles of HVIPs include the following:

> *"1) Violence is preventable,*
>
> *2) Hospitals should use public health-based principles to approach violence prevention, including working to address the following in the patients and communities they serve: poor education, lack of job opportunities, injury and criminal recidivism, socioeconomically deprived neighborhoods, substance abuse, complex posttraumatic stress disorder, lack of positive role models,*
>
> *3) There is a 'teachable' moment during which a patient may be more receptive to psychological first aid and prevention principles following a traumatic injury, and*
>
> *4) Intervention will begin in the hospital but must follow the patient and family into their community. Case management principles are implemented, ideally including professionals with therapeutic skill sets and 'credible messengers' with knowledge of the patient population."*[42]

Several studies have suggested that HVIPs are beneficial for patients who are exposed to community violence and who are survivors of interpersonal violence. A recent review found that HVIP programs that incorporate case management and at least some brief intervention observed decreases in recidivism, and that HVIPs are cost-effective. Furthermore, it must be emphasized that social determinants such as health, stable housing, and increase in income are important components to include in HVIPs.[49,50,51] Several studies have shown that HIVPs can decrease the reinjury rates of participants by up to 50% and that even applying a brief intervention to reduce violence among youth (ages 14 to 20) was associated with increased self-efficacy for avoiding fighting and a decrease in aggression frequency.[52,53]

It is feasible to integrate health data on violence and other patient characteristics (e.g., social determinants of health information) into ED electronic medical records across institutions, with minimal impact on workflow and triage times, to collectively gather data on violence and aid in public health surveillance of community violence data trends.[54] Organizations such as the Centers for Disease Control and Prevention could then use this data to fund HVIPs where they are needed the most.[55]

HVIPs can also incorporate digital health tools. One study of a technology-augmented violence and depression intervention tool for high-risk adolescents found a high level of acceptance among participants, who experienced less depression and less subsequent violence compared to the control group.[56]

Peers and community members with similar lived experiences as victims of violence should be included in the process of operating an HVIP. This approach has been effective for EDs trying to understand how their HVIP can improve the lives of individuals experiencing violence in their communities.[57,58] An HVIP housed at Drexel University in Philadelphia has an ongoing evaluation that assesses delivery of services and trauma symptom reduction. Preliminarily, the HVIP demonstrates that the services provided by the team decrease trauma symptoms. Using a focus on structural determinants of health to mitigate and eliminate gaps to thriving, HVIPs have served as models for health care systems aiming to sustainably reduce costs and improve health outcomes in the communities they serve.[59,60]

Boston University HVIP Model

A Boston University emergency medicine–based HVIP began with a "no assumptions" approach to building its program. The program engaged survivors of violence to help understand the root causes of the city's disproportionate geographic prevalence of community violence. Knowledge of the structural barriers in communities, and in their patients' lived experiences, shaped expectations of what was possible for them to achieve.[8] The program learned that its patients who were survivors of violence were coming from communities that had been disinvested in for decades and predictably experienced low income, education attainment, economic mobility, and opportunities to build wealth. These communities were among those negatively affected historically by redlining policies.[10] The Boston HVIP survivors of violence expressed overwhelming themes of hopelessness.

Guided by intervention models of the network of HVIPs nationally,[11] the Boston HVIP program made a conscious decision to set high bars to alter the quality of life course for their patients through intentional disruption of structural barriers. The program encouraged survivors of violence to identify their goals and then partnered with them to achieve those goals. Common goals were education, steady employment, stable housing, and safety. The program hired and embedded a career specialist for workforce development, hired a housing advocate, and expanded its multisector community partnerships in workforce development, financial literacy, education, and housing.

The Boston HVIP's hospital health care system is now using the same model expanded to all patients. This occurred in large part to a charge by its largest payer, Massachusetts Medicaid or Mass Health, in 2018. Its hospital health care system is the largest recipient of Medicaid payments in Massachusetts. Mass Health addressed its decadelong upward trajectory of rising costs and poor health outcomes by changing from a fee-for-service to value-based care reimbursement. It charged Boston health care systems, who are Medicaid payees, to lower cost and improve outcomes prescriptively by focusing on social determinants of health. HVIPs have years of experience in this area.

The Boston HVIP's hospital health care system is now using an HVIP model to alter life course for all patients. Examples of how the Boston HVIP hospital has targeted structural barriers to health to alter the quality of life course of its patients and communities where they live include the following:

1. Development and operationalization of a screening tool in ambulatory clinics that identifies gaps people have, and connects them to resources to mitigate and eliminate the gaps; the tool is embedded in their electronic medical record for providers to see. A built analytics platform evaluates and monitors results monthly.
2. The hospital joined the Healthcare Anchor Network, a national collaboration of 45 health care systems. Their goal is to build more inclusive local economies through hospitals being intentional about how they make daily decisions in three pillars; hiring, investment, and procurement.[12]
3. Invested in a private equity fund that explicitly funds developments that provide access to affordable housing, employment, green walking space, transit, and healthy affordable food.[13,14]

a. The investment contributed to what is becoming 323 units of new mixed-income housing to own and to rent.
b. Seventy percent of laborers at the construction site come from the community.
c. The hospital was able to help a grocery store mitigate expansion costs of moving to the site by giving it a no interest loan.

4. The hospital invested to support a local organization that invests in local small business development.
5. The hospital health care system expanded its procurement operations to include more local vendors. It built an analytics platform to monitor and evaluate progress.
6. The Affordable Care Act requires hospitals to conduct a community health needs assessment with an improvement plan every

three years. In 2019, the Boston hospitals conducted an assessment together. Prioritized improvement plan areas that emerged from the assessment are housing, finance and economic mobility, access, and behavioral health. The hospitals will collectively address the first two domains in communities with goals to have measurable impact.[60]

7. The Boston HVIP hospital created an innovative Stable Housing Initiative.[59] Subsequently, two other Boston academic medical centers joined them and together they have partnered and invested in innovative solutions to housing instability.

The HVIP model of altering quality of life course has served as a proof of concept for all patients who face perpetual life and health instability due to structural barriers.

CHAPTER 190: QUESTIONS AND ANSWERS

1. Which of the following statements correctly describes a difference between uninsured African American (AA) patients and uninsured white patients with depression?
- **a.** AA patients are less likely to be prescribed antidepressants.
- **b.** AA patients are less likely to be diagnosed with depression.
- **c.** AA patients are more likely to think about suicide.
- **d.** AA patients are less likely to need ongoing therapy.

Answer: A. A study observed that African American parents were much less likely to seek mental health care services for their children if they themselves held high levels of stigma towards mental health.[40] Furthermore, uninsured African Americans with depression are less likely to be prescribed antidepressants compared to those who are insured, and those who are insured are still less likely to be prescribed medications compared to their white counterparts.[41]

2. Which of the following statements is true regarding individuals who are survivors of interpersonal violence and are exposed to community violence?
- **a.** They are more at risk for reinjury/trauma recidivism.
- **b.** They are less at risk for retaliation.
- **c.** They are more likely to receive follow-up care.
- **d.** They are less likely to seek psychological support.

Answer: A and D. Victims of interpersonal violence may experience traumatic physical injuries and may seek treatment from hospitals/emergency departments/trauma centers. The vast majority of these centers focus exclusively on stabilizing patients and clinicians in these settings may not recognize the important of assessing psychological and mental health issues victims may be experiencing post-injury. Most trauma centers are not equipped with the resources, staff, and systematic approach to identify and address the social factors that contribute to persistent community violence among the patient population they serve.[42] Individuals who are victims of interpersonal violence and have exposure to community violence are more at risk for reinjury/trauma recidivism.[43] Furthermore, discrimination and limited access to mental health facilities increase disparities in mental health for communities of color.[38]

3. Which of the following young populations is most at risk for poor physical and mental health outcomes from exposure to physical violence (e.g., homicide and aggravated assault)?
- **a.** Men
- **b.** Women
- **c.** African Americans
- **d.** Latino Americans

Answer: C. African American youth in the United States disproportionately carry the largest burden of violence experiences in general. The homicide rate for African Americans in the United States is eight times higher than that of their white counterparts[3] and African Americans are 500 times more likely to die this way.[5] African American young adults and adolescents only make up about 2.4% of the US population, but they are disproportionately victims of injuries from assault (26%) and homicide (20.7%).[3,6]

4. According to Rosenblatt et al.,[42] several fundamental principles of HVIPs include all of the following except:
- **a.** Violence is not preventable, but it can be managed.
- **b.** Hospitals should use public health–based principles to approach violence prevention, including working to address poor education, lack of job opportunities, injury and criminal recidivism, socioeconomically deprived neighborhoods, substance abuse, complex posttraumatic stress disorder, and lack of positive role models.
- **c.** There is a "teachable" moment during which a patient may be more receptive to psychological first aid and prevention principles following a traumatic injury.
- **d.** Intervention will begin in the hospital but must follow the patient and family into their community. Case management principles are implemented, ideally including professionals with therapeutic skill sets and "credible messengers" with knowledge of the patient population.

Answer: A. Several fundamental principles of HVIPs include:

"**1.**Violence is preventable,

CHAPTER 190: QUESTIONS AND ANSWERS—cont'd

2. Hospitals should use public health-based principles to approach violence prevention, including working to address the following in the patients and communities they serve: poor education, lack of job opportunities, injury and criminal recidivism, socioeconomically deprived neighborhoods, substance abuse, complex posttraumatic stress disorder, lack of positive role models,
3. There is a 'teachable' moment during which a patient may be more receptive to psychological first aid and prevention principles following a traumatic injury, and
4. Intervention will begin in the hospital but must follow the patient and family into their community. Case management principles are implemented, ideally including professionals with therapeutic skill sets and 'credible messengers' with knowledge of the patient population."[42]

5. Racism is not correlated with which of the following factors?
   - **a.** Poor housing
   - **b.** Inferior education
   - **c.** Longer life
   - **d.** Access to health services

Answer: C. African Americans in the United States are exposed to constant racism that is systemic (organized socially and culturally) through exclusion, prejudice, and discrimination.[21] Racism is correlated with second-rate employment, housing, education, income, and access to health services. It is well known that racism is a factor in health disparities and inequities that is not explained by other demographic factors such as age, gender, and educational attainment.[21] Also, there are many risks for individuals who are racial or ethnic minorities such as occupational hazards, exposures to toxic substances and allergens in the home, low-quality schooling, and lack of availability of healthy foods.[20] While these risk factors are not clinical in nature, they make up the social determinants of health, which includes factors such as race/racism, poverty, education, housing, access to healthy food, environmental exposures, violence, and gender.

Sexual Assault

Jennie Alison Buchanan and Sarah Tolford Selby

KEY CONCEPTS

- Sexual assault is most common in women but can happen to gay and heterosexual men and to lesbian, gay, bisexual, transgender, and gender-nonconforming individuals.
- Sexual assault often results in no physical signs of injury.
- Optimal care includes creating a safe confidential environment while incorporating the principles of trauma-informed care. The patient should be included in decision making and ultimately decide treatment. Options include injury evaluation, treatment to prevent pregnancy and sexually transmitted infections (STIs), support and trauma counseling, evidence collection, and comprehensive toxicology testing if appropriate.
- The sexual assault evidence collection examination is an intensive, protocol-driven, multistep process, best performed by a certified sexual assault examiner.
- Adult sexual assault patients should be treated empirically according to Center for Disease Control (CDC) guidelines to prevent STIs (e.g., gonorrhea, syphilis, chlamydia, trichomonas, human immunodeficiency virus [HIV], human papillomavirus [HPV], and hepatitis B). Children and adolescents should be tested and, if symptoms develop, treated for STIs.
- All adolescent and adult female sexual assault patients should be offered pregnancy prophylaxis.
- HIV postexposure prophylaxis should be offered if the assailant is known to be HIV-positive, multiple assailants are involved, or if the HIV status of the assailant is unknown.
- Alcohol and drugs may have been ingested voluntarily or involuntarily by the patient. If the patient consents, comprehensive toxicology testing may be performed.
- A strangulation attempt with loss of consciousness, bowel and bladder incontinence, persistent voice changes, difficulty swallowing, or shortness of breath should be comprehensively evaluated in the emergency department (ED). Evaluation options include a chest x-ray, flexible laryngoscopy, and CTA or MRI of the neck. We recommend prolonged observation or hospital admission for persistent symptoms.
- Many victims will not have obvious physical injuries; this does not imply consent or refute a sexual assault.
- The emergency clinician should record observations, statements, and findings that were gathered during the course of ED treatment objectively.

FOUNDATIONS

Sexual assault is the deliberate act of sexual contact or behavior towards another person without that person's explicit consent. Rape is a form of *sexual assault* and is defined by the Federal Bureau of Investigation (FBI) as "penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim."[1] *Sexual assault* is a form of *sexual violence*. The term *sexual violence* is defined by the World Health Organization (WHO) as "any sexual act, attempt to obtain a sexual act, unwanted sexual comments or advances, or acts to traffic, or otherwise directed, against a person's sexuality using coercion, by any person regardless of relationship to the victim, in any setting, including but not limited to home and work."[2] Sexual assault is never the victim's fault and can lead to chronic physical and psychological adverse health effects.

According to the 2015 Centers for Disease Control and Prevention (CDC) National Intimate Partner and Sexual Violence Survey (NISVS), 43.6% of women and 24.8% of men have experienced some form of contact sexual violence in their lifetime.[3] During their lifetime, 1 in 5 women have been victims of completed or attempted rape and 1 in 14 men have been made (i.e., forced or threatened) to penetrate someone else (completed or attempted).[3]

National database estimates on nonfatal injuries treated in emergency departments (EDs) have revealed that 5.4% of all assault-related visits to the ED were for sexual assault.[4] Most of these victims were women. The lifetime prevalence of sexual assault for women and men respectively is 43.6% and 24.8%.[3] Male victims are often younger than their female counterparts with 26% of victimization occurring in males 10 years old or younger and 12.7% in females 10 or younger.[3] Given the prevalence and role in the evaluation and treatment of survivors of sexual assault, emergency clinicians should be comfortable evaluating, treating, and coordinating their care. In many areas, dedicated sexual assault teams or forensic examiners are available to assist with specialized care, detailed evidence collection, and thorough documentation. The team often includes a specialty-trained registered nurse, victims advocate, or social worker, and may involve local police or sexual assault detective(s). The emergency clinician's responsibilities include providing compassionate nonjudgmental care, diagnosing and treating acute injuries, administering medications to prevent pregnancy and sexually transmitted infections (STIs), offering forensic evidence collection and comprehensive toxicology testing when appropriate, and providing linkage to support and follow-up services.[4]

The ED evaluation and treatment can take hours and requires the coordination of multiple resources. Evaluation and treatment of the patient are nuanced, with intertwined medical, legal, and forensic components. Medical stabilization and evaluation take priority over forensic evaluation. The role of the emergency clinician is to objectively record information heard, observed, examined, or photographed. In many cases, a trained forensic examiner will be available to complete the formal forensic evidence collection process. The emergency clinician may be called to testify, sometimes years after the event, necessitating thorough and accurate documentation.

CLINICAL FEATURES

Many sexual assaults are never reported to police or health care providers. Victims who report to the police and who sustain injuries are more

likely to present to the ED for evaluation. Many victims present with concerns about injuries, risk of pregnancy, or contracting STIs (including human immunodeficiency virus [HIV] and hepatitis). Victims may present with mental health concerns, including depression, acute stress reaction, posttraumatic stress disorder (PTSD), and suicidal ideation. Acquaintance and intimate partner rape are less commonly reported to police and health care providers.[1,3] When these victims do present to the ED, they are more likely to present in a delayed manner, when medications to decrease pregnancy rates and STI transmission are less likely to be effective. Most patients who present to the ED with the complaint of sexual assault are women.[2,3] Although some studies have reported a similar age distribution for males and females, others have noted males are assaulted at a younger age (<9 years).[3] Populations at increased risk for sexual assault include the homeless, those with severe disabilities (e.g., serious injury, chronic disease, chronic mental health problems), incarcerated men and women, and the young.[1,5] Other populations at increased risk include college-aged women, non-heterosexuals, those who use illicit drugs and ethanol, and sex workers.[1,5]

Patients who come to the ED with the complaint of sexual assault or rape may present with injuries related to the assault, with general body injuries in up to 67%. It is not uncommon to have minimal or no genital injury from a rape. Genital findings depend on time to presentation, victim's age, parity, and methods used to evaluate for genital injury. Nonfatal strangulation, associated with rape, carries a risk of immediate and delayed psychological and medical sequelae, including airway obstruction, pulmonary edema, and vascular dissection leading to stroke. Nonfatal strangulation has also been associated with an increased risk of future lethality.

Rape can occur in the context of force or coercion or in the context of drug or alcohol ingestion. About 50% of all rapes are in the context of alcohol or drug ingestion, especially in the adolescent or college-aged population. Alcohol or drugs may have been ingested voluntarily by the victim or administered surreptitiously by the assailant. Comprehensive toxicology testing can be considered in those presenting within the specific jurisdiction's time limits (approximately 72–96 hours) but should be approached cautiously as false negatives are common.

Acute reactions to sexual assault vary and are influenced by prior sexual assault or trauma, events surrounding the assault, and preexisting mental health conditions. Victims may appear calm and collected, detached, agitated, angry, depressed, tearful, or anxious. Anger may be directed outwardly toward health care providers, making interactions between the patient and provider challenging. Victim advocates are helpful in supporting the patient and their reactions.

The neurochemical changes in the brain that occur in response to trauma can make recalling details difficult. Recall may be sporadic and disorganized but may become clearer with time and should not be construed as fabrication. Recent research has focused on the concept of tonic immobility, whereby the victim experiences paralysis, increased muscular rigidity, eye closing, and suppressed vocal cord activity in response to an extremely traumatic event. Increasing evidence has suggested that humans may respond this way to a life-threatening event when coupled with inescapability. Although tonic immobility may occur in any traumatic event, it is more common in victims of childhood sexual assault. Victims who report tonic immobility often experience increased feelings of guilt, are at increased risk of developing PTSD, and are much less likely to respond to pharmacologic mental health therapy.

DIFFERENTIAL DIAGNOSES

The purpose of the medical forensic sexual assault examination is to document history and physical findings and collect evidentiary material, not to determine whether or not a rape occurred. Final diagnosis and discharge instructions should avoid the words "rule out" and "alleged." Alternative medicolegal options may include "evaluation following sexual assault," or "sexual assault." As many as 71% of sexual assault victims sustain nongenital injuries. Fortunately, most injuries are minor and rarely require emergent medical or operative intervention. A majority of injuries are from blunt trauma and include contusions, lacerations, incised wounds, bruises, hematomas, sprains or strains, fractures, closed head injuries, intracranial injuries, and intra-abdominal injuries. Treatment of life-threatening injuries should follow advanced trauma life support (ATLS) protocol and take precedence over evidence collection.

BOX 191.1 Indications for Comprehensive Toxicology Screening[a]

- Period of unconsciousness
- Period of loss of motor control
- Amnesia or confused state with suspicion of sexual assault
- Patient suspicion or belief that she or he was drugged prior to or during sexual assault *and*
- Less than 72–96 hours since assault (depending on jurisdictional protocol)

[a]Toxicology screening should be approached with caution as false negatives are common.

DIAGNOSTIC TESTING

There are no specific diagnostic tests for sexual assault. Traumatic injuries should be evaluated per standard protocols. There is no test that can determine if a rape occurred; even visualization of sperm on wet mount by emergency clinicians is often inaccurate.

Sexually Transmitted Infections

Testing for STIs is controversial in adult sexual assault patients. Despite rape shield laws prohibiting the use of a victim's past sexual behavior in court cases, there remains concern that the presence of a preexisting STI may be used to discredit the victim's claim. Furthermore, STI prophylaxis is provided to sexual assault victims and, therefore, will treat any preexisting STIs. Proponents for testing cite public health concerns; identifying preexisting disease allows for notification of previous contacts.[1,2,3] In children, the presence of an STI can be conclusive proof of a sexual assault, and STI testing is uniformly recommended. We recommend testing adults for STIs if the patient complains of signs or symptoms of STIs or when the patient requests testing, along with routine testing of children and young adolescents.

Drug-Facilitated Sexual Assault

Drug-facilitated sexual assault (DFSA) occurs when alcohol or drugs are used to compromise a victim's ability to consent to sexual activity, inhibit the victim's ability to resist, and impair memory of the event. Alcohol is the most common drug used, but many other "drugs" are utilized including illicit agents, prescription medications, and over-the-counter substances. Comprehensive toxicology testing, often performed in specialized forensic laboratories, is recommended in cases of suspected DFSA and can test for multiple illicit, prescription, and over-the-counter substances. The most commonly detected substances include ethanol, cannabinoids, cocaine, amphetamines, and benzodiazepines.[6] Box 191.1 lists symptoms and conditions suspicious for DFSA. Because many substances have a short half-life, toxicology testing should be performed expeditiously; most protocols obtain specimens up to 72 to 96 hours post-assault or after ingestion. Many jurisdictions have specific collection requirements and kits that are sent to comprehensive crime laboratories. At least 100 mL of urine and 12 mL of blood (sodium fluoride tube) should be collected,

and specimens refrigerated, with the chain of custod carefully maintained (Fig. 191.1).

Evaluating the Victim of Attempted Strangulation

Strangulation is a serious and potentially life-threatening injury. Intimate partner violence (IPV) survivors with nonfatal strangulation have a sevenfold increased risk of future completed homicide. Hypoxia is the final common pathway in strangulation and can occur by three main mechanisms—jugular vein occlusion, carotid artery occlusion, or laryngeal occlusion. Symptoms of dysphagia, odynophagia, and dysphonia may accompany physical findings, including facial, periorbital, auricular, intraoral, and neck petechiae (Fig. 191.2) and subconjunctival hemorrhages, the result of venous occlusion causing increased intravessel pressure and rupture. Other possible findings include bruising in the shape of fingerprints on the neck (Fig. 191.3), and defensive scratch marks on the neck from the victim attempting to pry off the assailant's fingers (Fig. 191.4). Alteration in consciousness, neurologic complaints, and urinary or fecal incontinence may result from restricted blood flow to the brain. Direct laryngeal injury may lead to vocal cord injury and laryngeal or hyoid fractures. Carotid artery injury, dissection, or intraluminal thrombosis may cause stroke symptoms, which may not present until months or years after the assault.[7]

We recommend imaging for patients with facial petechiae, loss of consciousness, incontinence, stroke-like symptoms, or voice changes. Imaging modalities and strategies for patient evaluation are listed in Tables 191.1 and 191.2.[7] Consider chest x-ray to evaluate for early pulmonary edema or aspiration pneumonitis, fiberoptic imaging to assess upper airway patency, and computed tomography angiography (CTA) or magnetic resonance imaging (MRI) to evaluate for arterial dissection (most commonly, carotid).[7] Patients with persistent altered levels of consciousness, laryngeal fractures, carotid injuries, or neurologic symptoms should be admitted for close airway monitoring. We recommend that patients with reported loss of consciousness, incontinence, facial or conjunctival petechiae, or signs and symptoms of soft tissue neck injury, or who are under the influence of drugs or alcohol, be observed and monitored for delayed sequelae of injury. Patients with no loss of consciousness, minimal or no physical findings, no intoxication, and a safe discharge environment can be discharged with precautions relating to signs of delayed neurologic, pulmonary or laryngeal sequelae from strangulation.

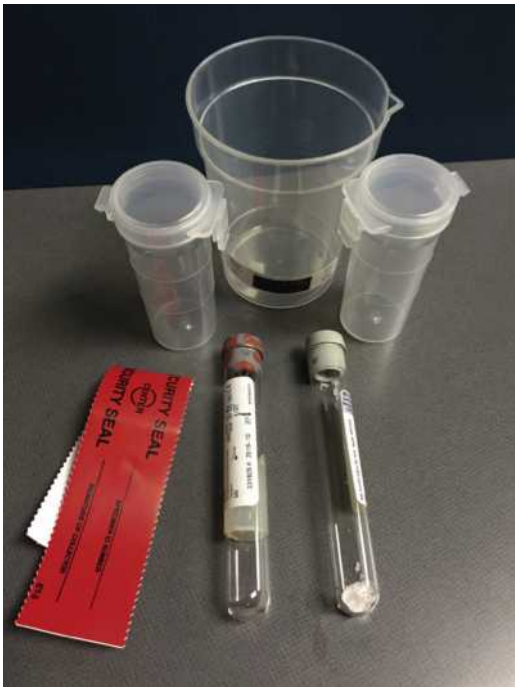

Fig. 191.1 Example of a forensic toxicology test kit for urine and serum specimens.

MANAGEMENT

Management of the sexually assaulted patient requires an organized victim-centered and trauma-informed approach, defined by institutional protocols and available support resources. In most cases, a sexual assault nurse examiner (SANE) or sexual assault forensic examiner (SAFE) will perform the evidentiary examination. Most hospitals should have a protocol concerning the activation of a sexual assault response team (SART), which includes a SANE/SAFE, social worker, and victim's advocate. If there is no SART available at the hospital,

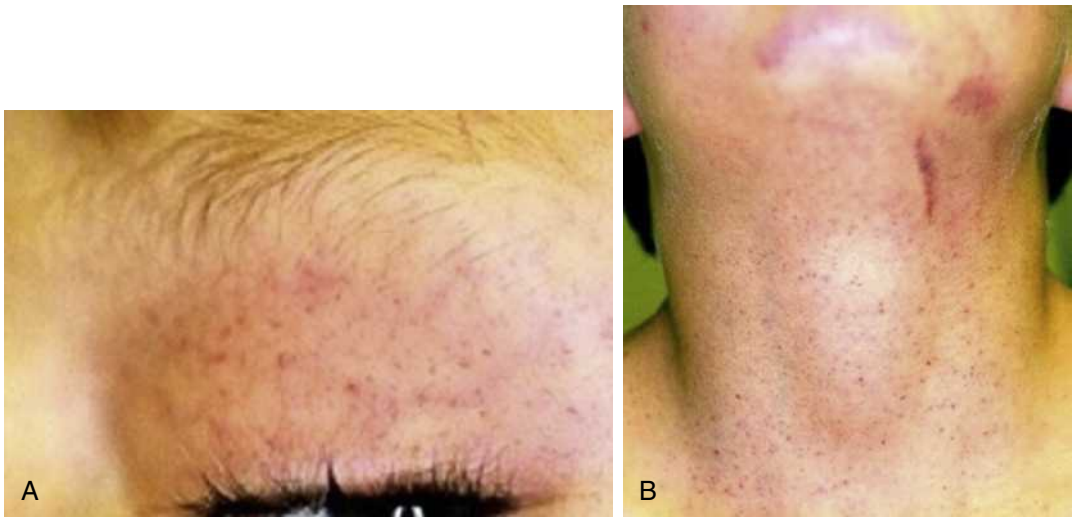

Fig. 191.2 Petechiae in nonfatal strangulation. (A) Eyelid petechiae following the nonfatal strangulation of a child. (B) Neck petechiae seen in the same patient. There is also an abrasion present on the left side of the neck and ecchymosis of the left and right mandibles. (Courtesy Training Institute on Strangulation Prevention, San Diego, CA; used with permission.)

Fig. 191.3 Neck bruising in nonfatal strangulation. (A) Circular neck bruising following manual strangulation. This injury is referred to as a fingertip bruise. (B) Other bruises of the neck on the same patient, most likely made by the assailant's fingers.

the American College of Emergency Physicians supports the triage of medically stable sexual assault victims to designated examination facilities for evidence collection by specially educated and clinically trained personnel.[7-9]

On arrival to the ED, the sexual assault patient should be triaged and placed in a private area or examination room. The SART should be mobilized, and depending on department protocol and patient complaints, the patient may or may not be evaluated by the emergency clinician immediately. The goal of the history is to rule out potentially serious injury, determine which medications are needed for prophylaxis, and decipher if the patient is in the time range for evidence collection; however, if there is a question, we recommend contacting the SART team. Some questions include the following:

- When did it happen?
- What types of assault occurred?
- Where did penetration occur?
- Were any objects used during the assault?
- Have there been symptoms since the assault?
- Was there loss of memory, incoordination, or suspicion for drug-facilitated sexual assault?

As with any ED patient, providers should elicit the patient's medical complaints, past medical history, current medications, allergies, and last menstrual period.

Fig. 191.4 Claw marks in nonfatal strangulation. The patient caused these injuries as she attempted to pry the assailant's hands off of her neck. (Courtesy Training Institute on Strangulation Prevention, San Diego, CA; used with permission.)

Medical Forensic Examination

The medical forensic examination should be organized, coordinated, and the patient should be informed of all steps during the exam. The examination can be conducted up to 7 days following assault, depending on jurisdiction policy, with most using 5 days as an evidentiary cutoff.[8-9] In cases of oral and anal assault, evidence is usually not collected more than 24 hours after the assault. In vaginal assaults, DNA and sperm may be recovered from the cervix up to 120 hours (5 days) later. Evidence is collected using a jurisdictionally specific sexual assault evidence kit or physical evidence recovery kit (rape kit). This kit contains all the supplies necessary to collect and properly store recovered evidence (Fig. 191.5).

The patient should consent to the examination and collection of evidence, forensic photography, and their decision on reporting to law enforcement (Fig. 191.6). The consent process begins with the forensic examiner explaining the purpose of the examination, steps, and process involved. The forensic examination process should proceed only after the patient has a thorough understanding of the examination process and has consented. The patient has the right to decline any or all parts of the examination and can revoke or change that consent at any time during the process—this is their decision and right and should be reinforced to the patient who may feel vulnerable after a sexual assault. The Violence Against Women Act (VAWA) creates and supports comprehensive, cost-effective responses to sexual assault, intimate partner violence, dating violence, and stalking. VAWA also allows for sexual assault examination without requiring law enforcement involvement. Many jurisdictions have policies that allow the patient to have evidence collected and stored for a given amount of time, leaving the patient the option to report to the police at a later date. The VAWA program also ensures patients are not required to pay for the services provided. VAWA's recent reauthorization in 2019 improved services for all victims, especially immigrants, lesbian, gay, bisexual, and transgender victims, Native American women, college students and youth, and public housing residents.

TABLE 191.1 Imaging Modalities in Nonfatal Strangulation

Modality	Indications	Advantages	Disadvantages
Plain radiograph (bone technique)	Visualize cervical vertebral fracture	Readily available in the emergency department (ED)	Limited information provided because C-spine fractures are rare
Plain radiograph (soft tissue technique)	Tracheal injury (subcutaneous emphysema, edema, tracheal deviation) Hyoid fractures	Readily available in the ED	Low sensitivity in detecting rare signs of deep soft tissue and laryngeal injury, and hyoid bone fracture is rare
Computed tomography (CT)	Soft tissue and laryngeal injuries Neuroimaging (brain)	Readily available in the ED High sensitivity Easy to perform	May need IV contrast, and screening for renal dysfunction
CT angiography (CTA)	Carotid artery injury, dissection, or thrombosis	Readily available in the ED High sensitivity	Requires IV contrast, and screening for renal dysfunction
Magnetic resonance imaging (MRI)	Soft tissue injuries of the neck and airway	Highest sensitivity	Not readily available Expensive
Doppler ultrasound	Visualize intimal injury (dissection) or thrombosis of carotid artery	Available in the ED Portable for unstable patients	Less sensitive for carotid injury or thrombosis
Fiberoptic laryngoscopy	Visualize vocal cords and adjacent structures	Sensitive for vocal cord and laryngeal injury	Availability depends on institution and expertise

TABLE 191.2 Imaging Strategy for Nonfatal Strangulation[a]

Scenario and Findings	Recommended Modality	Alternative Modality
No loss of consciousness, no physical complaints	None	None
No loss of consciousness, but voice changes	Four-vessel cervicocranial CT angiography with fiberoptic laryngoscopy	Magnetic resonance imaging (MRI) with and without contrast
Loss of consciousness and physical findings of force to the neck (e.g., bruising, petechiae)	Four-vessel cervicocranial CT angiography	MRI without contrast
Persistent unconsciousness	Four-vessel cervicocranial CT angiography	MRI without contrast
Intact consciousness with unilateral neurologic findings	Four-vessel cervicocranial CT angiography	Doppler ultrasound of the carotid artery—four-vessel angiography

[a]Imaging modality chosen will vary based on institution-specific protocols and availability of imaging modalities.

Fig. 191.5 Sexual assault evidence collection kit. Contents of kits vary by state and jurisdiction. This is an example of a customized jurisdictional evidence kit including envelopes, swabs, and microscope slides used to collect, package, and store evidence. This kit shows how the chain of evidence must be followed with signatures, seals, and appropriate transfer of property to establish integrity of the evidence. (Courtesy of the University of Colorado Forensic Nursing Program)

Questions regarding consent are often complex, especially when the victim is a minor, intellectually disabled, or incapacitated by drugs or alcohol. In the case of the minor who is unable to legally consent (due to age), the doctrine of the mature minor (one who has been supporting himself or herself, is a parent, or is in the armed forces, depending on state statutes) may allow the minor to consent without guardian notification. In many states, the minor who is in danger of having been exposed to pregnancy or an STI can also consent. If the minor does not assent to examination, the SANE/SAFE should not force the patient to undergo the examination—the minor also has the right to determine what happens to her or his body. An examination cannot be forced per the request of police or a parent or guardian. For the person unable to give consent due to mental health, psychological, or neurologic conditions, consent should be obtained from a guardian or legally authorized representative. In the case of the patient who is temporarily incapacitated due to drugs or alcohol, the examination can be delayed until the effects of the intoxicants have worn off and the patient is able to consent. In patients unable to give consent for a prolonged period of time (e.g., severe head injury or requiring intubation), the decision to proceed with a medical forensic examination is complicated, as lack of patient consent may be perceived as a further violation. Because many patients would desire evidence collection if incapacitated, and because there is a limited window of time for collection, institutional protocols should be crafted to address these specific scenarios.[8-9] At some institutions, a family member or guardian can consent to evidence collection on behalf of the patient. In these situations, evidence is collected (as an anonymous kit) and held until the patient is able to make the decision. Institutional legal counsel and ethics consults should be used when protocols have not been established.

The medical forensic examination begins with the detailed forensic history, followed by thorough physical examination, documentation

of injuries with diagrams, and evidence collection, including photographs. Medical record documentation should be securely protected from nonclinical personnel. Evidence collection kits often require their own supporting documentation. Key features of the forensic history are detailed in Box 191.2. The examination should proceed in a head-to-toe fashion, with the more intrusive parts (e.g., pelvic and rectal areas) examined at the end. Each part of the body is uncovered, one area at a time, to maintain as much modesty as possible. Each jurisdiction has a standard protocol for the sequence of evidentiary collection, modified by elements of the history. Table 191.3 highlights potential steps during the forensic examination and describes the technique for each step. Some jurisdictions may require additional steps (e.g., a wet mount to look for motile sperm and for slides to be made in addition to swabs). For victims who were unconscious or cannot remember specifics of the assault, oral, external genital, vaginal, cervical, anal and rectal, neck, and breast swabs should be obtained because these areas have a high likelihood of DNA recovery.

A recent study of over 2000 victims found that 27% sustained an anogenital injury; historically, the literature reports a variable rate of such injuries.[10] Anogenital injuries are usually seen at the posterior fourchette, fossa navicularis, and hymen (see Fig. 191.7 for diagrams and terminology of female genitalia). Injuries are documented using the face of a clock, with 12:00 representing anterior and 6:00 representing posterior injuries. Although genital injury can occur in up to 52% of women after consensual intercourse, sexual assault victims are more likely to have multiple injuries, abrasions, and a higher frequency of lesions beyond the posterior genital area.[10] The mnemonic TEARS (***t***ears/cuts, ***e***cchymosis,

COLORADO SEXUAL ASSAULT
CONSENT and INFORMATION FORM

Collection, Analysis/Release, and Consent Withdrawal of Sexual Assault Evidence/Information

▶ **You have the right to have this form explained and all of your questions answered.**
Please initial and sign where appropriate. You will receive a copy of this form after it is completed.

Law Enforcement Agency:	Case No:
Officer Name:	Phone No:

Medical Forensic Exam

▶ _____ **I consent to a medical forensic exam**. I understand I can stop the exam at any time and can decline any portion of the exam or collection of any sample.

Reporting Decision (initial only one)

▶ _____ **I am choosing to make a report to law enforcement**. I give permission for evidence collected and information gathered during my sexual assault exam to be released to law enforcement for use in investigation(s) and potential prosecution(s). I understand the investigating law enforcement agency will be given my name and contact information.

▶ _____ At this time, **I am choosing NOT TO REPORT TO LAW ENFORCEMENT OR PARTICIPATE** in any investigation. I understand I can change my mind and later report to law enforcement. I understand law enforcement may be given my name. I understand law enforcement may choose to investigate but I do not have to participate.

Evidence Analysis/Release of Results (initial only one)

▶ _____ **I consent for law enforcement to release the collected evidence to a forensic lab for analysis.** I understand law enforcement ***may*** submit the evidence to a lab no later than 21 days after receiving it. I understand if the evidence is analyzed, law enforcement ***will*** receive the results for the purposes of investigation(s) and potential prosecution(s).

▶ _____ **I consent only to the collection and storage of evidence** at a law enforcement agency. I understand this means the evidence will **NOT** be submitted to a forensic lab for analysis. I understand I can change my mind, make a report to law enforcement and possibly have the evidence analyzed at a forensic lab. I understand law enforcement is only required to hold the evidence for a minimum of 2 years.

Withdrawal of Consent for Evidence Analysis/Release of Results (only patients 18 years & older)

▶ _____ **I understand I may withdraw my consent for evidence analysis/release of results** by contacting the law enforcement agency listed on this form. I understand the withdrawal of consent becomes effective when law enforcement verifies my identity, but will not apply to any actions already taken. I understand that once analysis has begun, consent cannot be withdrawn.

abrasions, ***r***edness, and ***s***welling) can be used to describe specific findings (Figs. 191.8 to 191.11). The Genital Injury Severity Scale (GISS) is another available instrument that uses gross visualization, colposcopy, and toluidine blue staining. Variables include five types of injuries—swelling, color change, tissue break, hymen and introitus injury, toluidine blue dye uptake—and two classes of severity—tissue integrity intact and disrupted. The GISS can help distinguish sexual assault patients from consensual intercourse subjects based on type and class of injury. In a cohort of sexual assault victims, 40% had class B or tissue-disrupted injuries versus 10% in the consensual group. Although not commonly used in clinical practice by emergency clinicians, the GISS has been validated in defining and measuring external genital injury after sexual intercourse and is most commonly used by sexual assault experts.

General Principles of Evidence Collection

Gloves should be worn during collection, processing, and packaging of evidence and should be changed in between each step of evidence collection to avoid cross-contamination of evidence. Clothing should be collected, especially if it has been ripped or torn, taking care not to cut through existing holes or tears. Areas of clothing with possible DNA (including underwear not worn at the time of assault but put on later) should also be collected. Clothing and other evidence should be placed in paper bags because plastic promotes mold and bacteria growth and can destroy DNA evidence. If a piece of evidence is wet when collected, the package should be labeled as such, and the police or crime laboratory be made aware of this so that they can dry and repackage the evidence. A minimum of two swabs should be taken when swabbing an area, allowing the crime laboratory to save one swab for future analysis

BOX 191.2 Important Historical Information for the Medical Forensic Examination[a]

Patient History
- Pertinent past medical history
- Last consensual intercourse[b]—when? with whom? areas penetrated? ejaculation?
- Voluntary drug or alcohol use

Assault History
- Date
- Time
- Surroundings
- Assailant(s)
- Involuntary drug or alcohol ingestion
- Genital and nongenital injury, pain, bleeding
- Loss of memory
- Loss of consciousness
- Vomiting
- Injury inflicted on assailant? consumption?

Methods Used by Assailant
- Weapons—type? use? injury?
- Physical blows—slapping? hitting? punching?
- Grabbing, holding, pinching
- Threats of harm
- Physical restraints
- Choking/strangulation
- Burns
- Targets of threat

Victim Post-Assault Hygiene, Activity
- Urinated
- Defecated
- Genital, body wipes
- Douched
- Removed, inserted tampon
- Removed, inserted diaphragm
- Ate
- Drank
- Gargled
- Brushed teeth
- Changed clothes
- Washed clothes

Assault Acts[c]
- Vaginal penetration—penis? object? finger?
- Oral penetration—penis? object? finger?
- Anal penetration—penis? object? finger?
- Oral copulation of genitals—of patient by assailant? of assailant by patient?
- Oral copulation of anus—of patient by assailant? of assailant by patient?
- Nongenital acts—biting? sucking? licking? kissing? locations?
- Did ejaculation occur? location?
- Contraception or lubricant used—foam? jelly? lubricant? condom?

[a] These questions should only be asked by emergency clinician if they are performing the entire medical forensic examination, including evidence collection.
[b] This information is needed for uploading the DNA profile into CODIS to prevent confusion with DNA from a consensual partner.
[c] Yes, no, attempted, or unsure answer choices.

TABLE 191.3 Steps in Sexual Assault Evidence Collection Kit

Step	Technique
Clothing collection	Collect clothing the patient wore during the assault. • Have the patient disrobe on a sheet laid on the floor. Keep clothing articles separate. • Place each item of clothing in a paper bag; label and seal. • Fold the sheet and package the same way.
Debris collection	Scan the body from head to toe looking for potential evidentiary materials. • Document findings and collect objects using tweezers, tape, or lint roller. • Package each piece separately in an envelope; label and seal.
Biologic evidence	Scan the body for potential biologic material and fluids and bite or suck marks. • Use an alternative light source, location guided by patient history. • Use swab to collect evidence, air-dry, package, label, and seal.
Fingernail evidence	Obtain evidence from the fingernails if applicable. • Use rosewood stick, broken tongue blade, or moistened swab to scrape beneath the nails. • Nail clippers can be used to cut the nails. • Package, label, and seal.
Pubic hair combings	Obtain foreign material from pubic hair. • Place collection sheet under the buttocks. • Use plastic comb to comb through hair toward the sheet. • If pubic hair is absent or trimmed, a lint roller may be used. • Package sheet and comb, label, and seal.
Pubic hair pulling (painful, typically not collected unless requested by police)	To obtain reference DNA on patient: • Pull ≈25 pubic hairs, without cutting or using tweezers, trying to obtain the root. • Package, label, and seal.

TABLE 191.3 Steps in Sexual Assault Evidence Collection Kit—cont'd

Step	Technique
Head hair pulling (painful, typically not collected unless requested by police)	To obtain patient reference DNA: • Pull ≈25 head hair strands from different parts of the scalp to try to obtain the root. • Package, label, and seal.
External genital examination and swabs	Obtain biologic evidence from the external GU sites—vulva and perineum—while inspecting for injury. • Use retraction and separation technique to look for evidence of genital injury. • Use moistened swabs to swab the areas. • If matted pubic hair is present, use scissors to cut the matted section. • Package, label, and seal.
Internal genital swabs	Obtain biologic evidence from internal GU sites—vagina and cervix—to assess for genital injury. • Use swabs to collect fluid and evidence from the posterior fornices. • Collect any foreign object, such as a tampon or condom. • Insert swab into cervix and gently twirl. • Obtaining STI cultures is done at this time. • Package, label, and seal.
Anal examination and swabs	Obtain biologic evidence from the anus/rectum and assess for injury. • Gently retract the anus with slow steady pressure to allow natural dilation, and inspect for injury. • Gently insert swabs and twirl. • An anoscope can be used to assess for injury. • Package, label, and seal.
DNA reference sample	Obtain a DNA reference sample. • As per protocol, collect a blood or buccal swab sample.
General principles	• Two sterile cotton-tipped swabs are used simultaneously to collect samples. One will be used for the crime laboratory, and one is available for the defense, if requested. • Dry swabs are used to collect evidence from moist areas; swabs moistened with control sterile water are used to collect evidence from dry areas. • Swabs are air-dried, placed back in the sleeves, and then placed in an envelope. • All evidence is placed in paper (not plastic) because moisture may cause mold growth and destroy DNA.

GU, Genitourinary; *STI,* sexually transmitted infection.

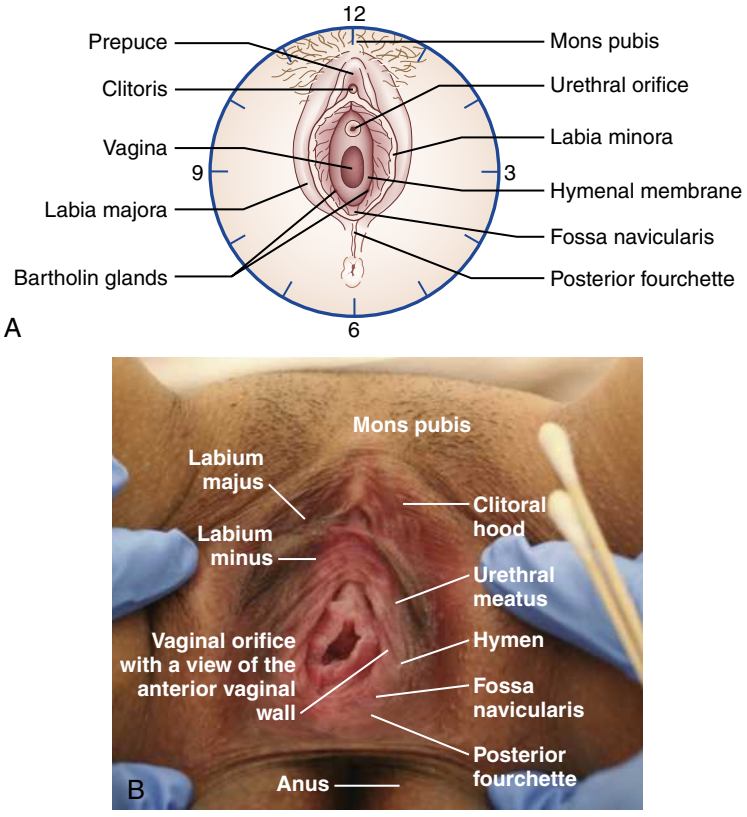

Fig. 191.7 Female genitalia. (A) Anatomy of the female external genitalia with the clock positions used in documentation. (B) Actual photograph highlighting the relative anatomy of the female external genitalia important in a medical forensic examination. (From: Roberts JR, Custalow CB, Thompsen TW. *Roberts and Hedges' Clinical Procedures in Emergency Medicine*, ed 6. Philadelphia: Elsevier Saunders; 2013.)

Fig. 191.8 Examination of the external genitalia. This illustrates foreign debris (presumed semen and piece of paper) on the external genitalia of a rape victim.

Fig. 191.9 External genitalia injury. Shown are marked swelling and ecchymosis of the right labia major, inguinal area, and buttocks in a middle-aged woman following sexual assault by a single perpetrator.

by the defense's laboratory. In general, wet stains should be collected with a dry swab or cotton-tipped applicator; dry stains are collected with a swab moistened with sterile or distilled water. For dried specimens and bite marks, a double-swab technique is performed. First, the area is swabbed in a rolling fashion with a moistened swab, and then a dry one is rolled over the area. All swabs should be allowed to dry by air, using a desiccant pack, or in a swab dryer. The evidence is packaged into envelopes once the examination is completed, and all swabs have dried. The completed evidentiary collection kit is labeled and sealed. While maintaining a chain of custody, the kit should be stored according to departmental policy or turned over to law enforcement.

The chain of custody describes the path evidence takes once it is collected from the body and ensures the evidence was not tampered with or mishandled. Failure to maintain the chain of custody calls into question the validity of the evidence and may make it inadmissible in court. Chain of custody documentation should describe how the evidence was handled and include a log of those who have had contact

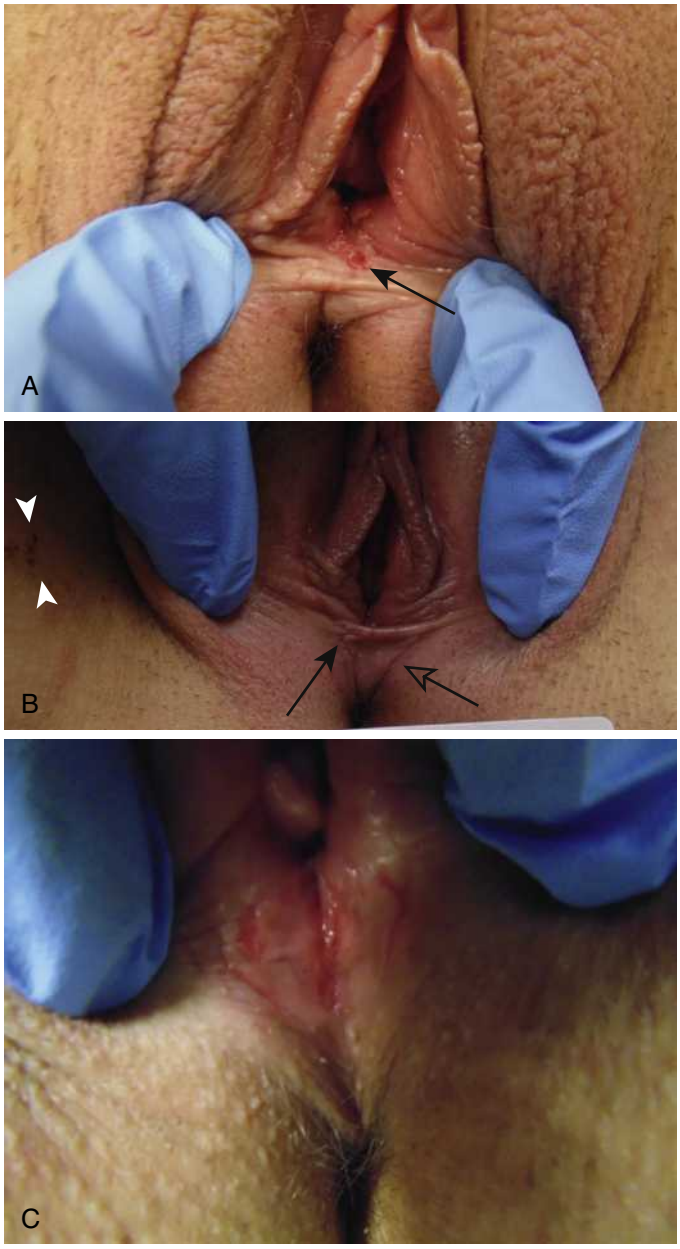

Fig. 191.10 External genitalia injury. (A) Tear and abrasion at the 6 o'clock position of the fossa navicularis. (B) *Closed arrow* is abrasion to the posterior fourchette at 6:30. *Open arrow* is abrasion of the perineum (anterior to the rectum). *Arrowheads* are abrasion and ecchymosis of right medial thigh. (C) The patient in this picture sustained multiple tears and abrasions. There is a large linear tear extending from the fossa navicularis through the posterior fourchette and onto the perineum all in the midline. There are also tears bilaterally on the labia minora, three at the 7 o'clock position and two at the 5 o'clock position.

with it. The medical forensic examination kit will typically contain chain of custody forms (Fig. 191.12.)

Special Techniques

Colposcopy. Colposcopy is a diagnostic procedure to illuminate, magnify, photograph, or digitally record external and internal genital structures. Having widespread application in gynecology, the colposcope microscopically improves gross visualization. The colposcope has a magnification of 4× to 30× and can be equipped with a still or video camera. Colposcopy is superior to gross visualization

Fig. 191.11 Anal injury. There is a linear anal abrasion and tear at the 6 o'clock position with the patient in the lithotomy position.

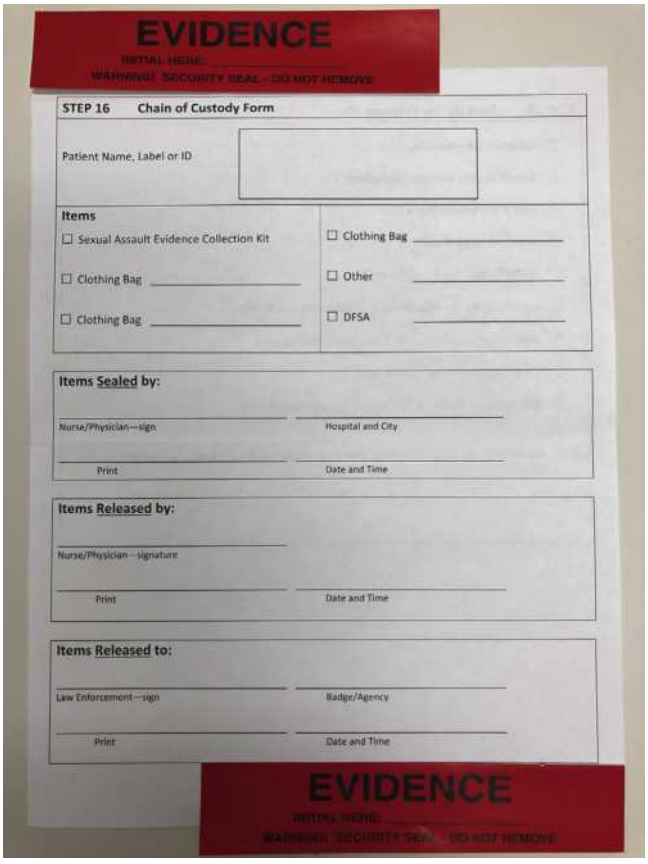

Fig. 191.12 Sample chain of custody form which includes inventory of items collected as well as names and signatures of the persons collecting, releasing, and law enforcement receiving the evidence. Evidence seals shown in image as well. (From the Ohio Commercial Kit.)

for detecting anogenital injuries. Most SANEs/SAFEs routinely use colposcopy in their evaluations. Limitations of colposcopy include the cost and size of the instrument, as well as the technical training required. Because of this, several programs use digital photography alone to detect and document genital injury. Although no study has directly compared colposcopy to digital photography for detecting injury, we recommend colposcopy when available; however, some studies have questioned the use of colposcopy due to the psychological trauma of examination with magnification.[11]

Toluidine Blue Dye. Toluidine blue dye (TBD) is a stain that adheres to nuclei in damaged epithelial cells and has not been shown to interfere with DNA testing. More tears were identified with TBD enhancement by direct visualization and colposcopy. The dye should be applied prior to speculum insertion since the speculum may introduce genital injury. The dye is applied to the external genitalia and then gently wiped with surgical lubricant, 1% acetic acid solution, or baby wipes to remove excess solution (Figs. 191.13 and 191.14) which can lead to false-positive findings of injury.

Alternate Light Source. An alternative light source (ALS) uses ultraviolet light to fluoresce biologic material. In sexual assault examinations, the ALS is used to scan the body and genitalia for areas of fluorescence that can be swabbed and submitted for potential DNA identification. Semen and saliva fluoresce under an ultraviolet (UV) light wavelength of 450 nm (range, 390–500 nm). Although the ALS is sensitive to semen, it is not specific. False-positive ALS results may be seen with hand cream, powder, body gel, laundry detergent, fabric softeners, soaps, and other ointments and creams. However, physician training can improve the ability to distinguish semen from other substances (e.g., hand cream, soap, and bacitracin). A Wood's lamp, which emits UV light at wavelengths less than 390 nm, is a poor substitute for an ALS device, and thus not recommended for detecting biologic evidence.

SPECIAL POPULATIONS

Older Adult Sexual Assault

From 2003 to 2013, the National Crime Victimization Survey reported 0.2/1000 cases of rape or sexual assault to elderly victims aged 65 years or older. Older persons may be at risk for sexual assault due to neurologic or cognitive disease, physical disabilities, frailty, and institutionalized living arrangements. In one study, older victims reported verbal threats more frequently.[12] Postmenopausal women are thought to be at particular risk for genital injury due to atrophy of connective tissue, loss of tissue elasticity, and atrophy of vaginal epithelium.

Studies have shown mixed results regarding the severity of genital injury. A recent study of 122 postmenopausal women found that 37% suffered a genital injury compared to 17% of premenopausal women. Although postmenopausal women had similar rates of extragenital injury, they were more likely to have sustained large bruises.[12] The locations of the genital injuries are similar to those of younger victims, but older victims tend to have more anogenital lacerations and abrasions.[12] The medical forensic examination of the older patient should proceed in the same manner as for other patients. The history may be difficult due to neurologic or cognitive impairment in the victim. Patient positioning may be more challenging due to physical disabilities; the typical dorsal lithotomy position may not be possible, and other positions (e.g., left lateral Sims, lateral recumbent, and dorsal recumbent) may be needed for a patient's comfort (Fig. 191.15). Prophylaxis against STIs and HIV infection should be offered while considering potential medication interactions or side effects. Older victims can also suffer major psychological trauma, including PTSD and rape trauma syndrome, and should be referred to rape crisis center services.

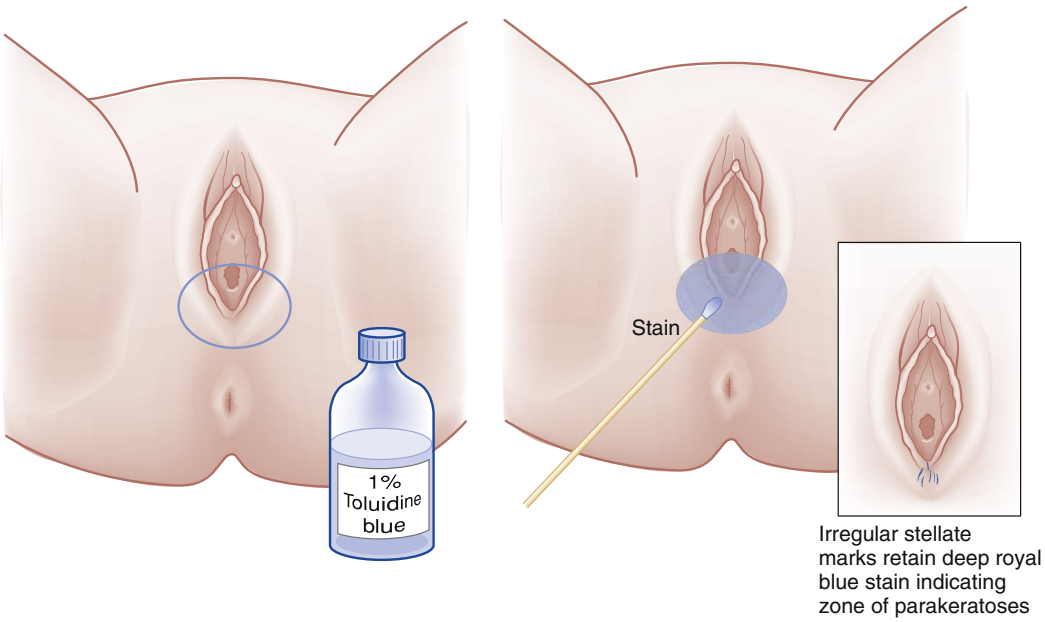

Fig. 191.13 Toluidine blue dye (TBD) application. This figure illustrates the application and removal of TBD during a forensic medical examination.

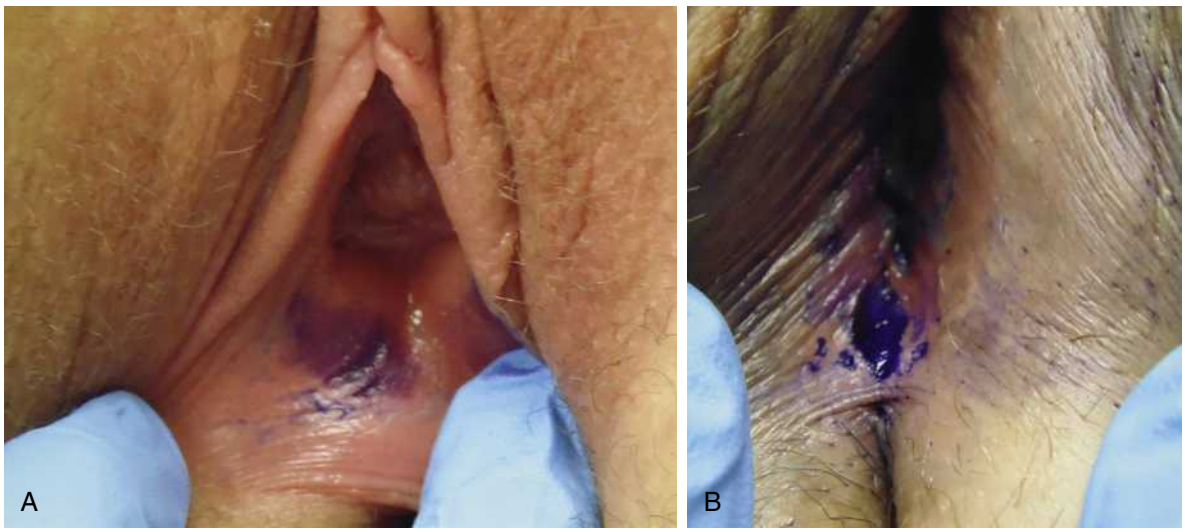

Fig. 191.14 External genitalia examination after toluidine blue dye (TBD) application. (A) After the TBD was applied, two tears of the fossa navicularis were seen between the 6 and 7 o'clock positions. (B) TBD application highlighting a large tear and abrasion of the fossa navicularis at the 6 o'clock position. There are also other scattered, smaller injuries present.

Male Sexual Assault

Male sexual assaults occur in straight, homosexual, and bisexual individuals, college students, prisoners, military personnel, gang members, and institutionalized individuals. According to the 2015 NISVS, nearly one-quarter of men (24.8%) in the United States. have experienced some form of contact sexual violence at some point in their lives, with about 2.6% experiencing completed or attempted rape victimization in their lifetime.[3] Males are raped by men or women, tend to underreport their rape, and seek medical services much less frequently than females.[3] Compared to women, males tend to be of a similar age (20–30 years), report more forcible penetration (52% anal, 15% oral, and 33% both), have more anal trauma and injury, suffer more object and digital penetration, have multiple assailants, have more weapons used, and know their assailant(s) less often. Male sexual assault includes forced oral copulation or vaginal and anal penetration of the victim or assailant. Male victims may ejaculate during the assault due to fear and physical stimulation.[3] This can cause increased feelings of guilt and shame and can be used to argue in a court of law that the victim was a willing participant.

The forensic history and physical examination proceed in a similar fashion to that for a female patient. During the physical examination, attention is paid to the oral cavity, penis and scrotum, and anus and rectum. See Fig. 191.16 for a diagram of the terminology for male genitalia. Swabs should be taken from the oral cavity, external genitals, and anus. When swabbing the genitals, all parts of the penis should be assessed, including the base of the penis and anterior scrotum. The anal and rectal examination should include visualization to look for potential foreign bodies and gross injury such as tears, abrasions, bleeding,

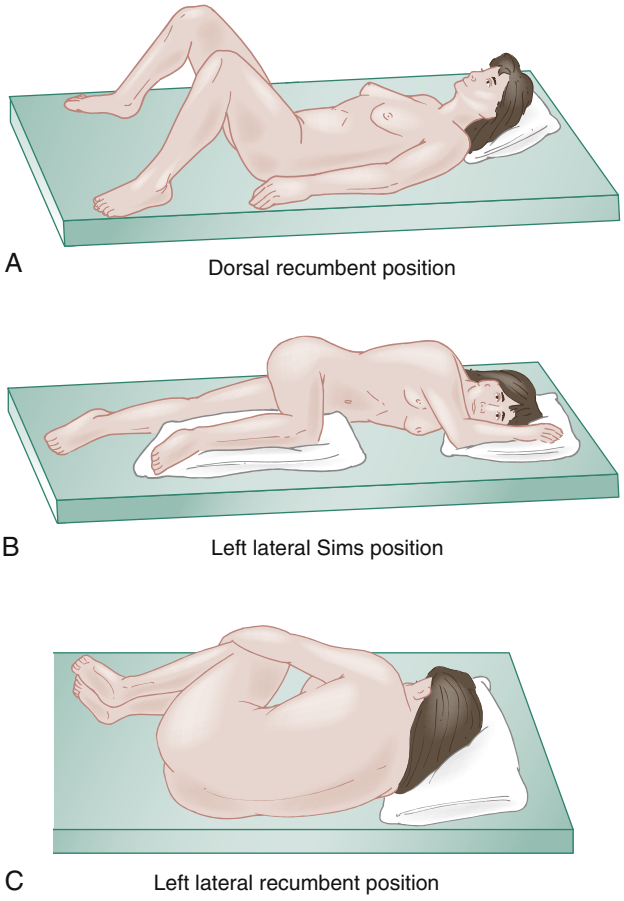

Fig. 191.15 (A) Dorsal recumbent position. (B) Left lateral Sims position. (C) Left lateral recumbent position.

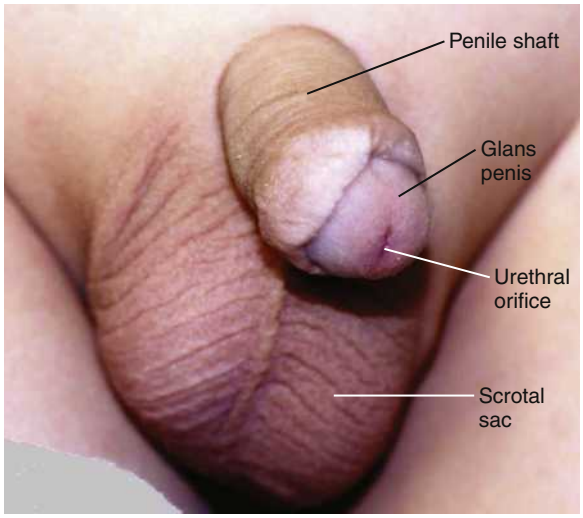

Fig. 191.16 Male genitalia. This picture highlights the relative anatomy of the male genitalia important in a medical forensic examination. (From: Roberts JR, Custalow CB, Thompsen TW. *Roberts and Hedges' Clinical Procedures in Emergency Medicine*, ed. 6, Philadelphia: Elsevier Saunders; 2013.)

erythema, hematoma, fissures, engorgement, and friability. Anal swabs should be inserted approximately 2 cm into the rectum. Visualization can be enhanced using TBD and anoscopy. Anoscopy has been shown to detect more injuries than colposcopy or an unassisted examination. Significant pain and an inability to tolerate anoscopy may warrant an examination under anesthesia, with some victims requiring surgical evaluation and treatment.

Male victims should be offered similar STI prophylaxis. HIV prophylaxis should be considered given the high risk of transmission from anal receptive and anal insertive intercourse. Victims should also be given (or referred for) rape crisis counseling services.

TABLE 191.4 Calculated Risks of Acquiring HIV from Isolated Sexual Contact With Known HIV-Positive Individual

Type of Contact	Risk[a]
Oral	Negligible
Anal	0.5%–3.0%
Vaginal	0.08%–0.3%
Health care worker percutaneous needlestick	0.3%

[a]Risk is higher in early or late HIV infection, higher viral load in assailant, presence of trauma or genital ulcers, and sexually transmitted infection in victim.

Data from: Dosekun O, Fox J. An overview of the relative risks of different sexual behaviours on HIV transmission. *Curr Opin HIV AIDS*. 2010;5:291-297; and Boily MC, Baggaley RF, Wang L, et al. Heterosexual risk of HIV-1 infection per sexual act: systematic review and meta-analysis of observational studies. *Lancet Infect Dis*. 2009;9:118-129.

Definitive Treatment to Prevent Sexually Transmitted Infections and Pregnancy

One of the most common concerns of survivors who present to the ED is that of becoming pregnant and acquiring STIs, including HIV. The risk of becoming pregnant after rape has been estimated at 5%, but depends on the age of the patient, use of birth control by the patient, condoms in the assailant, and timing in the menstrual cycle. The risk of acquiring STIs after a rape depends on the local prevalence of the infections. Prior research has shown the risk is greatest for acquiring bacterial vaginosis (19%), trichomonas (12%), *Neisseria gonorrhea* (4%), and chlamydia (2%).[1,3,13] The risk of acquiring HIV is very low, estimated to be 0.1% to 0.3% for receptive vaginal intercourse and 0.5% to 3.0% for receptive anal intercourse (Table 191.4).[1,3,13] However, estimates do not take into account the increased risks associated with sexual violence and injuries. The risk of HIV transmission is also related to viral load in the assailant (highest in very early and very late HIV infection), route of assault, and presence of STIs in the victim.

According to CDC recommendations, all sexual assault victims presenting to the ED should be offered treatments for STIs (i.e., gonorrhea, chlamydia, and trichomonas), emergency contraception, postexposure hepatitis B vaccination, human papillomavirus (HPV) vaccination, and HIV postexposure prophylaxis (PEP) (Table 191.5). Many states mandate that emergency clinicians offer pregnancy prevention to sexual assault victims (www.ncsl.org/research/health/emergency-contraception-state-laws.aspx). Emergency contraceptives prevent pregnancy by inhibiting ovulation, fertilization, or implantation, and do not disrupt an existing pregnancy. Emergency contraception may be taken up to 5 days after sexual contact, but ideally within 72 hours. See Table 191.6 for emergency contraception options. All victims should also be given a tetanus booster if indicated. HIV PEP should be offered to sexual assault patients who have been assaulted by multiple assailants, a known HIV-positive assailant, or high-risk exposure. Unfortunately, because the HIV status of the assailant is usually unknown, the CDC recommends offering prophylaxis

TABLE 191.5 Recommended Treatment to Prevent Sexually Transmitted Infection and Pregnancy

Infection or Condition	Medication
Gonorrhea[a]	Ceftriaxone, ≤150 kg 500 mg IM; >150 kg ≥ 1 gm. Alternative treatment, cefixime 800 mg PO daily; not preferred due to treatment failure risk. For moderate to severe penicillin allergy gentamicin 240 mg IM daily and azithromycin 2 gm PO daily (note: poor efficacy in OP, do not use this regimen in pregnancy)
Chlamydia	Doxycycline, 100 mg PO bid × 7 days *or* Azithromycin, 1 g PO *or* Amoxicillin 500 mg PO TID × 7 days; toc in 21 to 28 days
Trichomoniasis	Metronidazole, 2 g PO (recommended to take at home later)
HIV	See most recent CDC guidelines[b] and Fig. 191.17 for decision to treat
Hepatitis B	First dose of 3-dose vaccination series if not vaccinated or unsure if vaccinated
HPV	First dose of 2- or 3-dose vaccination series, approved for ages 9 to 45 years old
Tetanus	Tdap, 0.5 mL IM
Pregnancy	Levonorgestrel, 1.5 g PO within 72 hours *or* Ulipristal acetate, 30 mg PO within 120 hours
Antiemetic	Practitioner's discretion

[a]If patient reports a severe penicillin allergy (anaphylaxis, TEN, or Stephens-Johnson syndrome), treat with gentamicin 240 mg IM once plus azithromycin 2 gm PO once. There has been an increase in *N. gonorrhea* resistance to azithromycin, so follow-up testing is recommended in this scenario.
[b]Centers for Disease Control and Prevention. 2015 sexually transmitted diseases treatment guidelines. https://www.cdc.gov/std/tg2015/default.htm.

on a case-by-case basis, taking into account patient preferences and ability to comply with the 1-month course of medications and follow up. See Fig. 191.17 for the CDC algorithm on the decision to treat possible nonoccupational HIV exposures. When HIV PEP is recommended, the emergency clinician should refer to hospital guidelines or infectious disease consultation for the recommended triple-drug regimens and provide the victim at least a 3-to-7-day starter pack with prompt infectious disease follow up. The National HIV Clinician's Consultation Center offers online information and telephone consultation for providers who do not have access to a local HIV expert (nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/).[3,13]

DISPOSITION

Most sexual assault patients will be discharged from the ED. There are websites that can assist the emergency clinician who is caring for the sexual assault patient (Box 191.3). If available in the ED, social services and a victim's advocate can help formulate a safe discharge plan. Victims of attempted strangulation, especially those with loss of consciousness, bowel or bladder incontinence, or persistent shortness of breath or voice changes, should be admitted for observation. If safe house resources or respite are unavailable, consider admitting patients who do not have a safe place to go. The discharge instructions should include the number of the forensic kit collected. Patients should be encouraged to follow up with their local rape crisis center, primary care provider (or another medical provider), and mental health provider, as needed. Medical follow up should include any needed completion of the hepatitis B series, repeat pregnancy testing, vaccines, STI testing (if they did not get treated), and repeat HIV testing (at 6 weeks). If they received HIV prophylaxis, they should follow up with local HIV experts or clinics to have follow-up laboratory testing, assess for medication compliance, and be monitored for side effects.

Patients may experience subsequent symptoms of PTSD or rape trauma syndrome (RTS). Symptoms may include depression, anxiety, flashbacks, and difficulty sleeping and interacting with friends and

TABLE 191.6 Emergency Contraception

Method	Brand Name	Dose	Timing After Intercourse	Efficacy	Adverse Effects	Relative Contraindications[a]	Notes
Copper IUD	Paragard	Single IUD	0–120 h	>99%	Pain, bleeding	Infection, copper allergy, uterine anomalies	Consider in IPV where recurrent assault more likely (effective up to 10 yr) Most effective, but often not feasible or desirable from the ED after assault
Levonorgestrel[b]	Plan B, Plan B One-Step, Next Choice	1.5 mg	0–72 h (may be used with decreased efficacy up to 120 h)	85%	Nausea, vomiting, headache, menstrual changes		Less effective if >72 h or BMI >26
Ulipristal acetate[c]	Ella, Ella One	30 mg	0–120 h	85%	Nausea, vomiting, headache, menstrual changes	Renal, hepatic impairment, uncontrolled asthma, breast-feeding	More effective than LNG at 72–120 h More effective for BMI 26–35 (less effective in BMI >35)

BMI, Body mass index; *ED,* emergency department; *IUD,* intrauterine device; *IPV,* intimate partner violence; *LNG,* levonorgestrel.
[a]There are no absolute contraindications to EC, except for an established pregnancy, because they will not be effective.
[b]Levonorgestrel is not an abortifacient and is not teratogenic.
[c]Ulipristal acetate is not an abortifacient. It has not been tested adequately in human studies in pregnancy or breast-feeding; animal studies showed increased pregnancy loss.

loved ones. Acute pain after sexual assault is common and often undertreated, sometimes involving areas that were not traumatized. Delayed or worsening pain in many regions of the body has been shown to occur in up to 60% of sexual assault survivors at 6 weeks and 3 months post-assault.

TESTIFYING IN COURT

Although good medical care is the primary goal of ED treatment, the emergency clinician may at times be responsible for collecting sexual assault evidence. In this case, the emergency clinician may be asked to testify in court. The key to competent testimony is preparation and knowledge of the court process.

In most cases, the emergency clinician will be called on as a fact witness or as someone who testifies to what the patient said or did, as well as findings on physical examination. Occasionally, the emergency clinician may be called as an expert witness. An expert witness has specific training and may be called on to provide an explanation or educate the jury, even if he or she did not actually care for the patient. Box 191.4 outlines the steps in court testimony and includes some helpful suggestions for the emergency clinician in preparation for trial.

BOX 191.4 Steps in Court Testimony

Preparation for Trial

1. Respond to the subpoena in a timely fashion; a delay can result in criminal charges for you.
2. Notify and consult with the institutional legal counsel.
3. Update your CV and be able to recite dates of education and certification.
4. Ask to meet with the prosecutor to review the medical records, evidence collection kit, and a list of questions the prosecutor plans to ask the emergency clinician.

Day of the Trial

1. The day of the trial may change due to motions and order of witnesses.
2. Arrive early and dress in professional attire—a suit is preferred rather than a white coat.
3. Before testifying, the emergency clinician will be sworn in and seated in the witness box. There are three parts to the testimony—questioning by the prosecution (testimony), cross-examination by the defense attorney, and redirect by the prosecution.
4. In general, the emergency clinician should look at the prosecution or defense attorney when being questioned, and the jury when answering questions; this is the provider's opportunity to educate the judge and jury.
5. Responses to questions should be brief and answer only the question; do not add information and explanations unless asked, and resist using medical jargon such as *ecchymosis* in favor of clearly understood terms such as *bruising*.
6. All answers should be verbal, taking care not to nod in response. The line of questioning will often start with asking the provider to state her or his name and then describe training and certification, including how long he or she has been practicing emergency medicine.
7. Do not refer to the patient as the "victim."
8. If an answer cannot be recalled, then just simply state, "I cannot recall."
9. Documents can be reviewed in court (e.g., medical or evidentiary kit records) on request.
10. If the question is not understood, the emergency clinician can ask the attorney to repeat the question or clarify it prior to answering.

ACKNOWLEDGMENT

We would like to thank Judith A. Linden and Ralph J. Riviello for their significant contribution to the prior edition of this chapter.

CHAPTER 191: QUESTIONS AND ANSWERS

1. Which of the following statements best describes hepatitis B infection prevention for victims of sexual assault?

a. Give HBIG and hepatitis B vaccine if the patient has not been immunized.
b. Give HBIG only if the patient has not been immunized.
c. Give hepatitis B vaccination if the patient is unimmunized or uncertain.
d. Give hepatitis B vaccine only if serologic testing shows that the patient is not adequately immunized.
e. Serologic testing is always required, followed by hepatitis B immunoglobulin (HBIG).

Answer: C. Give hepatitis B vaccination if the patient is unimmunized or uncertain. Follow-up doses should be given at 1 to 2 months and 4 to 6 months (total of three doses). This strategy, which avoids the need for serologic testing, has been shown to be effective. HBIG is not recommended by the CDC after sexual assault unless the assailant is known to be HBsAg-positive and the victim is unimmunized.

2. Which of the following empirical antibiotic regimens is indicated for sexual assault patients to prevent sexually transmitted infections?

a. Cefixime 400 mg PO
b. Cefixime 400 mg PO once plus doxycycline 100 mg PO bid for 10 days
c. Ceftriaxone 1 g IM (intramuscularly)
d. Ceftriaxone 1 g IM plus azithromycin 2 g orally (PO)
e. Ceftriaxone 250 mg IM plus metronidazole 2 g PO plus azithromycin 1 g PO

Answer: E. Ceftriaxone is given to cover gonorrhea, azithromycin to cover chlamydia, and metronidazole (Flagyl) to cover *Trichomonas*. Ceftriaxone is preferred over oral cefixime to cover incubating syphilis and due to increasing gonorrhea resistance. Many providers opt to give the metronidazole to take at home because it increases the risk of nausea and vomiting, a common side effect of many of the medications (including emergency contraception and HIV postexposure prophylaxis).

3. Which of the following statements best describes sexual assault in males?

a. Ejaculation should not occur in the victim during male sexual assault.
b. Males are more likely to overreport sexual assault.
c. Males are more likely to require sexually transmitted infection (STI) prophylaxis.
d. Males do not require referral to rape crisis centers.
e. Males may require anoscopy to detect anogenital injuries.

Answer: E. Males may actually suffer more anogenital injuries than women; injury detection can be aided or enhanced by using an anoscope. Males underreport the crime, do not seek medical attention, and absolutely need referral to a rape crisis center for post-rape care and counseling. Males are not more likely to require STI prophylaxis because the risk of transmission per act does not change based on gender. Ejaculation may occur during sexual assault due to prostatic stimulation and fear arousal. This should not be taken to infer that the assault was consensual.

4. Which of the following factors reduces the likelihood of finding genital injury during the sexual assault examination?

a. Digital penetration
b. Increased time since sexual assault occurred
c. Penile penetration
d. Use of foreign object during the assault
e. Victim sexual immaturity

Answer: B. The genital structures heal quickly, so the longer the time since the sexual assault occurred, the less likelihood of finding evidence of injury on examination. All the other factors increase the likelihood of finding genital injury at the time of the sexual assault examination.

CHAPTER 191: QUESTIONS AND ANSWERS—cont'd

5. A 25-year-old woman presents 4 days after vaginal penetration. Her body mass index (BMI) is 33. Which of the following is true about emergency contraception (EC)?

- **a.** A pregnancy test is mandatory prior to offering EC.
- **b.** She should be offered levonorgestrel because it is more effective in this situation.
- **c.** She should be offered ulipristal.
- **d.** She should have an intrauterine device (IUD) inserted because this is the most effective form of EC for her.
- **e.** She should not receive EC because it will likely be less effective due to her BMI.

Answer: C. Emergency contraception should be offered up to 5 days after vaginal assault. Ulipristal, levonorgestrel, and high-dose birth control pills are options. Ulipristal is more effective after 72 hours and in women with a BMI greater than 26. At a BMI above 35, both forms of oral EC are less effective, but should still be administered if there is no alternative. IUD placement is the most effective form of EC; it can be placed up to 5 days after assault. IUD placement allows for ongoing birth control in situations where there is likely to be loss of reproductive control (intimate partner assault) but is often less desirable after assault. IUD placement is most often not available in a timely manner. A pregnancy test is not mandatory before giving EC because it will not harm an existing pregnancy. A pregnancy test is suggested prior to ulipristal administration, given the lack of large studies in pregnant women.

Intimate Partner Violence and Abuse

Carolyn Joy Sachs

KEY CONCEPTS

- Intimate partner violence encompasses a pattern of controlling behaviors, including intentional physical assault, sexual assault, psychological violence, and financial control.
- Intimate partner violence (IPV) patients are best served by a coordinated system response plan that includes staff training, social work, victim advocates, and a close relationship with area IPV service provider groups and law enforcement.
- The emergency clinician's role in caring for patients affected by intimate partner violence involves 4 basic steps.
  1. Identification (asking the patient)
  2. Treatment (supporting messages and medical issues)
  3. Documentation (regarding violent actions and threats)
  4. Referral (e.g., community, social services, legal)
- Sequelae of IPV include chronic pain, mental health issues (e.g., depression, posttraumatic stress syndrome [PTSD], substance abuse), sexually transmitted infections (STIs) and unintended pregnancy, and worsening of medical illnesses.

FOUNDATIONS

Background

Intimate partner violence (IPV) consists of acts or threats of physical, psychological, or sexual violence between intimate (or formerly intimate) partners. Physical violence includes any behavior with the potential to cause death, disability, injury, or other harm: pushing, hitting, slapping, punching, kicking, biting, burning, strangulation, and aggressive use of objects or weapons. Exact legal definitions of criminal IPV acts vary by country and even within countries by local and state laws. Each state in the United States (US) maintains separate penal codes for IPV crimes, with differing legal definitions of IPV. Definitions and crimes also differ under federal law, military law, and tribal law, among others. Psychological or emotional violence also fulfills the medical and sociologic definitions of IPV: words and behaviors meant to intimidate, degrade, humiliate, or isolate the victim from family and friends; threats; controlling access to clothing, transportation, money, and other basic needs; and limiting professional and social activities. Sexual violence involves threats or physical force to attempt or complete sexual contact and includes any physical contact with a sexual organ with a person unable to consent. Sexual violence within a current or former dating or intimate relationship most often fulfills criteria for a separate crime, in addition to IPV. Reproductive coercion, a relatively recently described subset of sexual IPV, involves prevention of (or interference with) the use of birth control and refusal to use condoms to prevent the transmission of sexually transmitted infections (STIs) and human immunodeficiency virus (HIV).

The Centers for Disease Control (CDC) periodically performs a National Intimate Partner and Sexual Violence Survey (NISVS) which assesses sexual violence, stalking, and intimate partner violence victimization among adults in the United States. According to the 2015 NISVS, 36.4% of US women experience physical violence, rape, or stalking during their lives. One in three of those reporting IPV experienced multiple forms of IPV.[1]

Emergency department (ED) patients suffering from injuries due to IPV may present with a clear history of the IPV but may also fail to disclose the true nature of the injuries due to shame or fear of retaliation. Thus, national estimates of IPV injuries among ED patients likely underestimate the true prevalence. In ED studies, observed IPV prevalence among women ranges from 12% to 19%. Though the majority of injured IPV patients are females injured by a male partner, men may also be victims; IPV is at least as common in same-sex relationships as in heterosexual relationships.[2,3] Eleven percent of US men self-report IPV during their lifetime, including contact sexual violence, physical violence, or stalking by an intimate partner.

The high prevalence of IPV reported by men may be partly understood by the frequently bidirectional nature of partner conflict and violence. In a simplified model, IPV falls into two distinct forms: intimate terrorism and situational couple violence. Intimate terrorism is defined as "the attempt to dominate one's partner and to exert general control over the relationship," whereas situational couple violence is "violence that is not connected to a general pattern of control." Situational couple violence is usually less physically severe and more likely to be engaged in by either member of the couple. Intimate terrorism characteristically involves more severe injury, occurs more frequently, and is perpetrated more often by men against women. The type of IPV is unlikely to change the role of the ED clinician, which remains identification, treatment, documentation, and referral (Box 192.1). Overall, women continue to be the primary targets of violence, and to experience high rates of health sequelae. Therefore, health care responses to IPV, as well as community resources for survivors, are largely directed toward women. This may translate to decreased community resources available for male victims who also deserve our compassionate and complete care. Although this chapter often assumes the more common female victim and male perpetrator, principles herein apply to all IPV victims, irrespective of gender identity.

IPV affects many aspects of health and is associated with risky health behaviors, such as cigarette smoking, heavy alcohol and drug use, and physical inactivity, as well as mental illness (e.g., depression, anxiety, posttraumatic stress disorder [PTSD], suicidality).[3,4,5,6] IPV patients often have poor maintenance of chronic medical conditions, such as asthma, diabetes, and chronic pain syndromes. Pregnant IPV victims tend to seek prenatal care late and are at risk for termination of pregnancy, placental abruption, preterm delivery, and low infant birth weight.[7,8,9]

BOX 192.1 Emergency Department Role in IPV

Identification (Ask)

- Injured patients may self-present or be transported by prehospital care with trauma known to be IPV or they may require additional physician queries to uncover the true cause of injuries.
- Directed screening involves questioning those with risk factors about IPV
- Routine screening involves asking all patients about IPV

Treatment

- Medical
- Support: This most often involves giving support and information and does not mean a victimized patient will always leave her/his perpetrator. Emergency clinicians should accept that intervention in intimate partner violence may be an ongoing process and most often not resolved in one ED visit.
- Danger assessment (often with social work or IPV advocate)

Documentation

- Medical record
- Reporting forms in applicable
- Photography if applicable and available

Referral (Will be patient specific)

- Minimum: IPV community resources
- Hospital social work
- IPV community/legal advocate
- Law enforcement (depending on patient preference or mandatory reporting)
- Reporting is mandated by state law in certain cases
  - Patients with certain injuries/weapon use
  - When children are involved (to child protective services)
  - When the victim is also a dependent adult or elder (to adult protective services)
  - The mandate reporting supersedes the patient's right to privacy under HIPPA

The majority of all assaults on women worldwide and in the US are by intimate partners. Approximately half of all female homicides with a known perpetrator are committed by a former or current partner.[10] Partner violence is a precursor in 75% of IPV homicide cases, and many IPV homicide victims see a health care provider within the year before their death. ED visits provide an opportunity to identify IPV and those at high risk for future severe injury or death.

The morbidity and mortality associated with IPV translates to an economic burden of 3.6 trillion US dollars over the lifetime of those suffering. Both victims and perpetrators generate some of these costs with lost productivity and criminal justice activities, however, more than half of the estimated costs have been attributed to medical care.[11] Encouragingly, survivor health care use has been observed to return to normal rates several years after the cessation of IPV, suggesting that interventions against IPV may have a positive overall effect on health.

Causes and Natural History of Intimate Partner Violence

Clinicians may find it difficult to comprehend why humans choose to physically, sexually, or psychologically hurt someone whom they purport to love. Potential answers to this paradox involve multiple societal, community, relationship, and individual factors. Individual-level risk factors for both perpetration and victimization include childhood exposure to IPV or other abuse, presence of a physical or mental disability, and use of alcohol or drugs.[12] Though prevalent in all socioeconomic groups, IPV occurs at increased rates among those with lower income, job or housing instability, and male unemployment. Housing instability also increases the risk of sequelae, such as PTSD, depression, and increased ED use in IPV victims. Lack of social support for women, and delinquent peer associations for men, have been associated with victimization and perpetration, respectively.

Finally, human beings are not uniform and reflect different cultures with their own laws, attitudes, norms, and biases, including degrees of societal tolerance toward violence. Historically and worldwide, increased violence against women can be seen in societies with greater gender inequity. All aspects of our community, including law enforcement agencies, schools, the media, social services, and medical professionals play a role in changing dangerous attitudes that ignore IPV and helping those who are already affected find refuge. The literature overwhelmingly supports the concept that IPV victims want help from their doctors, and that they frequently seek help in the medical setting. Though medical resources alone cannot solve the societal problems that lead to IPV, through a collaborative community response and the four principles of identification, documentation, treatment, and referral, emergency clinicians can give their patients a chance to live without the excess burden of IPV.

Identification

Optimal medical intervention for IPV requires systematic screening for identification, and multidisciplinary care for treatment and referral. In addition to providing acute medical care, emergency clinicians need resources to secure that patients with positive IPV screens have access to primary care physicians and IPV community agencies for what is often a long-term, recurring problem, requiring long-term physical and mental health care, counseling and advocacy, legal aid, and long-term strategies for financial and social independence. Due to the human suffering and potential efficacy of treatment, the US Preventive Services Taskforce (USPSTF) recommends routine screening for IPV in women of childbearing age, even in the absence of overt injuries.[13]

Emergency clinicians may perceive barriers to identification, treatment, documentation, and referral of patients suffering from IPV. For the last few decades, medical schools have included some education on the identification and treatment of victimized patients, but many current emergency clinicians lack comprehensive training. In busy clinical settings such as the ED, the high volume of patients and acuity of disease may preclude private screening and more in-depth discussions of partner abuse. Given the complex psychosocial issues that may accompany IPV, emergency clinicians may also fear opening a Pandora's box, uncovering additional interventional needs that may be impossible to effectively address during an ED visit.[14]

Furthermore, ED providers may harbor their own prejudices and misunderstandings that can interfere with identifying and treating IPV victims. Despite obstacles, the majority of EDs endorse screening patients for IPV, and most EDs provide universal screening during triage nurse evaluations. Though nurses most often verbally query patients and record the screening information in the patient's chart, paper or computer self-administered private surveys may provide improved disclosure rates.

Screening

Asking all patients about partner violence (past or present) is called IPV screening. The USPSTF recommends routine screening of asymptomatic women of childbearing age for IPV in the health care setting, with referral to intervention services. Directed screening for IPV involves questioning patients presenting with illnesses and conditions associated with IPV (e.g., chronic pain, multiple ED visits, STIs, unintended pregnancy, mental health issues such as depression, anxiety, PTSD, and suicide, alcohol and drug presentations).

BOX 192.2 Screening Question Options for Intimate Partner Violence

Partner Violence Screen

- Have you been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?
- Do you feel safe in your current relationship?
- Is there a partner from a previous relationship who is making you feel unsafe now?

Modified Abuse Assessment Screen

- Has your partner or someone important to you ever emotionally or physically hurt you?
- Within the last year, have you been hit, slapped, kicked, or otherwise physically hurt by someone?
- Within the last year, has anyone forced you to participate in sexual activity?
- Are you afraid of your partner or anyone listed above?

Indirect Questioning

- Because relationship conflict and violence are problems in many of my patients' lives, I ask all my patients about this: Is violence at home occurring in your life?
- You seem bothered by something today. Often relationship problems are a source of concern in my patients' lives. Do you have concerns about your relationship?
- All couples argue sometimes. What happens when you and your partner argue? Do the arguments ever become physical?
- Often when I have seen this type of injury, it is due to a punch or a slap. Is this how your injury happened? (This may be used for a patient with a suspicious injury.)
- Often when I have seen patients with these symptoms, it is due to stress or fighting at home (or with a partner). Is this going on in your life? (This is an approach to a patient with complaints potentially related to anxiety/mental health/pain syndrome.)
- What happens when your partner wants to have sex but you don't?

Although studies have shown an increase in identification, proving a decrease in violence and increase in quality of life for ED screening has remained a challenge.[15] The USPSTF screening recommendation does not name a specific medical site, but given that IPV survivors use the ED at high rates, the ED provides a safe place for intervention. When surveyed in the ED, 26% of women in a past-year relationship screened positive for IPV; at 1 week and 3 months follow-up, there was no report of increased violence or harm as a result of screening.

Despite the organizational recommendations and institutional protocols to screen for IPV, practical implementations of screening cast doubt on the efficacy of the protocols. Challenges to ED protocol implementation include time constraints, privacy issues, and continued provider discomfort or indifference. Documentation of screening is often included in the triage section of the medical record and tasked to the triage nurse in a hectic and sometimes public area. This approach puts privacy and security at risk, because IPV survivors may be accompanied by their abusive partner. Additionally, other companions with the patient may not be aware of the situation and patients will rarely disclose without privacy.

Some well-studied IPV screening tools—the Partner Violence Screen (PVS) and Modified Abuse Assessment Screen (AAS)—are presented in Box 192.2. Studies that investigate the incidence and prevalence of IPV most often use a second longer survey, the Conflict Tactics Scale (CTS), as a gold standard to determine sensitivity and specificity of the tool. However, the CTS was developed for purposes of research rather than detecting IPV in the acute medical setting and may not be the most applicable gold standard for ED use. Emergency clinicians should ask about specific actions and avoid using the terms "victim" and "abuse," as patients may not yet see the actions as abuse or themselves as victims. Paper and electronic screening, an underutilized method, are at least as effective as face-to-face screening and more likely to be universally applied with less bias introduced by interprovider variability.[16] Patients should be informed about state-specific reporting requirements that may accompany disclosure of IPV. Triage screening should be followed up privately, after all visitors have been asked to step out of the room. Initial framing statements can normalize and destigmatize IPV and may improve victims' disclosure to providers (Box 192.2). Patients are more likely to disclose abuse if the provider asks at least one additional related question.

We recommend asking open-ended questions to give patients a chance to tell their story. Questioning about IPV should be done in a nonthreatening manner, devoid of blame and judgment. An atmosphere of support and understanding will facilitate patient disclosure. We recommend inclusive terms, such as *partner,* for those in same-sex or gender nonconforming relationships. Those in same-sex relationships may feel added challenges to disclosing abuse. Abusive partners may use the threat of outing a victim's sexuality to intimidate them into silence.[2,17]

Partners should be asked to leave the room before the patient is asked about IPV. Patients will rarely admit to abusive acts unless they are guaranteed privacy. Moreover, when asked in the presence of an abusive partner, questions about IPV can put the patient in future danger. Usually, a patient's companion will agree to leave cooperatively before the physical examination. If a companion is resistant to leaving, the patient may be taken to the restroom (e.g., for a urine sample) or taken to the radiology area and privately asked about IPV.

CLINICAL FEATURES

Injuries and Comorbidities

Classic injury patterns (e.g., facial injuries, multiple injuries, extremity fractures) have demonstrated limited predictive value in screening for IPV. Most IPV victims present to the ED for non-injury visits, including gynecology-related complaints, mental health and substance abuse complaints, pain syndromes, and uncontrolled medical illnesses. Historical elements that may suggest an abuser is preventing the patient's access to care include a delay in seeking medical care, noncompliance with medications, or missed medical appointments. Unless probed about IPV, these patients may not be identified. If an injury is a result of IPV, the patient may be reluctant to divulge the information. Additional historical clues of IPV are a vague or changing history, a history that is inconsistent with the injuries, a statement by the patient that he or she is accident-prone, and a past history of injuries.

IPV is often considered in women who present with injuries or assault but should also be considered in men and teenage boys with injuries. Presenting injuries in male patients are commonly less severe (e.g., abrasions) and the mechanism is often scratching, punching, or being hit with a blunt object. Though rarely discussed, emergency clinicians treat perpetrators who might be suffering from mental illness or substance abuse. These patients may want help with their violent behavior but lack assistance to accomplish a change. While making known the obligations of mandatory reporting (see later), clinicians should give patients a chance to disclose perpetration of IPV, providing treatment resources and helping attenuate abuse.[18]

Questioning Injury Presentations

Emergency clinicians should inquire about abuse in an open-ended and non-accusatory way, asking how injuries occurred and if another

Fig. 192.1 Central location of injury common in IPV. (Image copyright of Malinda Wheeler RN, NP, SANE.)

Fig. 192.2 Pattern injury: perpetrator carved his initials on the patients back and buttock. (Image copyright of Malinda Wheeler RN, NP, SANE.)

person played a role. Victimized patients may come to the ED with acute injuries, or injuries may be an incidental finding discovered during the physical examination. The emergency clinician should look for clues that an injury may be intentional. Injuries more likely to be intentional include: a central location (e.g., trunk, breasts Fig. 192.1); bilateral injuries (i.e., both arms or both legs); defensive injuries (e.g., ecchymoses on the ulnar aspect of the forearm or back of the hand); and patterned injuries (i.e., markings of an object—sole of a shoe, a cigarette or imprint pattern burn, or knife tip carving Fig. 192.2). Common locations for IPV injuries are the head, face, mouth, and neck (Fig. 192.3). Common ED head injuries from IPV include: facial contusions, lacerations, or fractures; alopecia from the perpetrator chronically pulling the victim by the hair; or acute scalp lacerations from pulling injuries. Strangulation can cause neck abrasions and contusions, facial and conjunctival petechiae, or subconjunctival hemorrhages (Figs. 192.4 and 192.5). Strangled patients may report a loss of consciousness or difficulty swallowing, speaking, or breathing. Patterned fingertip-shaped contusions (i.e., grab marks) to the upper arms suggest a violent relationship (Fig. 192.6). Emergency clinicians should document injury location, size, swelling, tenderness, coloration, evidence of healing, and presence of a pattern. The electronic medical record often provides a format to upload photographic images with patient consent.

SPECIFIC ISSUES

Gynecologic-Related Presentations

IPV victims commonly present to the ED with obstetric and gynecologic complaints.[19] Presentations related to IPV include unintended pregnancy-related complications, requests for emergency

Fig. 192.6 Contusions suggestive of fingertip marks from forceful grabbing by perpetrator. (Image copyright of Malinda Wheeler RN, NP, SANE.)

contraception or termination of pregnancy, and frequent sexually transmitted infections. Unintended pregnancy and STIs may be a consequence of loss of reproductive control or sexual assault. Sexual violence is a common tactic used for intimidation and control in IPV; approximately half of abused women admit to sexual assault in the context of abuse. Similarly, approximately half of sexual assault patients name an intimate or formerly intimate partner as the perpetrator. If the sexual assault occurred within 3 to 5 days (depending on state law) of the ED visit, a forensic sexual assault examination should be offered to the patient (see Chapter 191).[20]

The sequelae of intimate partner sexual abuse are at least as serious as those of stranger sexual assault and those who disclose and submit to examination display more nongenital injuries than victims of stranger assault. IPV screening tools should include questions about sexual abuse or reproductive coercion but often fail to do so. Emergency clinicians should ask all patients reporting sexual assault about IPV and safety at home, including what happens when the patient does not want to have sex. Patients may not label forced sex from a partner as sexual assault, a message given by the perpetrator or incorrect societal views. Providers can inform patients that, as of 1993, forced or incapacitated sex with a spouse carries the same legal felony charges as stranger assault in all states with specific state laws available at the RAINN website.[21]

Mental Health Presentations

Repeated physical, sexual, and psychological assaults often carry serious mental health consequences for those living with IPV. Patients presenting to the ED with depression, suicidal ideation, homicidal ideation, PTSD, eating disorders, and alcohol and drug misuse are more likely to have a history of IPV.

Alcohol and Drug Use and Intimate Partner Violence

Substance abuse in either or both parties in an IPV relationship places women at greater risk for physical and sexual intimate partner victimization. Alcohol and drug use may be used to cope with the emotional and physical sequelae of IPV, but can also increase perpetrator violence and leave impaired victims more vulnerable. Victims with substance abuse issues often face negative social and provider bias, reducing the likelihood of accessing medical and community intervention resources. Despite the added difficulties, emergency clinicians play a key role in identifying IPV victims and connecting them with needed help.

Chronic Medical Conditions

IPV patients commonly seek care for chronic medical conditions from previous injuries or those associated with abuse, including mental health disorders, musculoskeletal disorders, and gynecological complaints. Other common medical presentations of IPV include cardiorespiratory illnesses (e.g., palpitations, chest pain, asthma exacerbations, or shortness of breath), gastrointestinal disorders (e.g., abdominal pain and functional bowel disease), and general constitutional complaints (e.g., weakness, fatigue, dizziness, and pain syndromes).

Pain Syndromes

As seen with other posttraumatic syndromes, patients recovering from IPV often suffer from chronic pain, including headache, abdominal pain, back pain, and bone and joint pain, with disability and pain symptoms persisting for years after leaving the violence. Those with more severe abuse, sexual abuse, and childhood abuse report more symptoms. Identifying past abuse facilitates referral to critical resources and decreases use of ineffective medical interventions.

Human Trafficking

Because a trafficker often maintains a sexually intimate relationship with the victim, a victim of human trafficking (HT) can be mistaken for an IPV victim. Human trafficking perpetrators often use physical, emotional, and sexual violence to control victims, frequently forcing the use of drugs or alcohol. Human trafficking entails unique dynamics, challenges, and approaches to intervention and resources (see Chapters 187 and 172).

DIAGNOSTIC TESTING

Diagnostic testing for specific injuries and illnesses related to IPV follows general medical, trauma, and injury guidelines.

MANAGEMENT

After identifying a patient suffering from IPV, the next steps are treatment and documentation. To ensure safety for staff and patients, we recommend notifying hospital security of high-risk situations, such as a victim presenting immediately after leaving their perpetrator.

ED screening for IPV should be determined by a coordinated institutional response: ED staff training; development of institution-wide easily accessible policies and protocols; and in-person resources that include an advocate with IPV expertise (e.g., social worker). Hospitals often partner with local IPV shelters to provide real-time responses to a patient in crisis and safety planning. The US Veteran's Affairs (VA) coordinated and comprehensive program is one example of an effective multifaceted institutional response. Every VA medical facility implements and maintains an IPV Assistance Program for veterans and their intimate partners. Those impacted by IPV have access to resources, assessment intervention, and referrals, and some interventions have demonstrated successful primary prevention outcomes.[22] For institutions that lack a hospital-based IPV program, partnering with a local domestic violence agency or shelter increases resources and can facilitate coordination of care.

IPV victims should receive a trauma-informed approach that recognizes the effect of past and present trauma on the individual and their community, as well as how this trauma is impacted by treatment in the health care system. Emergency clinicians should sympathize with the victim's situation, while emphasizing the strengths of the survivor. Victims should be recognized as the experts in their situation, allowing them to use their unique insights to determine needed interventions.

Physician-Delivered Messages

IPV patients with traumatic injuries or medical conditions should be treated appropriately, and physical symptoms should not be

BOX 192.3 Simple Steps for Discussing IPV Post Disclosure

1. Give supportive messages, for example:
   - "Thank you for sharing this with me. I know it took courage."
   - "No one deserves to be treated this way. It doesn't matter what you did or what your partner said you did, you do not deserve to be hit."
   - "You are not the only one who has suffered this kind of abuse. IPV is a common problem."
   - "You don't have to deal with this alone. We have people here (or in the community) who can help you."
2. Explain that you would like to help them today. Ask permission to get an advocate or social worker involved. Ask how else staff can help today.
3. Safety and danger assessment—assess immediate safety concerns; have further discussion and planning with the social worker or advocate.
4. Make a plan for follow-up. Reinforce that IPV is a health care problem and that the patient can return for assistance.

minimized or ascribed solely to IPV. Psychological treatment and support are essential; supportive counseling from an emergency clinician can facilitate catharsis for a victim who has been suffering in silence. Victims universally feel they deserve the abuse, because abusers introduce and reinforce this notion throughout the relationship. Emergency clinicians should unequivocally tell IPV victims that the abuse is *not* their fault, emphasizing that no one deserves to suffer physical, psychological, or sexual abuse. Use compassionate and supportive statements that acknowledge the abuse experience, commend the patient for disclosing, and explain how information will facilitate good care. A few kind and supportive words from a provider can help alleviate the guilt and shame felt when revealing the abuse. Box 192.3 provides examples of comforting phrases and dialogue.

Documentation

Physicians should document the identity of the other person involved in the injury, including that person's relationship to the patient. A victim living with their assailant will need unique resources, and the nature of the relationship is also needed for appropriate diagnostic coding. Medical record documentation can help future health care providers deliver optimal care. Medical records may also be used in court to help victims seeking legal recourse, child custody, or restraining orders. Patient statements should be documented in quotes or preceded with "patient states." Injuries should be described, recording the size or length, type of injury (e.g., bruise, incised wound, abrasion), and location. Injuries should be digitally photographed (usually by law enforcement or forensic specialist) with adequate quality for legal use. We recommend at least 4 photographs of every injury:

- 1 long-range picture, including the face for identification,
- 1 medium range,
- 1 close range without ruler, and
- 1 close range with ruler.

Many electronic medical records incorporate a way to upload photographs directly into the medical record with the time and date recorded. Patients who decline photography in the ED should be encouraged to privately document their injuries with their own cameras or phones, as self-obtained images have been used successfully in prosecution of IPV. Referral agencies, social work, and law enforcement involvement, follow-up, and referrals should be recorded in the medical record. The diagnosis of IPV or suspected IPV should be documented for possible use in legal proceedings.

Immigration Issues

Due to cultural norms that embrace husband-to-wife marital violence and control, immigrant women are less likely to reveal abuse. Many cultures blame the woman for any type of marital discord, including violence. A victim's own family may desert her if she leaves her partner for any reason, even fear of homicide. As abuse draws the attention of law enforcement agencies, undocumented immigrant women may fear deportation of themselves or their partners. Additionally, a citizen perpetrator may use the victim's immigration status to force the victim to remain in the violent relationship (including marriage). Language barriers may further impede a victim's ability to obtain help. In recent years, federal and state governments have attempted to correct some of the legal problems that plague immigrant IPV victims. According to the federal Violence Against Women Act (VAWA), victims who depend on their perpetrator to legally stay in the United States may self-petition for legal permanent residence as they attempt to separate.[20,23] Programs and protocols for treating IPV victims should include information on local resources for ethnic minorities and immigrants.

Referral

Referral services can help assess the risk of acute danger to the patient or their children, determine readiness to separate from the perpetrator, and provide specific means to increase safety. Protocols should include intervention (e.g., from IPV advocates or social workers) and referral resources, including safe housing. If separating from the violent partner, patients may need legal advice (e.g., orders for protection, custody, or other official charges), shelter placement, and ongoing support groups. A discussion about past strategies, what has or has not been successful, can help guide management. Discussing the scope and consequences of the violence (e.g., on the patient or their children) may help the patient make the safest decisions. Orders for protection have been shown to be effective in decreasing future violence, but cannot guarantee safety, and perpetrators with past criminal records may be less likely to respect law enforcement directives. Although survivors may not be ready to leave an abusive situation, the provider should support the survivor and encourage disclosure to future health care providers or IPV agencies.

If children are present in the home, have experienced violence, or are at risk for becoming targets of violence, the emergency clinician may be mandated by law to report the situation to child protective services. Emergency clinicians should explain that reporting helps keep the children safe, demonstrates the victim's desire to protect the children, and is more likely to reflect positively on the victim in the event of future custody hearings. A brief discussion about the long-term health effects of violence on children may be helpful, as victims are often more focused on the immediate consequences to children.[24] Individualized safety planning may be complex and time consuming and is best accomplished by an experienced social worker or IPV advocate.

If the patient has not disclosed, but the emergency clinician suspects IPV, a disclosure should not be forced. It is more important to express concern for the patient, explain how the condition may be related to stress, and offer support, community domestic violence resources, and the opportunity to return for assistance. "My Plan" is a valuable smart phone or computer resource to assess danger and plan for safety (available at https://www.myplanapp.org/home) (Fig. 192.7). In the absence of an advocate, social worker, or law enforcement specialist, victims can use My Plan to learn more about IPV and develop a detailed safety plan. Clinicians can also consult or advocate using the national 24-hour IPV hotline (1-800-799-SAFE).

Danger Assessment

Campbell and colleagues have developed a 20-item danger assessment tool (Fig. 192.8) that was developed and validated based on reviews

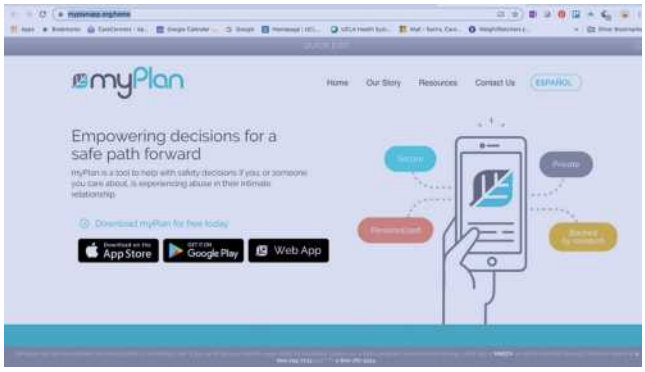

Fig. 192.7 Downloadable My Plan for smart phone and computer application with danger assessment.

of IPV-related homicides across 11 cities. This study identified factors more often correlated with IPV leading to homicide or attempted homicide and can assess immediate risk for future severe violence and lethality, however, the tool is somewhat complex to score and requires familiarity. A self-administered version of this tool is available through the MyPlan application for IOS and Android (see Fig. 192.7). A brief, five-item version of this tool (Box 192.4) can identify ED patients at high risk; a threshold of three "yes" answers has shown an 83% sensitivity for predicting future severe or potentially lethal assault. This information should be shared with the patient, ideally in conjunction with social work and an advocate to help the patient in planning for safety and the desired course of action upon discharge. The MyPlan app also contains specific recommendations for safety planning.

DANGER ASSESSMENT

Jacquelyn C. Campbell, Ph.D., R.N. Copyright, 2003; update 2019; www.dangerassessment.com

Several risk factors have been associated with increased risk of homicides (murders) of women and men in violent relationships. We cannot predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation.

Using the calendar, please mark the approximate dates during the past year when you were abused by your partner or ex-partner. Write on that date how bad the incident was according to the following scale:

1. Slapping, pushing; no injuries and/or lasting pain
2. Punching, kicking; bruises, cuts, and/or continuing pain
3. "Beating up"; severe contusions, burns, broken bones
4. Threat to use weapon; head injury, internal injury, permanent injury, miscarriage or choking" (use a © in the date to indicate choking/strangulation/cut off your breathing- example 4©)
5. Use of weapon; wounds from weapon

(If any of the descriptions for the higher number apply, use the higher number.)

Mark **Yes** or **No** for each of the following. ("He" refers to your husband, partner, ex-husband, ex-partner, or whoever is currently physically hurting you.)

_____ 1. Has the physical violence increased in severity or frequency over the past year?
_____ 2. Does he own a gun?
_____ 3. Have you left him after living together during the past year?
3a. (If you have *never* lived with him, check here: ___)
_____ 4. Is he unemployed?
_____ 5. Has he ever used a weapon against you or threatened you with a lethal weapon?(If yes, was the weapon a gun? check here: ___)
_____ 6. Does he threaten to kill you?
_____ 7. Has he avoided being arrested for domestic violence?
_____ 8. Do you have a child that is not his?
_____ 9. Has he ever forced you to have sex when you did not wish to do so?
_____ 10. Does he ever try to choke/strangle you or cut off your breathing?
10a. (If yes, has he done it more than once, or did it make you pass out or black out or make you dizzy? check here: ___)
_____ 11. Does he use illegal drugs? By drugs, I mean "uppers" or amphetamines, "meth", speed, angel dust, cocaine, "crack", street drugs or mixtures.
_____ 12. Is he an alcoholic or problem drinker?
_____ 13. Does he control most or all of your daily activities? For instance, does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car? (If he tries, but you do not let him, check here: ___)
_____ 14. Is he violently and constantly jealous of you? (For instance, does he say: "If I can't have you, no one can.")
_____ 15. Have you ever been beaten by him while you were pregnant? (If you have never been pregnant by him, check here: ___)
_____ 16. Has he ever threatened or tried to commit suicide?
_____ 17. Does he threaten to harm your children?
_____ 18. Do you believe he is capable of killing you?
_____ 19. Does he follow or spy on you, leave threatening notes or messages, destroy your property, or call you when you don't want him to?
_____ 20. Have you ever threatened or tried to commit suicide?

_____ Total "Yes" answers

Thank you. Please talk to your nurse, advocate, or counselor about what the Danger Assessment means in your situation.

Fig. 192.8 Danger assessment tool.

BOX 192.4 Brief Danger Assessment

1. Has the physical violence increased in frequency or severity over the past 6 months?
2. Has [he/she] ever used a weapon or threatened you with a weapon?
3. Do you believe [he/she] is capable of killing you?
4. Have you ever been beaten by [him/her] while you were pregnant?
5. Is [he/she] violently and constantly jealous of you?

Mental Health Screening

Given the increased prevalence of mental health disorders in IPV survivors, including depression, anxiety, and suicide, providers should refer for supportive counseling and treatment.

Privacy and Confidentiality Considerations

Privacy is a concern for many IPV survivors. Any referrals or records should only be released with permission of the survivor. IPV should not be reported to police without the consent of the survivor, unless mandated by law in cases of coexisting child, elder, or disabled abuse or based on state-specific reporting statutes (e.g., burns or injuries inflicted by weapons). Links to state legislation governing the reporting of injuries due to assault may be found at the victim rights website.[25] If reporting is mandated, the emergency clinician should make every effort to involve the patient. Health Insurance Portability and Accountability Act (HIPAA) violations do not apply in this circumstance; the privacy rule contains a provision allowing disclosure of protected health information to law enforcement in the case of reporting required by law.

Involvement of Law Enforcement Agencies

Unless required by mandatory reporting laws, patients should be given the choice of whether or not to involve law enforcement. Consultation with law enforcement personnel may enhance victim safety through immediate access to restraining orders (in some states). Additionally, acute injuries to the victim can lead to the immediate arrest of the perpetrator, thus temporary victim safety. Almost all states have laws that require medical personnel to notify law enforcement agencies in special circumstances, such as when a patient presents with injuries caused by a firearm or other deadly weapon. Many states also require that emergency clinicians report any victim of aggravated assault or a violent crime. In the last few decades, many states, counties, and cities have implemented IPV training for law enforcement officers. Courses can provide the sensitivity-training and knowledge needed to appropriately interview and counsel victims. However, this training is not universal, and clinicians should be aware of the limitations of their local law enforcement agencies.

Intimate Partner Violence Coding and Diagnosis

International Classification of Diseases (ICD)–10 coding provides increased specificity for the coding of IPV (Table 192.1). New codes added to the primary category allow the provider to include adult maltreatment and neglect. Other codes added include suspected IPV (T codes) and past IPV and counseling (V codes). Similar to ICD-9, ICD-10 also includes E codes, which are used to describe the nature of the cause of the injury—for example, "Who committed the act of violence" (E967.0–E967.9), the nature of the abuse (E960–E968), the intent of the abuse or neglect (E904.0–E968.4), and the intentionality of the abuse (E980–E989).

TABLE 192.1 ICD-10 Coding Categories Used for Intimate Partner Violence

ICD-10 Code	Description
995.8_	Maltreatment (abuse)
995.81	Physically abused adult
995.82	Adult emotional and psychological
995.83	Adult sexual
995.84	Adult neglect
995.85	Other, multiple forms
E	Who, intentionality, nature of abuse
T4	Suspected abuse
T7	Confirmed abuse
V	Past history of abuse

ICD, International Classification of Diseases.

DISPOSITION

Patients with potentially life-threatening injuries, particularly attempted strangulation, are at high risk of future violence and should have safe plans for discharge or be offered temporary admission. Although shelters are one option, they may not be available in all locations. Patients who qualify and choose to go to an IPV shelter are typically required to disengage from their lives to protect the location and safety of the shelter. They cannot contact family or friends, nor can they contact their job or their children's schools. Even when present, local shelters may lack enough space to take a victim with children, or may not accept patients with substance abuse issues, teenage male children of survivors, or male or transgender survivors.

All survivors who are being discharged should receive patient-appropriate resources for IPV, mental health, substance abuse, and social services. The emergency clinician may not agree with the choices made by the survivor but should always respect these decisions and offer encouragement and validation. This approach will increase the chances of a positive interaction and increase the likelihood of further help-seeking behavior.

CHAPTER 192: QUESTIONS AND ANSWERS

1. Intimate partner violence occurs in which of the following population of patients?

- **a.** Restricted to lower socioeconomic classes and is never seen in wealthy highly educated individuals.
- **b.** Found only amongst women in heterosexual relationships and not in other individuals.
- **c.** Patient has injuries from a weapon used in the assault.
- **d.** Similar prevalence in same-sex and gender nonconforming individuals as in heterosexual couples.

Answer: D. IPV occurs with at least as high a prevalence in same-sex and gender nonconforming individuals as in heterosexual couples. It also is found commonly in wealthy and highly educated individuals. Most patients who present to the ED with conditions related to IPV do not have injuries at the time of the visit. Finally, IPV violence consists of acts or threats of physical, psychological, or sexual violence between intimate or formerly intimate partners who need not ever have been married.

2. The emergency clinician after identifying a patient suffering from IPV should employ which of the following strategies?

- **a.** Call the police and have the perpetrator immediately arrested.
- **b.** Validate the disclosure of abuse and communicate the importance of leaving the situation immediately to ensure personal safety.
- **c.** Provide kind and supportive messages and information.
- **d.** Report to the public health department.

Answer: B. Emergency clinicians should validate the disclosure of abuse, emphasize that the victim is not at fault, and encourage future discussions with IPV community agencies or other health care providers. Immediate safety should be assessed, but most patients will not want to leave the abuser immediately; however, a positive initial conversation may begin the process of ending the abusive relationship. Reporting to law enforcement or health department should be done only with victim consent or if mandated by law. A templated list will allow the ED staff to create a basic safety plan with the patient; an individualized plan is best done in conjunction with trained domestic violence advocates, typically in follow-up. Referral to couples counseling is inappropriate and ineffective in violent relationships and potentially dangerous.

3. The best practice for inquiring about IPV is which of the following?

- **a.** Use open-ended questions that describe actions and feelings.
- **b.** Use the term "abuse" when questioning the patient.
- **c.** Ise the term "victim" to ensure the patient knows the clinician is concerned.
- **d.** Question the patient's partner about what happened.

CHAPTER 192: QUESTIONS AND ANSWERS—cont'd

Answer: A. Partners should be asked to leave in a routine manner before the patient is asked about IPV. Patients will rarely admit to abusive acts unless they are guaranteed privacy, and initiation of the topic is potentially dangerous in the presence of an abusive partner who should not be questioned by providers. Providers should query the patient with any reasonable options that provide an empathetic and open approach facilitating improved screening rates. Providers should ask about specific actions and avoid use of the terms "victim" and "abuse" because patients may not yes see the actions as abuse or themselves as a victims.

4. Which of the following is most suspicious for intentional injury from IPV?
   - **a.** Ecchymosis of lower extremity
   - **b.** Paronychia
   - **c.** Pattern injuries
   - **d.** Infected earring

Answer: C. Signs of an intentional injury include a central location (i.e., trunk and breasts), bilateral injuries (both arms or both legs), defensive injuries (i.e., ecchymoses on the back of the hand as a result of protecting the face), and patterned injuries (such as carved words on the back, a cigarette burn or other pattern of an object,).

5. By the state law where Dr. Jane works, emergency clinicians practicing in the state are mandated reporters for suspicious injuries from assaultive or abusive conduct. After identifying a patient with such suspicious injuries from IPV Dr. Jane should do which of the following regarding reporting?
   - **a.** Not report because the Health Insurance Portability and Accountability Act (HIPAA) prohibits reporting of this patient's injuries.
   - **b.** Report without telling the patient so the patient cannot object.
   - **c.** Report as required by state law because it supersedes patient's HIPAA consent rights.
   - **d.** Obtain a signed consent to make the report.
   - **e.** Call the legal department before reporting.

Answer: C. Some states have laws that require injury reporting to local authorities. Patients should be informed about state-specific reporting requirements that may accompany disclosure of abusive injuries. Mandatory reporting of health conditions required by local laws are exempted from HIPAA regulations. In general, IPV should not be reported to police without the consent of the survivor unless mandated by law (as in this case) or in cases of coexisting child, elder, or disabled abuse or based on state-specific reporting statutes (e.g., burns or injuries inflicted by weapons). If reporting is mandated, the provider should make every effort to involve the patient. However, concerns for HIPAA violations do not apply in this circumstance; the privacy rule contains a provision allowing disclosure of protected health information to law enforcement in the case of reporting required by law.

Global Emergency Medicine

Global Emergency Medicine

Sean M. Kivlehan and Stephanie Kayden

KEY CONCEPTS

- World Health Assembly resolution 72.16, "Emergency care systems for universal health coverage: ensuring timely care for the acutely ill and injured," was passed in 2019 and calls for the strengthening of emergency care delivery through a detailed list of initiatives across the prehospital, facility, public health, and disaster preparedness fields.
- In low- and middle-income countries (LMICs), substantial excess mortality amenable to emergency health care exists, and the development of high-quality emergency care can be a significant systemic contribution to improving mortality.
- Global emergency medicine (GEM) is an academic subspecialty of emergency medicine focused on the strengthening of the specialty worldwide and on improving international humanitarian response.
- GEM can be divided into development and humanitarian work. Development work is typically focused on strengthening local systems in a sustainable manner, while humanitarian work involves an acute response to large-scale crises in which local resources are overwhelmed.
- The model curriculum for a GEM fellowship includes experiences in emergency medicine systems, humanitarian relief, disaster medicine, public health, travel and field medicine, program administration, academic skills, and clinical skills.

FOUNDATIONS

Recognizing that emergencies will occur and that patients will seek care regardless of a system's preparation, global emergency medicine (GEM) strives to strengthen emergency care delivery in all settings. Further recognizing that patients present to the emergency department (ED) without a diagnosis, but with a complaint, GEM focuses on presentation-based solutions for conditions for all age groups, both trauma and medical, infectious and noninfectious, and pregnancy. GEM seeks to ensure early access to quality emergency care for all people, regardless of gender, ethnicity, age, or ability to pay.

In low- and middle-income countries (LMICs), substantial excess mortality amenable to emergency health care exists.[1] This is due to both access to care and quality of care, both of which the development of high-quality emergency care systems can impact.[2,3] As a central hub of health care access, the ED provides both a safety net for the community and a point of entry into the medical system. Programs that seek to strengthen emergency care should be coordinated with other medical and surgical specialties, prehospital care, public health authorities, and social services to identify gaps and provide a seamless continuum of care.

GEM is an academic subspecialty of emergency medicine focused on the strengthening of the specialty worldwide and on improving international humanitarian response. Although much of the work focuses on low-resource settings, its mission is broad and can apply to all countries. The academic subspecialty of GEM emphasizes specialty development programs that are long-term and sustainable, in contrast to short-term international clinical experiences or "medical missions."

GEM is one of many fields of global health. *Global health* is a broad term that encompasses all aspects of health care with global interest, such as primary care, surgery, and preventative care such as vaccine programming. As in traditional emergency medicine, there is substantial overlap between GEM and the many other fields within global health. For example, preventative programs such as tetanus vaccination are frequently incorporated into global emergency care.

The Academic Practice of Global Emergency Medicine

The GEM physician is a trained subspecialist who works to strengthen the practice of emergency medicine worldwide. In the United States (US), the subspecialty of GEM has been recognized by national professional associations including the American College of Emergency Physicians (ACEP), Society for Academic Emergency Medicine (SAEM), and the American Academy of Emergency Medicine (AAEM) through their respective GEM-oriented sections. Many GEM specialists have completed GEM fellowships: 1 to 2 years of additional post-residency training, often including a graduate degree focused on global health. A growing number of academic EM departments in the United States maintain a division of global emergency medicine which provides an academic home to GEM specialists.

Fellowship training programs in the United States coordinate their efforts through the Global Emergency Medicine Fellowship Consortium (GEMFC), which maintains a website describing active fellowships and facilitating the annual application process.[4] Curricula vary based on an individual fellowship's goals, which may be more heavily oriented to systems building, research, education, direct clinical care, or humanitarian work. Most fellowships incorporate a combination of these areas. Model curricula have been proposed, which include experiences in the following domains: EM systems, humanitarian relief, disaster medicine, public health, travel and field medicine, program administration, academic skills, and clinical skills (Table e1.1). Approaches to meeting knowledge and skill goals may include a variety of educational programming, such as a Master of Public Health degree, short courses such as the International Committee for the Red Cross (ICRC) Health Emergencies in Large Populations, tropical medicine courses, and international field experiences. Proposed competency assessment frameworks for fellows training in GEM must adapt to the diverse fellowship curricula and focus on the following key domains: professionalism, communication, medical knowledge, patient care, research skills, quality improvement, and social accountability to partners and stakeholders.[5]

SPECIFIC ISSUES

History of Global Emergency Medicine

The first emergency medicine residencies in the United States began in the early 1970s and emergency medicine was formally recognized as a

specialty by the American Board of Medical Specialties in 1979. In the following decades, emergency medicine grew both within the United States and globally. It was recognized as a specialty in Canada in 1980, Australia in 1981, soon followed by Hong Kong, Singapore, the United Kingdom (UK), and others.

The first emergency physicians building the specialty came together to form academic societies and advocacy groups to build collaboration, facilitate idea exchange, and advance the field. ACEP was formed in 1968, and similar organizations in other countries soon followed. In 1989, recognizing the need for international support in developing emergency medicine, the International Federation for Emergency Medicine (IFEM) was chartered by its founding members, ACEP, British Association for Accident and Emergency Medicine (UK; now the Royal College of Emergency Medicine), Australasian College for Emergency Medicine (Australia), and Canadian Association of Emergency Physicians (Canada). IFEM has grown to include over 50 full members and creates core standards, curricula, and policy briefs on emergency medicine through its committees and interest groups. ACEP created its section on international emergency medicine in 1998, reflecting the growing interest among emergency physicians to engage in global activities. As other societies followed with their own committees or interest groups focusing on emergency medicine development internationally, the specialty of GEM took its modern form.

Fellowship training in GEM arose from the combined need of trained emergency physicians practicing internationally who realized they had inadequate preparation and residents expressing increased interest in entering the field. The first fellowships in the United States were started in the mid-1990s with a curriculum largely based on a consensus panel of emergency physicians practicing GEM. As the specialty of GEM has matured, fellowships have grown significantly in number both in the United States and in other countries. The GEMFC was created in 2012 to bring GEM fellowship directors together to further define the specialty and agree on common curricular goals and assessment criteria.

The practice of GEM has grown in scope and quality. GEM research has raised awareness of the burden of emergency care amenable conditions, the economic value of emergency care, and the central role of emergency care systems in public health and health security.[3,6,7] In 2013, SAEM hosted the "Global Health and Emergency Care: A Research Agenda" Consensus Conference during which priorities were discussed and agreed upon across eight focus areas. These priorities formed a foundation for the currently maturing GEM research priorities.[7,8]

The World Health Organization (WHO) supported numerous efforts related to GEM in the early 2000s, including trauma care and prehospital care in low-resource settings, later forming the Emergency, Trauma, and Acute Care Programme in 2015 which is led by an emergency physician.[9] This program has refined definitions of emergency care systems, essential functions, quality indicators, and emergency care itself[10] (Fig. e1.1 and Table e1.2). In 2019, the National Institutes of Health (NIH) Fogarty Center for Global Health Studies initiated the Collaborative for Enhancing Emergency Care Research in LMICs (CLEER), which has further defined the research agenda for GEM.[7,11]

Several resolutions related to emergency care have been issued by the World Health Assembly (WHA), the governing body of the WHO. Passed in 2019, WHA resolution 72.16, "Emergency care systems for universal health coverage: ensuring timely care for the acutely ill and injured," calls for the strengthening of emergency care delivery through a detailed list of initiatives across the prehospital, facility, public health, and disaster preparedness fields.[12] This resolution is aligned with the three Sustainable Development Goals (SDG) that are directly affected by emergency care: Goal 3 (Ensure healthy lives and promote well-being for all at all ages), Goal 11 (Make cities and human settlements inclusive, safe, resilient and sustainable), and Goal 16 (Promote peaceful and inclusive societies for sustainable development, promote access to justice for all and build effective, accountable and inclusive institutions at all levels).[13] Prior resolutions have focused on surgical and anesthesia care, mental health, disaster management, emergency care systems, and road safety (Table e1.3).

Global EM Organizations

Emergency medicine is represented globally by a variety of professional organizations whose objectives differ based on their core missions. A growing number of countries have a national professional society focused on the development and support of the practice of domestic emergency medicine. In the United States, ACEP is the largest organization, and analogous organizations exist in at least 50 other countries. The IFEM maintains a current list of these organizations on its website.[14]

Regional societies are composed of several organizations representing the specific interests and needs of emergency medicine in a

particular area of the world. An example is the African Federation for Emergency Medicine (AFEM), which has developed African context-specific educational material for emergency medicine and supports the development of the specialty across the continent.[15] The Consortium of Universities for Global Health (CUGH) is based in Washington, DC, and brings together academic institutions from around the world that have a focus on global health. CUGH provides an important forum for discussion among academics working in the field of global health and is not limited in scope to health care or emergency medicine.[16]

AREAS OF FOCUS IN GLOBAL EMERGENCY MEDICINE

GEM can be divided into development and humanitarian work. Development work is typically longer term and proactive with the goal of strengthening local systems in a sustainable manner. Humanitarian work tends to be more reactive, focused on the response to large-scale crises in which local resources are overwhelmed. These two subfields complement each other: an emergency care system strengthened through development work should be able to surge during a crisis to enhance humanitarian efforts, and an effective humanitarian response will include strengthening the local system to provide resilience against future crises. Humanitarian response is discussed in detail in Chapter e2. This chapter on GEM will focus on the development of EM systems globally.

Strengthening the specialty of emergency medicine globally is a large and complex task that requires efforts within the fields of education, research, and policy. For example, as an emergency care system is strengthened, provider training must be expanded to provide the level of care needed, while policy efforts must establish credentialing pathways for these new providers. Locally applicable processes and outcome measures must be defined, and interventions must be measured through research. These interdependent efforts are equally critical to GEM.

Education

Field educational programs can be categorized by duration, content, and learner type. Programming should be needs-driven and context-appropriate.

TABLE E1.3 World Health Assembly Resolutions Relevant to GEM

Resolution	Title	Year Passed
56.24	Implementing the Recommendations of the World Report on Violence and Health	2003
57.10	Road Safety and Health	2004
60.22	Health Systems: Emergency Care Systems	2007
64.10	Strengthening National Health Emergency and Disaster Management Capacities and Resilience of Health Systems	2011
66.8	Comprehensive Mental Health Action Plan 2013–2020	2013
68.15	Strengthening Emergency and Essential Surgical Care and Anesthesia as a Component of Universal Health Coverage	2015
69.1	Strengthening Essential Public Health Functions in Support of the Achievement of Universal Health Coverage	2016
72.16	Emergency Care Systems for Universal Health Coverage: Ensuring Timely Care for the Acutely Ill and Injured	2019

A systematic review of EM training programs in LMICs supported by high-income country partners found that the majority of training programs were one month or less in duration; focused on physicians and less commonly nurses; and most frequently oriented to EM in general, trauma, pediatrics, or ultrasound.[17] Prior to any educational intervention, a needs assessment should be performed in coordination with local stakeholders. Development of a new program or adaptation of existing programs should be performed in collaboration with local stakeholders, which may include clinical providers, educators, students, the community, administrators, and policymakers. It is critical to ensure that graduates from an educational program will be recognized locally through a credentialing mechanism such as certification or licensure. Program sustainability can be supported through two equally important pathways: (1) identifying future educators among students and preparing them to eventually take local ownership of the program, and (2) ensuring program graduates are employable and able to practice within their scope.

Systems Development (Systems Strengthening)

Emergency care systems exist nearly everywhere in some form, though they may be unrecognizable to an emergency care clinician from a high-resource setting. The strengthening of a system begins by understanding the components that already exist and how they interact. An emergency care system has three key components: scene care, transport care, and facility care. These related components each contain a series of functions and connect to both the local population through community-based training and to the remainder of the health care system through access to inpatient care, critical care, surgical care, and rehabilitation. Work to strengthen emergency care systems may involve analysis of any of these components, or the referral systems that connect them, in addition to program implementation.

Research

Most GEM activities involve some form of research effort. Understanding existing emergency care systems requires analyses that use both quantitative and qualitative methods. Process and outcome measures should be defined in a context-appropriate manner, and measurement of the effect of interventions is required to understand the impact.

Validated assessment tools to characterize the capacity and gaps in EM systems exist and should be used.[18-20] Any research undertaking should be performed with local input and ethical board approval, which should be reflected in authorship.

National Societies

As emergency care evolves in an area, regional representation is required to further strengthen the specialty. Bringing like-minded emergency care clinicians together in a manner that allows for the discussion of the strengths and weaknesses of their system can provide a rich source of information exchange and partnership. These societies can provide a unified voice for emergency care clinicians in their region to advocate for their providers and patients.

Policy

Sustainable change to an emergency care system requires government support. For each component of the emergency care system to succeed, certain legislative tools must be in place. These include Good Samaritan laws, universal emergency service access numbers, minimum standards for training, equipment, and processes, provider certification, billing guidelines, and credentialing for ambulances and facilities. Guidelines and tools to determine the presence of minimum standards exist and should be used.[21,22] GEM practitioners help to advocate for these legislative tools directly with government agencies or guide emergency clinicians and societies in ways to lobby for these changes.

Humanitarian Assistance

Many GEM clinicians are involved in humanitarian activities such as international disaster response or refugee health (see Chapter e2). A gap exists between humanitarian and development work, and GEM supports efforts to bridge the gap between short-term humanitarian actions and longer-term development efforts.[23]

Direct Clinical Care

While education and system strengthening are important to support sustainability, providing clinical care in settings foreign to the GEM clinician is also an important part of the specialty. This occurs in several ways: planned clinical rotation at a partner site, humanitarian or surge response, or in an educational program with bedside teaching and supervision. Clinicians should always function within their level of training and scope of practice, typically as defined by their home credentials. For example, if a resident requires supervision for clinical practice in their home environment, the resident will require it in a foreign environment as well.[24] Direct patient care should only be provided under an active medical license issued by the country where the care will be provided. Prior to providing any direct patient care as a GEM clinician, written agreements should be in place with the host institution outlining provider credentialing, supervision, the chain of command for conflict, documentation requirements, translation (if needed), and quality assurance.[25]

Clinical Rotations Abroad

Interest in global health among medical students and residents has grown substantially, with 24% of US medical students completing electives in global health, and 91% of emergency medicine residency programs offering international rotations.[26,27] It is the responsibility of the GEM specialist to support the development of sustainable, educational, responsible, and safe experiences abroad for institutional trainees. Milestones for emergency medicine training in global health were developed based on the 11 CUGH global health domains (Box e1.1) and should be used to guide educational activity.[28]

BOX E1.1 Consortium of Universities for Global Health (CUGH) 11 Domains

Global burden of disease
Globalization of health and health care
Social and environmental determinants of health
Capacity strengthening
Collaboration, partnering, and communication
Ethics
Professional practice
Health equity and social justice
Program management
Sociocultural and political awareness
Strategic analysis

From: Jogerst K, Callender B, Adams V, et al. Identifying interprofessional global health competencies for 21st-century health professionals. *Ann Glob Health*. 2015;81(2):239-47.

Clinical rotations abroad should be formalized through written agreement between the host and sending institutions which includes the leadership structure, policies, and procedures. Similar to the ethical standards discussed in the previous section, the rotator must practice within their normal scope of practice and be supervised if not independently licensed to practice in the destination country. Educational opportunities should be bidirectional between institutions, ideally with exchange programs. Rotations are often with organizations other than universities and hospitals, such as NGOs or government organizations. It is important to understand partner organizations' missions and goals to ensure they align with the principles of sustainable, educational, responsible, and safe practice.

Preparation of the Traveler

In one survey of EM residencies, only 15% of programs responding provided specialized training prior to deployment.[29] Many resources exist to prepare travelers, and while many organizations will have a mandatory onboarding process it is the responsibility of the traveler to ensure adequate preparation. Travelers should become familiar with the state of emergency medicine in the destination: specialty existence, provider levels, training and education process, emergency department existence and level of function, mechanisms of access, referral networks, and availability of specialty care. Some components of preparation are common to all types of travel, such as itinerary planning and personal item packing. However, specific resources are recommended depending on the type of experience. If clinical work will be performed, ensure that adequate professional liability coverage is obtained. In one survey, only 47% of EM residents working abroad reported having appropriate liability coverage.[29]

Safety and Security

The responsible practice of GEM involves detailed attention to safety and security. Security situations can change abruptly with little warning, and plans should be in place to cover possible events ranging from minor illness to a major regional crisis. Those traveling abroad or supervising others who do should have a structured travel security plan that is kept current and available to key contacts. This plan should include the itinerary, contact information, destination information, and security measures. Travel insurance, including evacuation insurance, should be obtained specific to the destination. A sample plan and predeparture checklist is shown in (Box e1.2). In addition to

BOX E1.2 Sample Predeparture Checklist

- Project overview
- Personnel list with contact information and emergency contacts
- Itinerary details
- In-country project contacts
- Emergency resource list

- Communication plan
- Medical plan including vaccinations and insurance
- Hazard risk and mitigation identification and plan
- Equipment and packing list
- Translation plan
- Key documents including passports and visas
- Security plan with special considerations for high-risk travel

organization-specific preparation, there are reputable online resources for security training such as the UN B-SAFE program.

Research Ethics in Global EM

The GEM body of literature has expanded rapidly along with the growth of the subspecialty. The Global Emergency Medicine Literature Review (GEMLR) was founded in 2005 and performs an annual review of the most important GEM research. In 2018, their Medline search of GEM-related keywords identified 15,893 articles, a number that has increased annually.[30] The regionally focused *African Journal of Emergency Medicine* (AfJEM) was first published in 2011 and by 2018 had grown to 327,000 full-text downloads a year.[31]

Although GEM research, particularly in LMICs, remains inadequately funded as compared to the burden of disease, funding has grown and arises from a wide variety of sources including governments, academic institutions, and philanthropic organizations.[32,33]

While much of this research takes place in LMICs, there is a persistent disparity in first authorship between HICs and LMICs.[34,35] Additionally, researchers from LMICs have difficulty accessing published articles. One study concluded that one out of six research articles on emergency medicine could not be accessed without institutional subscriptions, and others were cost-prohibitive.[36] There are efforts to improve, such as the AfJEM Author Assist program, in which LMIC authors whose paper was rejected are paired with an editor mentor to revise and resubmit the paper.[37]

There are challenges specific to GEM research, which are essential to acknowledge and overcome in order to continue advancing the field. Regulations vary across countries, and many LMIC countries do not have emergency care–specific research guidelines. Researchers must engage local stakeholders and obtain institutional review board (IRB) approval both at the project site and their home institution. Project funding can be complicated by currency differences and the challenges of transferring money internationally. Cultural barriers must be understood and overcome, making community engagement critical to success. Project coordination challenges include time zone and language differences. Finally, any GEM research project is subject to external forces that researchers may have little control over, such as natural disasters, political changes, and travel disruptions. Special attention should be paid to the distinctive ethical challenges of GEM research, which include differences in access to standard care, vulnerable populations, power differentials, and consent quality.[32]

The ultimate mission of GEM is to improve timely access to quality emergency care for patients. This goal should be at the center of all GEM work, whether it is a clinical rotation, educational program, research project, or humanitarian response. More often than not, the GEM specialist is a guest in the country they are working in and should always act as such. The GEM specialist must rely on local partners to fully understand the reasons and motivations for the current system. Interventions should be context appropriate, feasible, and always performed in coordination with local stakeholders.

While longer-term deployments and commitments are key to building relationships and sustainability, shorter experiences abroad can be useful when performed correctly. Prior to embarking on any GEM project, detailed preparation should occur. A review of the destination should include local history and cultural and ethical practices. Ensure that knowledge transfer is bilateral and that the project is not a burden to the local system.

Emergency medicine is a diverse specialty positioned at the center of the health care system, interfacing directly with public health and social issues. This positioning and the diverse skill set possessed by emergency medicine clinicians uniquely qualifies them for this work. Emergency care systems already exist everywhere in the world, and the goal of GEM is not to recreate or replace them, but rather to understand and strengthen them. When faced with uncertainty, always prioritizing what is in the best interest of the patient will ensure success.

CHAPTER E1: QUESTIONS AND ANSWERS

1. Research projects based in settings outside of the GEM physician's home country require which of the following special considerations with regard to research ethics?

- **a.** Ethical approval must be obtained only at the GEM physician's home institution.
- **b.** United States-based IRBs do not cover international settings, and as such the GEM physician does not need to seek ethical approval.
- **c.** Ethical approval is required from both the GEM physician's home institution and any partner institutions or research sites.
- **d.** If the research is planned in a country that does not have an IRB, no formal ethical approval is required.

Answer: C. Ethical approval for any research project must be obtained from the GEM physician's home institution, any partner institutions, and any research sites. In the event that a formal IRB does not exist for a certain research site, efforts must be made to obtain and document ethical approval from an appropriate site representative.

2. Which of the following is required when planning a clinical experience abroad in which the GEM physician will be providing direct clinical care without supervision?

- **a.** Current medical licensure from the country within which care will be delivered.
- **b.** Current medical licensure from the GEM physician's home country.
- **c.** Written agreement between the GEM physician and a licensed physician in the country within which care will be delivered.
- **d.** No local medical license is required as long as the GEM physician is practicing within the same scope as allowed by home licensure.

CHAPTER E1: QUESTIONS AND ANSWERS—cont'd.

Answer: A. The direct delivery of unsupervised medical care should only be provided by a GEM physician with a current and valid license issued by the appropriate regulatory body of the country within which care will be delivered. Additional requirements, such as hospital credentialing, are also generally required.

3. The practice of global emergency medicine is an academic subspecialty that focuses on which areas of medicine and public health?
   - **a.** All areas of medicine are represented except for surgical conditions, as these are addressed by global surgeons.
   - **b.** All areas of medicine for all age groups are represented, inclusive of trauma or surgical conditions, infectious and noninfectious conditions, and pregnancy.
   - **c.** All adult areas of medicine are represented, but not pediatrics as this field is addressed by global pediatricians.
   - **d.** GEM focuses only on emergency conditions, excluding chronic disease as this generally does not contribute to the need for GEM.

Answer: B. Recognizing that patients present to the emergency department (ED) without a diagnosis, but with a complaint, GEM focuses on presentation-based solutions for conditions for all age groups, both trauma and medical, infectious and noninfectious, and pregnancy. GEM seeks to ensure early access to quality emergency care for all people, regardless of gender, ethnicity, age, or ability to pay.

4. What is the relationship between humanitarian work and development work as it pertains to the GEM physician?
   - **a.** Humanitarian work and development work are best performed separately to avoid confusion around roles, tasks, and funding commitments.
   - **b.** GEM physicians provide only development work and do not focus on humanitarian response, which requires separate training and expertise.
   - **c.** Humanitarian and development work are the same thing, and the difference in terminology is a function of who is performing the actual work.
   - **d.** Humanitarian work and development work complement and strengthen each other.

Answer: D. While GEM is broadly divided into humanitarian and development work, these two subfields are closely related and complement each other. An emergency care system strengthened through development work should be able to surge during crises to enhance humanitarian efforts, and an effective humanitarian response will include strengthening the local system to provide resilience against future crises.

Humanitarian Aid in Disaster and Conflict

Humanitarian Aid in Disaster and Conflict

Shawn D'Andrea and Stephanie Kayden

KEY CONCEPTS

- A key feature of humanitarian crises is the mass displacement of large numbers of people from their homes. Displaced populations are designated either as internally displaced persons (IDPs) or refugees.
- The international response community has developed practice guidelines that stem from international law, research, and expert consensus. Responders should be familiar with these international standards and laws to ensure that intervention is appropriate and ethical.
- The *Sphere Handbook*, a collaborative project of humanitarian response experts, sets international standards for the provision of humanitarian aid and is widely considered to define the gold standard of global humanitarian response.
- Demand for humanitarian responders is likely to rise in the future as global urbanization and an increase in climate-related disasters conspire to create more frequent and severe crises.

FOUNDATIONS

When a natural disaster or armed conflict forces thousands of people from their homes, or an epidemic overwhelms a country's health system and threatens pandemic spread, a humanitarian emergency arises that requires a global response. Increasingly, emergency clinicians are called upon to assist. This chapter will provide an overview of key concepts in global humanitarian emergencies and the role of the emergency clinician in humanitarian response.

Types of Humanitarian Emergencies

A humanitarian emergency, or humanitarian crisis, is "a critical threat to the health, safety, security, or wellbeing of a community or other large group of people, usually over a wide area."[1] Humanitarian crises can be natural disasters (floods, earthquakes, tsunamis), human-made disasters (armed conflict, industrial accidents), or complex emergencies. A complex emergency occurs "where there is total or considerable breakdown of authority resulting from internal or external conflict and which requires an international response."[2]

A key feature of humanitarian crises is the mass displacement of large numbers of people from their homes. Displaced populations are designated either as internally displaced persons (IDPs) or refugees. An IDP is someone who has been forced from his or her home but who remains within the country of origin. If an IDP crosses an international border to seek help in another country, she or he becomes a refugee. The distinction is important. While refugees enjoy protections and rights guaranteed by international treaty, IDPs must depend (in the absence of international aid) on their own government for help, even though the actions—or inaction—of their government often caused their displacement.[3]

Many people assume that humanitarian clinicians spend most of their time treating serious injuries: fractures and crush injuries from earthquakes, infected flesh wounds in floods, or blast and penetrating injuries in conflict. While this is true in some emergencies, the reality is that most medical relief in humanitarian crises is spent reinforcing primary care and basic medical services that have been destroyed or bolstering public health programs to prevent diseases in displaced populations.

A significant portion of the disease burden in humanitarian emergencies is brought on by the displacement itself. Forced into crowded and often unsafe conditions and removed from their usual sources of medical care, displaced people suffer from the lack of access to basic health services. Chronic conditions such as hypertension and diabetes go untreated. Women and infants die from the lack of safe perinatal care. Children may not receive lifesaving vaccinations. Densely packed refugee camps promote outbreaks of measles and other infectious diseases. The breakdown in basic public health is another critical threat. Lack of clean water, latrines, washing facilities, proper shelter, and good nutrition are often the main causes of poor health among displaced people.

Mass urban migration in the 20th and 21st centuries has led to a dramatic increase in city populations worldwide.[4] Crises in urban environments pose unique challenges to humanitarian response because security considerations, logistic and supply chain factors, and distribution systems are very different from those in rural settings. Increasingly, humanitarian response training includes a focus on urban humanitarian response methods and how to work within dense urban settings that require close coordination with municipal governments and city-based organizations.

Natural Disasters

Humanitarian crises are broadly described as either natural or human-made disasters. Natural disasters, often seen as random acts of nature, can attract media attention and public sympathy that spur a robust aid response. The effects of natural disasters, however, are generally predictable. The type of medical and public health response needed varies by the type and location of disaster (Table e2.1) and is also affected by the preexisting vulnerabilities of the population. Damage to health facilities is common in most natural disasters, and medical relief is often focused on reestablishing primary care and basic health services.

Earthquakes cause uniquely high rates of complex injuries: fractures, crush injuries, burns, and even hypothermia. Search-and-rescue teams may need help with confined space medicine and field amputations. Surgical field hospitals are often needed in the first hours and days after an earthquake to provide lifesaving neurosurgical or orthopedic care. The need for inpatient postoperative wound care, rehabilitation services, and prosthesis care continues for months or even years.

TABLE E2.1 Predictable Effects of Natural Disasters.

Parameter	Earthquakes	Hurricanes	Tsunamis	Floods	Landslides	Volcanoes
Deaths	+++	+	+++	+	+++	+++
Complex injuries	+++	++	+	+	+	+
Infectious diseases	Always a risk: increases with overcrowding, poor sanitation					
Damage to health care facilities	+++	+++	+++ (local)	+++ (equipment)	+++ (local)	+++
Damage to water systems	+++	+	+++	+	+++ (local)	+++
Food shortage	+	+	+++	+++	+	+
Mass displacement	Rare (heavily damaged cities)				Common (generally limited)	

(Adapted from: Pan American Health Organization. *Natural Disasters: Protecting the Public's Health*. Washington, DC: Pan American Health Organization, Pan American Sanitary Bureau, Regional Office of the World Health Organization; 2000: 2.)

In contrast to earthquakes, most natural disasters produce less severe, more easily survivable injuries. Medical care in these disasters usually focuses on restoring baseline health services. Surgical field hospitals, if needed, typically perform wound care and everyday emergency surgeries (cesarean section, appendectomy). In disasters that produce high death rates—earthquakes, tsunamis, landslides, and volcanic eruptions—postmortem services may be emergently needed. Psychological first aid and mental health care are also key to the health response to sudden-onset natural disasters.

Unlike sudden-onset natural disasters, droughts develop slowly over months and are characterized by crop shortages, skyrocketing food prices, and disruption of food markets. Poor or isolated populations can suffer a lack of access to food that, if unchecked, leads to famine. The acute medical needs in drought often stem from severe malnutrition (especially in young children) and subsequent infections.

Certain populations faced with an acute humanitarian crisis, such as those with widespread undernutrition at baseline, may be more vulnerable to acute malnutrition than others. Special training in therapeutic feeding programs and supplemental food distribution is needed for clinicians responding to famine, or to any emergency in which a population's baseline rate of severe malnutrition is high.[5]

Disease Epidemics/Pandemics

Despite two large-scale Ebola virus disease (EVD) epidemics in the 2010s (the 2014 West Africa outbreak and 2018 Democratic Republic of Congo outbreak), epidemics that cause humanitarian emergencies were still relatively uncommon until 2019 with the severe acute respiratory syndrome coronavirus-2 (COVID-19) pandemic (see Chapter 120). Nevertheless, the EVD outbreaks highlight the need for more international aid agencies to be able to respond to large global epidemics. Disease outbreaks, such as the cholera epidemic in Haiti, can further complicate humanitarian efforts, threaten vulnerable populations, and erode public trust in international responders. Future epidemics, especially those that spread to densely populated areas with an underdeveloped public health infrastructure, may require a specialized form of international response. Response to epidemics in urban areas will require a response coordinated with attention to special conditions created by an urban setting, such as crowded slums, general population density, and mass transport systems.

Armed Conflict

Armed conflicts are a major cause of global humanitarian emergencies, leading to direct threats to and displacement of civilians, destruction of infrastructure, and deprivation of access to resources. Lack of access to basic services and appropriate health care due to insecurity creates a significant vulnerability that disproportionately targets women, children, and the elderly. The lack of access to medicines, providers, and the collapse of medical and public health services create major challenges for civilian populations in conflict settings. In addition, armed conflicts cause a prolonged breakdown in local security, access, and civil society structures, which can inhibit the restoration of health services. Responders in conflict settings must prepare for the complexity of operating in insecure environments and prolonged deployments.

Violent injuries are typically limited to civilians who are either trapped in active conflict zones or directly targeted by fighting forces. The number of civilians who suffer injuries is usually small in proportion to the total number of people affected by armed conflicts.[6] Conflict is also often associated with high rates of interpersonal violence, abuse, and sexual assault. Survivors of these forms of trauma will require both appropriate medical care and culturally adapted mental health services.

SPECIFIC ISSUES

Standards in Humanitarian Response

The international response community has developed practice guidelines that stem from international law, research, and expert consensus. Responders should be familiar with these international standards and laws to ensure that their response efforts fulfill the rights of the people affected by crisis.

International Law

Humanitarian aid is not simply a charitable act. Rather, it is intended to fulfill the rights to assistance that all civilians have during humanitarian crises. To fulfill these rights, responders must understand the genesis of human rights. Two bodies of international law set forth these rights: international humanitarian law (IHL) and international human rights law (IHRL).

IHL is often described as the law of war. Its core documents are the Geneva Conventions.[7] IHL gives special protections to people not taking part in conflict (civilians and those soldiers rendered incapable of fighting due to injury, illness, surrender, or having been taken prisoner). It mandates that these non-combatants be treated humanely and provided food, water, shelter, and medical care. IHL not only ensures noncombatants the right to humanitarian assistance but also grants humanitarian aid workers the right to offer that assistance. This means that humanitarian responders must be allowed to provide lifesaving aid uninterrupted and must not become war targets as long as they remain neutral in the conflict.

Indeed, IHL is one of the primary tools used to ensure protection in conflict zones for aid workers, who, as neutral actors, do not carry weapons.

Humanitarian aid agencies often use IHL to negotiate with conflict commanders for safe access to civilian populations, as these commanders can be individually prosecuted for legal violations or war crimes.

Although IHL applies only during conflict, human rights law applies at all times. The 1948 Universal Declaration of Human Rights, the core document of human rights law, states that "all human beings are born free and equal in dignity and rights," and are entitled to life, liberty, security of person, and "a standard of living adequate for…health and well-being."[8] The Declaration and other human rights laws enshrine specific civil,[9] political, economic, social, and cultural rights;[10] prohibit torture,[11] genocide,[12] and racial discrimination;[13] and provide special protections for women,[14] children,[15] refugees,[16] and internally displaced persons.[17]

IHL and human rights law govern the scope of activity of humanitarian response. More importantly, it is by virtue of these international laws that humanitarian responders legitimately can enter a country and intervene in the lives of its citizens.

Codes of Conduct

Nongovernmental organizations (NGOs) use codes of conduct to specify behavioral, professional, interpersonal, and ethical standards for their workers. Humanitarian response often requires long work hours in uncomfortable and insecure settings. Personnel must maintain appropriate conduct despite challenging circumstances and near-constant stress. Maladaptive coping behaviors such as drug and alcohol abuse, inappropriate relations with national staff or locals, and security protocol violations put individuals and organizations at risk. Codes of conduct help establish behaviors necessary to ensure an ethical and effective response.

Sphere Standards

The *Sphere Handbook*,[18] a collaborative project of humanitarian response experts, sets international standards for the provision of humanitarian aid. It is widely considered to define the gold standard of global humanitarian response. The *Sphere Handbook* begins with the Humanitarian Charter, which distills international law, humanitarian principles, and the humanitarian code of conduct into a five-page document that establishes the legal and ethical essence of the humanitarian imperative.

The *Sphere Handbook* provides a single set of uniform standards for aid agencies to follow in humanitarian response. These standards are the measures by which aid agencies evaluate their responses, and as such are the basis of accountability for international response efforts. The *Sphere Handbook* provides minimum response standards for water and sanitation, food and nutrition, shelter and settlement, health care, and protection. It also sets forth a core humanitarian standard that applies to all sectors, such as partnering closely with beneficiaries in the response (Fig. e2.1). These minimum standards are supplemented by specific indicators, numerical signposts that help responders know when they are on track to meet the standards. For example, the first

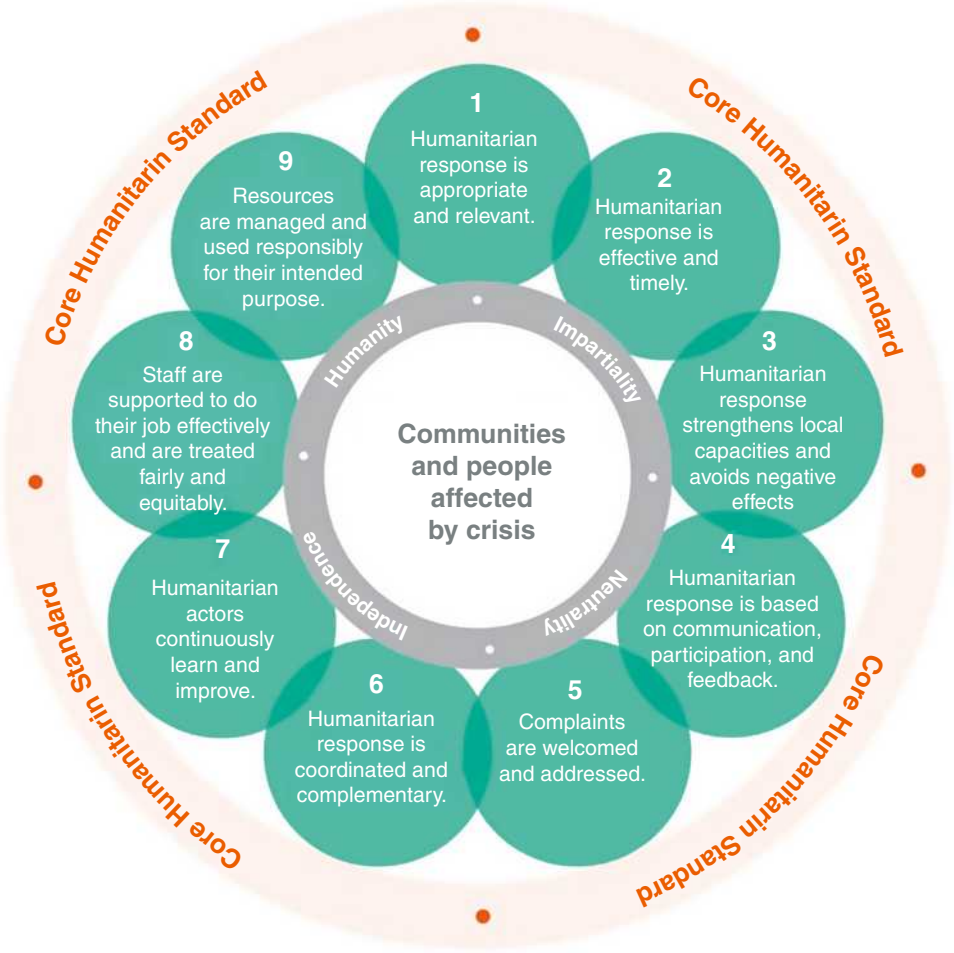

Fig. e2.1 Core Humanitarian Standard. (From: UN Office for the Coordination of Humanitarian Affairs. Core Humanitarian Standard image obtained from Sphere. [https://spherestandards.org/humanitarian-standards/core-humanitarian-standard/.])

Sphere standard for water supply is "People have equitable and affordable access to a sufficient quantity of safe water to meet their drinking and domestic needs."[19] But how much water is that? While the exact answer may vary depending on the context, the key indicator for this standard is at least 15 liters of clean water per person per day.[20] Similar standards and indicators are given for other sectors of humanitarian aid. Box e2.1 lists a few of the key indicators from the *Sphere Handbook*.

Priorities in Global Humanitarian Emergencies

The goal of humanitarian response is to save lives, restore livelihoods, and rebuild communities. Effective humanitarian response centers around several key priorities.

Protection

The first priority—before food, water, shelter, or medical care—is the protection of people caught in the crisis. The humanitarian protection principles are outlined in the *Sphere Handbook* as follows:

1. Enhance people's safety, dignity, and rights, and avoid exposing them to further harm.
2. Ensure people's access to impartial assistance according to need and without discrimination.
3. Assist people to recover from the physical and psychological effects of threatened or actual violence, coercion, or deliberate deprivation
4. Help people to claim their rights.[21]

The *Sphere Handbook* provides detailed guidance to help aid agencies adhere to these principles. Some protection measures are simple (fences around refugee camps in insecure areas, good lighting near latrines); others are more complex (issuing identification cards so that refugees can claim benefits; tracking unaccompanied children to help reunify families). Without adequate protection, other response measures may fail.

BOX E2.1 Examples of Sphere Handbook Indicators of Minimum Standards

Water, Sanitation, and Hygiene

- 15 L of water per person per day
- 250 people per water tap
- Two 10- to 20-L capacity water containers per household
- 1 toilet per 20 people
- Toilets no more than 50 meters from dwellings

Food Security and Nutrition

- 2100 kcal per person per day
  - 10% of total energy from protein
  - 17% of total energy from fat
  - Adequate micronutrient intake
- >90% of target population live within one day's walk of a supplemental feeding program site

Shelter, Settlement, and Non-Food Items

- 3.5 m^2 per person of covered living space in shelters
- 45 m^2 per person of total area of displacement camp
- Fuel-efficient stoves with the appropriate fuel

Health

- 1 to 2 community health workers per 1000 people
- 80% of births attended by skilled personnel (doctors, nurses, midwives)
- 23 skilled birth attendant personnel (doctors, nurses, midwives) per 10,000 people
- 1 health care facility (basic health post) per 10,000 people
- 1 health care center (inpatient hospital) per 50,000 people
- 1 district or rural hospital (with surgical capability) per 250,000 people
- >18 inpatient (excluding maternity care) beds per 10,000 people
- <1 death per 10,000 people per day, or less than double the baseline crude mortality rate
- <2 under 5-year-old deaths per 10,000 or under-5-year-old mortality rate less than double the baseline
- When measles vaccination coverage is <90% or unknown, conduct a mass measles vaccination campaign for children aged 6 months to 15 years

Data from: Sphere Project. The Sphere Project: humanitarian charter and minimum standards in humanitarian response. Rugby: Sphere; 2018.

Rapid Assessment

A rapid assessment should always be conducted before large-scale aid operations begin. This may seem counterintuitive, but rapid assessments are critical to ensuring that the right aid arrives in the right amount at the right time. Aid funds are always limited, and rapid assessments help avoid wasted resources and can avoid duplicating services.

Most initial rapid assessments focus on needs over all response sectors, but some target specific areas such as health or shelter. Responders in the acute phase should be familiar enough with humanitarian aid to be able to participate in a multisector rapid assessment. A rapid assessment takes a few hours or, at most, a few days. Even in large-scale disasters, initial rapid assessments are complete by the end of the first week. Information gathered in a rapid assessment is shared with responding agencies to identify vulnerable populations and aid priorities.

Food, Water, and Shelter

The major sectors of humanitarian response are water and sanitation, food, shelter, and health care. Although specific interventions will depend upon the findings of the rapid assessment, most emergencies will require a response in each of these sectors.

Clean water, latrines, and washing facilities are among the most important public health measures in emergencies. Lack of water causes people to stop washing, and poor hygiene is a major cause of disease in overcrowded refugee camps. Sanitation facilities must be provided to prevent fecal cross-contamination. Defecation fields, separated by gender, can be used until there is time to construct proper latrines.

Food insecurity is common in humanitarian crises. When local markets are functioning, the default mechanism to supply food should be the distribution of cash or food vouchers for use in the market. Distributions of food rations are necessary when markets are disrupted or the allocation of cash or vouchers is not feasible. Food distribution should be organized, equitable, and culturally appropriate. Nutritionally balanced dry rations of staple foods (flour, beans, oil) are typical provided, but wet rations of prepared meals can be used if people lack the ability to cook for themselves. Supplemental rations are given to pregnant and breastfeeding women, children, and sick or malnourished people.

Emergency shelter can be provided by housing displaced people with local host families, in vacant apartments, or—as a last resort—in tented camps. Careful camp planning is needed to reduce the impact of displaced populations on local communities because camps typically last not for weeks or months, but rather for years or decades.

Health Care

Health care in humanitarian emergencies focuses on primary and preventive care, the control of communicable diseases, and the restoration of basic health services. Communicable disease control and public health surveillance are two key interventions in displaced groups (who

often have low baseline vaccination rates) living in densely populated camps. Measles vaccination campaigns for children are often the first medical priority after disasters.

Noncommunicable diseases can also pose a threat to the affected population. Although medical services are often a key need in humanitarian crises, most humanitarian emergencies do not require large medical or foreign surgical teams. When surgical teams are needed, they should respond to specific surgical needs, such as those disasters that are accompanied by large numbers of traumatic injuries, like earthquakes. These teams will need to be deployed rapidly if they are to make a significant impact on traumatic injuries. Less recognized is the need for postsurgical follow-up care and rehabilitation services. Surgical field hospitals must plan to provide inpatient wound care and physical therapy for the full duration of surgical recovery and wound healing to patients whose homes and local health services have been destroyed. Amputees requiring prosthetics may need to be followed for years. Surgical responders have a responsibility to ensure that all patients have access to comprehensive postoperative care.

Transition and Exit

The decision to respond to a crisis is much simpler than knowing how and when to end the relief effort. When is a humanitarian crisis over? How should deployed services be removed from an area that chronically lacks basic resources? Withdrawing relief aid may leave gaps in medical care, employment for local workers, and support for local livelihoods. Rather than abruptly pulling out, a successful relief effort will transition many activities from the relief phase to the development phase. Planning for this transition and exit must start early in the response and often will require collaboration with other agencies.

International Actors in Humanitarian Response

The government of a country affected by a humanitarian emergency or refugee crisis has the primary responsibility to provide aid. If that government cannot (or does not) sufficiently respond, the international community may offer assistance. If the government invites this assistance, a variety of humanitarian actors will arrive to provide relief. Responders should understand the roles that the major humanitarian actors—response organizations, the United Nations, government funding agencies, and militaries—play in funding, coordinating, and carrying out the response.

Response Organizations

Among international responders, NGOs are the primary operational responders. Humanitarian clinicians typically work with these groups. NGOs sometimes have access to vulnerable populations that may be inaccessible to government agencies. Although many international NGOs offer a range of response services, some are known for expertise in certain sectors. Doctors Without Borders, for example, is known for its specialized medical care; Oxfam for food and water expertise.[22]

The International Committee of the Red Cross (ICRC) and the International Federation of Red Cross and Red Crescent Societies (IFRC) also represent response organizations; however, the two groups have very different mandates. Founded in Switzerland in 1863, the ICRC is neither a governmental nor nongovernmental organization. Instead, the ICRC is a neutral body mandated by the international community to aid and protect civilians in violent emergencies under the tenets of international humanitarian law. The ICRC provides health care, water and sanitation support, and international legal advocacy for refugees and IDPs.[23]

In contrast, the IFRC is comprised of 192 National Societies of the Red Cross and Red Crescent. The National Societies primarily work to support emergency preparedness and response in their own countries. A few of the National Societies (including the American Red Cross and the Turkish Red Crescent), in coordination with the IFRC, also assist in emergencies outside their home countries.[24]

Despite the prominence of international groups in humanitarian emergencies, it is important to remember that most humanitarian aid comes from local sources: neighbors, community organizations, religious groups, and local government agencies. When international aid agencies arrive, they often partner with local community organizations that know the area well and have preexisting relationships with the affected communities. This allows the international agency to provide efficient aid while helping to train and strengthen local organizations.

United Nations

The United Nations' (UN) primary role is to coordinate the international response. The UN Office for the Coordination of Humanitarian Affairs (OCHA) leads the Cluster Approach (see later, "Coordination of Global Humanitarian Response"), which coordinates local and international humanitarian actors in each sector of the field response. Some UN agencies also provide services directly to disaster survivors or to NGOs in the field. For example, the World Food Program, which helps more than 86 million people in 83 countries,[25] provides logistical support for the transport and warehousing of NGO relief goods and food rations. Several UN agencies play pivotal roles in the humanitarian sector.

Foreign Governments

Most funding for global humanitarian response comes from government agencies. Government funding agencies, such as the US Agency for International Development (USAID) or the United Kingdom's Department for International Development (DFID), often send representatives to the field to assess the scale of the emergency and to offer aid. These foreign governments provided a total of US $22.6 billion worldwide in 2018.[26] These funds are directed to the local government of the affected country, to the UN, or to NGOs to fund specific aid proposals. USAID, via its Office of US Foreign Disaster Assistance, also guides the use of US military forces in humanitarian response missions.

Militaries

International militaries increasingly are engaged in humanitarian work. Although militaries can offer a range of services, the main gap they fill is in large-scale transport and logistical support. Unlike most NGOs, militaries have the technical and logistical capacity to deliver aid, rebuild bridges, reopen damaged airports, or transport equipment by ground, sea, or air transport. The militaries of the United States, Canada, Israel, and the United Kingdom are common responders worldwide, typically alongside the military of the local government. A government dictates the actions of its military in accordance with its national interest and may decide to respond to some crises but not others.

Regardless of political motives, militaries may not always be perceived as neutral parties by beneficiaries, and NGOs that work with militaries risk a similar perception. This loss of perceived neutrality may cause NGOs to face rejection or targeted violence, even in distant countries. NGOs who partner with militaries must therefore work to ensure an accurate perception of their neutrality.

Individual Responders

Given the complex nature of humanitarian emergencies, there is little place for individual responders who appear without an organizational affiliation. Most lone responders arrive ill-equipped to be truly self-sufficient and ultimately siphon scarce resources (lodging, food and water, ground transportation) away from the response. For this and

many other reasons, individuals should not respond to humanitarian emergencies unless they do so as part of an experienced humanitarian relief organization.

Would-be responders who cannot join an international NGO can be more effective by donating money (not goods). This produces a triple benefit. NGOs use donated funds (which require no transport or warehousing) to buy culturally appropriate relief supplies in the exact quantities needed (which reduces waste and is best for survivors), often from local markets (which boosts the damaged economy and promotes faster recovery).

Coordination of Humanitarian Response

Humanitarian relief can seem haphazard to the casual observer. In fact, global humanitarian response is carefully coordinated by the UN Cluster Approach, or cluster system, which is activated in large-scale international emergencies. Professional humanitarians are trained to coordinate with other NGOs via the cluster system to avoid duplication, omission, and inefficiency of humanitarian aid. The cluster system was implemented in 2005 to increase coordination and accountability in relief aid. It is designed to accompany and advise, not supplant, the host government in its coordination of international response efforts. The cluster system divides humanitarian response into 11 sectors, or clusters (Fig. e2.2): camp management, early recovery, education, emergency telecommunications, food security, health, logistics, nutrition, protection, shelter, water, sanitation, and hygiene.[27]

Each cluster is overseen by a UN agency or other response organization called the cluster lead, which fills this role in every response (the World Health Organization is always the health cluster lead). Cluster leads gather and share information, promote adherence to international standards, coordinate NGO activities, and report progress to the UN Office for the Coordination of Humanitarian Affairs (OCHA). OCHA, led in the field by the Humanitarian Coordinator, is responsible for overall coordination among the clusters and with the larger international community.

Cluster meetings, held daily in the early response and less frequently over time, are the mainstays of coordination. They are often co-led by representatives of the host government (perhaps the Minister of Health in health cluster meetings) and the cluster lead agency (the World Health Organization). Representatives from NGOs, government agencies, and other groups working in the sector attend cluster meetings to share information and plan next steps.

Ongoing Coordination

Between emergencies, the 11 clusters work together on an ongoing basis to improve future responses. These global clusters are standing bodies that work to strengthen response preparedness, disseminate

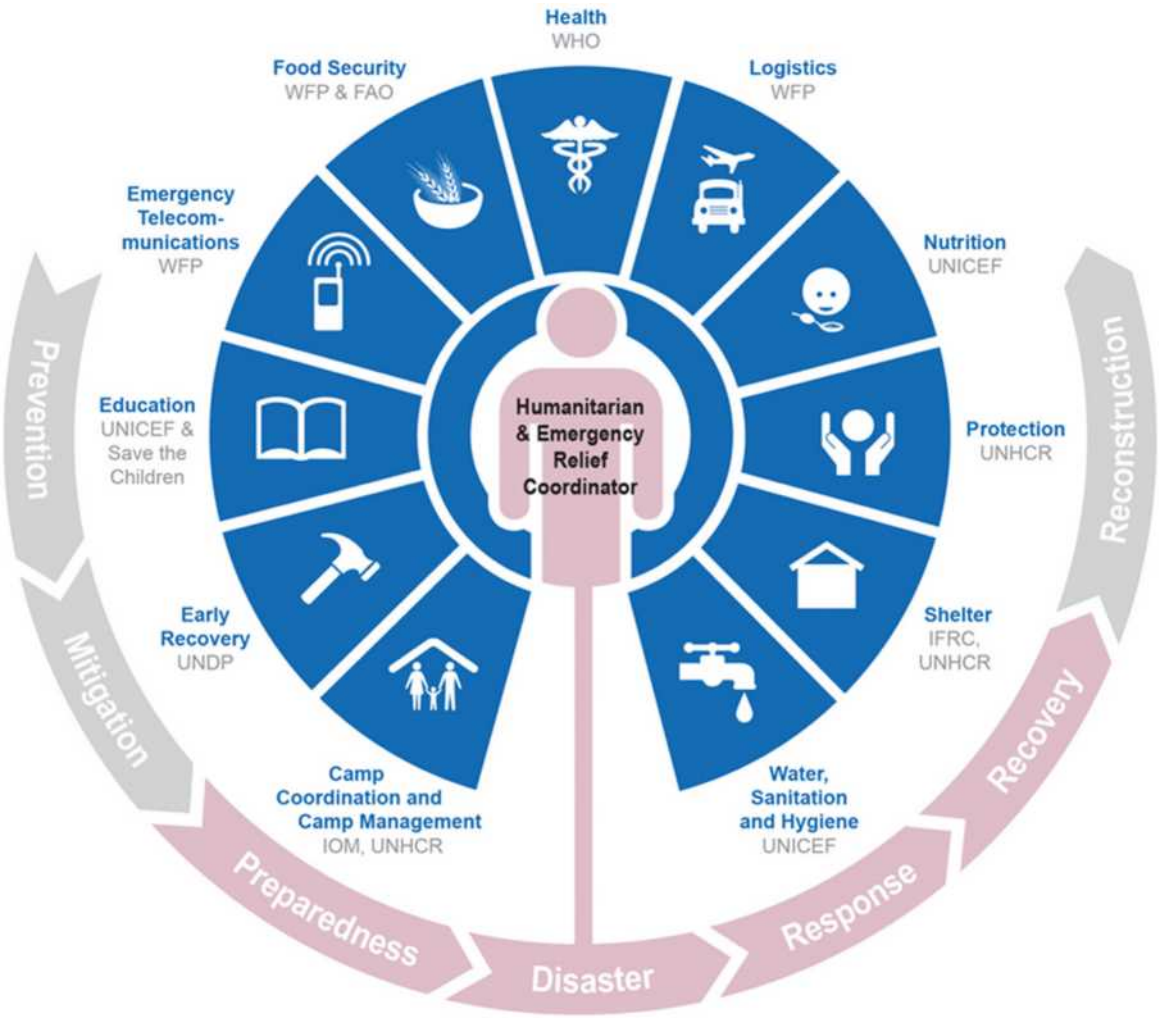

Fig. e2.2 Organization of the UN Cluster Approach. (From United Nations Office for the Coordination of Humanitarian Affairs: Cluster coordination. https://www.humanitarianresponse.info/en/coordination/clusters/what-cluster-approach.)

best practices, and support in-country clusters during disasters. Leaders of the global clusters report to the UN Under-Secretary General for Humanitarian Affairs and Emergency Response Coordinator (ERC),[28] who also leads the Inter-Agency Standing Committee (IASC). The IASC brings together UN agencies, NGOs, the ICRC and IFRC, the World Bank, and the International Organization for Migration to set policies and guidelines for effective humanitarian aid.

The Emergency Clinician in Humanitarian Crises

Emergency clinicians are well suited for humanitarian response. They are comfortable working in stressful, chaotic environments. They can nimbly rearrange priorities and see the big picture in an ever-changing situation. They have uniquely broad medical skills that are useful in emergency response. But emergency medicine training, by itself, does not make a good humanitarian responder. They must consider whether relief work is right for them and be willing to seek training in the public health aspects of humanitarian response. Emergency clinicians should also be careful to choose an experienced aid agency with which to deploy.

Preparing for Humanitarian Response

Humanitarian response can be life changing, usually for the better, sometimes for the worse. Humanitarian crises are stressful and unpredictable. To ensure an effective, rewarding experience, clinicians should carefully consider whether they are properly prepared for humanitarian work.

Work in a humanitarian crisis often involves long hours, unfamiliar cultures, and uncomfortable accommodations. Electricity, running water, and mobile phone and Internet service may be unavailable. Insecure environments may require curfews and restrictions to the NGO compound. Clinicians who are new to unfamiliar living conditions might try backpacking in a low-income country before deploying to a humanitarian emergency.

The ability to cope with prolonged stress and personal discomfort is key. In a humanitarian response, toxic coping mechanisms (drugs, alcohol, sex) can endanger you and your team. Music, journaling, movies, and exercise are better ways to relax. You will be living in close quarters with your teammates for weeks or months and should make every effort to keep morale high and conflicts to a minimum.

Medical resources are often quite limited in the field. It can be useful to review certain procedures that are more common in austere medical environments (regional blocks instead of procedural sedation). Alternatively, volunteer to teach for a while in an emergency department in a developing country.

Humanitarian deployments can be a challenge for professional and personal relationships. Many aid workers find that long deployments in such challenging settings create disruptions in their relationships at home. It is important for field workers to continue contact at home and with loved ones and realize that returning after a mission may be challenging. Likewise, work life may also be affected. NGOs often require prolonged deployments, and hospitals or practices may be reluctant to grant leave. After the deployment, some clinicians may find it difficult to readjust to the clinical and administrative routine of the emergency department. Remember that these feelings are common.

Training for Humanitarian Response

Humanitarian professionals are expected to be familiar with a large and growing body of humanitarian literature, guidelines, and procedures. Emergency clinicians considering humanitarian work should seek additional training well before considering a deployment. Formal educational opportunities include humanitarian certification courses, fellowships, and graduate degrees.

Certification courses in humanitarian aid are available through several universities and organizations. Both the Humanitarian Academy at Harvard[29] and the ICRC offer courses in humanitarian assistance. The ICRC's Health Emergencies in Large Populations (HELP) course is taught in several locations around the world.[30] Lasting a few days to a few weeks, certification courses can be a great way to prepare for a deployment or explore a career in humanitarian aid.

Some fellowships in Global Emergency Medicine prepare physicians for humanitarian response. Global Emergency Medicine specialists work to develop emergency care and improve humanitarian response worldwide. Fellowships typically last 1 to 2 years and can be found at www.iemfellowships.com.

Humanitarian tracks exist in some graduate school degree programs such as international affairs, engineering, and public health. A few programs, such as the Master of Arts in humanitarian assistance offered at Tufts University,[31] cover all aspects of humanitarian response. Emergency clinicians who wish to obtain deeper training than is offered in certification courses, but need more flexibility than fellowships offer, may enroll in a master of public health program that specializes in humanitarian studies.

Choosing a Deployment

Emergency clinicians who are trained and ready to start humanitarian work may look for a deployment that fits their skills and experience. An active conflict zone is probably not a good choice for a first deployment. Well-established NGOs are usually good at ensuring that applicants have the right experience.

In general, large relief organizations such as those in Box e2.2 have extensive field experience and logistical capability. They provide proper accommodations, reliable transportation, and security and evacuation resources necessary for a safe deployment. Responders should also ask about an NGO's reputation in the field. Avoid NGOs that do not provide security briefings as part of field orientation. Unethical practices, such as requiring beneficiaries to participate in religious services, are also a red flag.

Safety and Security

Humanitarian crises are often set in dangerous and insecure environments with inadequate public safety and medical facilities. A 2019 USAID report showed an increase in violence toward aid workers in the preceding decade.[32] Responders should understand and adhere to their organization's safety protocols even if the advice seems overcautious. Mandatory seatbelt use, for instance, helps prevent the most common cause of unintentional injury to aid workers: road traffic accidents.

BOX E2.2 A Sample of Major Humanitarian Response Agencies

Action Against Hunger
CARE
Catholic Relief Services
Concern
Doctors Without Borders
International Committee of the Red Cross
International Medical Corps
International Rescue Committee
Islamic Relief
Mercy Corps
Oxfam
Save the Children
World Vision

Unfortunately, violent attacks on humanitarian aid workers are on the rise. Modern conflicts often directly target civilians and aid workers, and hostage ransoms are an increasingly important source of revenue for some fighting forces. Responders should be aware of how their own identity or the reputation of their NGO affects their level of risk.

Although it is extremely unlikely that any single aid worker will be a victim of violence, responders should review their insurance policies before deployment to an insecure area. Health, life, and disability policies, particularly if provided by your home hospital, may not cover death or injury while working in a humanitarian crisis. Responders can improve their awareness of field security via training programs such as the online United Nations BSAFE course.[33]

Ethical Dilemmas

Humanitarian clinicians often face ethical dilemmas in the field that would never occur at home. At home, triage usually decides who gets care first; in a humanitarian crisis, triage often decides who gets care *at all*. This unfamiliar territory can lead clinicians into ethical pitfalls in humanitarian medicine.

A common pitfall is deciding to work outside of one's scope of clinical practice because of an incomplete understanding of referral capability. Non-surgeons may attempt a makeshift emergency appendectomy, rationalizing that this care is better than nothing. In our experience, this physician is usually unaware of surgical resources a few hours (or minutes) away. Even in disasters, humanitarian clinicians have a responsibility to arrange a referral and transport system for patients needing higher care. In the few cases when referral is truly impossible, the patient and family must be fully informed of your lack of experience and given the option to refuse.

Many ethical dilemmas are better addressed by a group. Group consensus, especially when beneficiaries are represented, helps avoid war zone decision making and removes the burden of an emotional decision from the individual. Having a standard protocol for the use of prearranged ethics groups will allow for quick decisions.

CONCLUSION

Demand for humanitarian responders is likely to rise in the future as global urbanization and an increase in climate-related disasters conspire to create more frequent and severe crises. At the same time, the growing professionalization of humanitarian aid will move the field closer to a model of international standards and cooperation among relief agencies. Emergency clinicians have a skill set well suited for humanitarian response. Those who seek appropriate training and experience will have the opportunity to expand their professional practice while providing an essential service to the world's most vulnerable populations.

CHAPTER E2: QUESTIONS AND ANSWERS

1. Which of the following scenarios often creates ethical dilemmas for those providing humanitarian assistance?
- **a.** Availability of water
- **b.** Creating housing for patients
- **c.** Local government policies
- **d.** Triage of patients by local custom

Answer: D. Although all these issues are important, humanitarian workers often have ethical concerns about triage based on local customs versus severity of illness

2. Which of the following best describes the *Sphere Handbook*?
- **a.** A global compilation of nongovernmental agencies
- **b.** A description of legal decisions in international courts
- **c.** An educational guide to global relief efforts
- **d.** A guide that sets internal standards for humanitarian aid

Answer: D. The *Sphere Handbook*, a collaborative project of humanitarian response experts, sets international standards for the provision of humanitarian aid and is widely considered to define the gold standard of global humanitarian response.

3. What is the distinction between internally displaced persons and refugees?
- **a.** Internally displaced persons may remain in country or reside in another country.
- **b.** Refugees are persons who are displaced and reside in another country.
- **c.** Internally displaced persons have more rights and benefits than refugees.
- **d.** The refugee is dependent on the number of displaced persons.

Answer: B. Displaced populations are designated either as internally displaced persons (IDPs) or refugees. An IDP is someone who has been forced from his or her home but who remains within the country of origin. If an IDP crosses an international border to seek help in another country, she or he becomes a refugee. Although refugees enjoy protections and rights guaranteed by international treaty, IDPs must depend (in the absence of international aid) on their own government for help, even though the actions—or inaction—of their government often caused their displacement,

Emergency Ultrasound

Emergency Ultrasound

L. Connor Nickels and Petra Duran-Gehring

KEY CONCEPTS

- Over the past 20 years, emergency ultrasound (EUS) has become an integral part of emergency medical care in the United States and has become standard in the evaluation of emergency medical conditions.
- EUS answers specific, often binary questions, and is therefore neither sufficient nor intended to diagnose all of the broad range of pathologic processes encountered in emergency medicine.
- During cardiac arrest, ultrasound can be used to rapidly detect ventricular motion in asystole and pulseless electrical activity and confirm cardiac standstill.
- The subcostal four-chamber view, as in the focused assessment of sonography in trauma, is ideal for assessment of pericardial effusion and useful during cardiac arrest because it does not interfere with chest compressions.
- Although cardiac tamponade is a clinical diagnosis, there are several suggestive echocardiographic features, including diastolic collapse of the RV, loss of respiratory variation of the inferior vena cava (IVC), and transvalvular flow velocity paradoxus.
- EUS is more sensitive and specific compared with supine chest radiography for the detection of pneumothorax, approaching that of CT.
- Pneumonia on EUS appears as dynamic air bronchograms, hyperechoic areas within bronchi that move with respiration usually visualized within the consolidated lung, and are highly specific for alveolar consolidation.
- Color Doppler can help differentiate mild hydronephrosis from renal vasculature, and possibly accentuate any renal stones by producing the renal twinkle artifact.
- EUS has reduced the morbidity of ectopic pregnancy by shortening the time to diagnosis and operating room treatment.
- In the ED, ultrasound-guided internal jugular cannulation is associated with decreased time to vessel penetration and improved success in the difficult access patient, improved overall and first-attempt success rates, reduced time to insertion, and reduced complication rate.

FOUNDATIONS

Emergency ultrasound (EUS), also known as bedside ultrasound (US), clinical US or point-of-care US (POCUS), is the imaging examination performed and interpreted simultaneously at the patient's bedside by the treating clinician. This focused sonographic examination may be used for diagnosis, resuscitation, physiologic monitoring, procedural guidance, and assessment of specific symptoms or signa (e.g., shortness of breath) in emergency medicine. EUS provides clinically important information that cannot be gleaned from the physical examination (inspection, palpation, auscultation, etc.) and therefore, is not an extension of the physical examination but an additional modality.[1] Over the past 20 years, EUS has become an integral part of emergency medical care in the United States and has become standard in the evaluation of emergency medical conditions. In 2001, the American College of Emergency Physicians (ACEP) published guidelines for the use of EUS and, in 2016, expanded the scope of practice to 12 core applications: (1) trauma, (2) pregnancy, (3) cardiac/hemodynamic assessment, (4) abdominal aorta, (5) airway/thoracic, (6) biliary, (7) urinary tract, (8) deep vein thrombosis (DVT), (9) soft tissue/musculoskeletal, (10) ocular, (11) bowel, and (12) procedural guidance.[1] EUS training is required by the Residency Review Committee and residents have to demonstrate competency in this milestone before graduation.[2-4] For those emergency clinicians who trained prior to the EUS residency requirements, initial training often occurs through continuing medical education courses, followed by a period of proctoring or supervision. Recent educational advances, such as simulation, task trainers, internet-based training, and nontraditional media (e.g., electronic books, mobile device applications, social media) may also enhance US training.[5]

EUS answers specific, often binary questions, and is therefore neither sufficient nor intended to diagnose all of the broad range of pathologic processes encountered in emergency medicine. Consequently, if the clinical question cannot be answered with EUS, it is up to the emergency clinician to choose another modality for diagnosis. Although typically performed in the emergency department (ED), the portability of EUS allows its use throughout the hospital, as well as out-of-hospital use in mobile transport, disaster areas, military engagements, international rescue work, resource-limited settings, and remote locations. The recent proliferation of handheld US machines further increases the availability of EUS for clinical use; however, these handheld or pocket-sized devices must still be used in the same manner as their predecessors.[6] The main risk management issues reported concerning EUS are failure to perform the examination in a timely manner, or at all, when within the scope of practice defined by the ACEP EUS guidelines.[1,2]

SPECIFIC ISSUES

Basic Ultrasound Information

Physics and Knobology

A brief summary of relevant terminology is presented in (Box e3.1). Readers seeking more in-depth reviews of US physics, machine controls, US modes, and instrumentation are encouraged to visit the Sonoguide website (https://www.acep.org/sonoguide/basic/ultrasound-physics-and-technical-facts-for-the-beginner/). Other relevant lectures on this topic can be accessed through the Academy of Emergency Ultrasound (AEUS) Vimeo Channel (https://vimeo.com/aeus) or website (https://www.saem.org/about-saem/academies-interest-groups-affiliates2/aeus/education/aeus-narrated-lecture-series), as well as various sites noted at the end of this chapter.

Transducer Selection

In general, image resolution is inversely proportional to penetration and the emergency clinician should choose the transducer with the highest resolution for the depth needed to obtain appropriate images. There are 4 basic transducer types, and selection criteria for each is listed in (Table e3.1).

BOX E3.1 Common Definitions

Ultrasound (US)—sound waves with frequencies >20,000 Hz. Modern diagnostic US typically operates in the 1- to 18-MHz range
Window—soft tissue where transducer is placed to interrogate tissue in the body
B mode or brightness mode (grayscale or two-dimensional)—graphs the amplitude of reflected US waves as shades of gray from black to white on a monitor screen
Gain—adjusts the amplitude of signals on the ultrasound display (brightness)
Time-gain compensation (TGC)—changes gain at specific depths
M mode (motion mode)—displays reflected waves over time and distance; used to calculate rates (e.g., fetal heart rate) and evaluate moving structures (e.g., cardiac valves)
Color flow Doppler—displays direction and velocity of flow
Power Doppler (power angiography)—displays velocity of flow, but not direction
Pulsed wave Doppler—demonstrates velocity and direction of flow in a waveform display
Focus—image area where US beam is narrowest and lateral resolution is greatest
Near field—area on display from transducer to focus
Far field—area on display from focus to the bottom of the display
Anechoic—without sounds (black)
Echogenic—with sounds (white)
Hyperechoic—with more reflected sounds than adjacent tissue (more echogenic)
Hypoechoic—with less sound than adjacent tissue (less echogenic)

TABLE E3.1 Ultrasound Transducers

Transducer Type	Screen Image Shape	Examination Types
Flat linear array High frequency	Square or rectangular	Superficial structures: soft tissue, musculoskeletal, appendicitis in a thin child or adult, lung evaluation for pneumothorax, and procedural guidance
Endocavitary array High frequency	Pie shaped	Early pregnancy, peritonsillar abscess
Curved linear array Low frequency	Pie shaped	Abdominal and lung
Phased array Low frequency	Pie shaped	Cardiac, abdominal, and lung
Transesophageal echocardiographic		Cardiac

Safety and Disinfection

US biosafety includes use of the ALARA (***a**s **l**ow **a**s **r**easonably **a**chievable) principle, appropriate Doppler usage, and appropriate microbiologic disinfection of the US transducer and system. Following the ALARA principle, emergency clinicians should perform EUS only when indicated and limit the time of sonographic investigation. Doppler modes should be minimized over sensitive tissue, including early gestation and germinal, mucosal, ocular, and neural tissues.[7] All transducers should be cleaned according to the various types of examinations and the indicated disinfection type, either low-level or high-level.[8] Surface transducers should be cleaned at the bedside with mechanical removal of gel and debris, followed by low-level disinfection with an appropriate spray or wipe. Endocavitary transducers require high-level disinfection, a more prolonged and substantial cleaning method, because they come into contact with mucous membranes. Safety also includes the use of appropriate barriers over transducers, nonsterile and sterile, as well as sterile gel or clean water.[8a]

Focused Assessment with Sonography in Trauma

The focused assessment with sonography in trauma (FAST) examination was the original EUS application, developed as a noninvasive alternative to diagnostic peritoneal lavage, and evaluates for hemoperitoneum, hemopericardium, and hemothorax. The FAST was then extended to include evaluation for pneumothorax as the E-FAST examination and now plays a valuable role in the evaluation of patients with blunt or penetrating thoracoabdominal trauma. The FAST examination is accurate and clinically relevant in hypotensive patients with traumatic injuries, decreasing patient morbidity, time to operating room and hospital charges.[9] Stable patients with a positive FAST examination will often still require computed tomography (CT) imaging due to the growing trend for nonoperative or interventional management of blunt solid organ injury. EUS-diagnosed traumatic pericardial effusions receive more rapid operative intervention and have lower mortality rates. Furthermore, EUS is more sensitive and specific compared with supine chest radiography for the detection of pneumothorax, approaching that of CT.[10,11]

Image Acquisition

The FAST examination technique uses a low-frequency broadband transducer (2–6 MHz) to evaluate dependent peritoneal spaces, pleural spaces, and the pericardium for free fluid, which in the trauma patient is presumed to be blood. There are four main components of the basic FAST examination: (1) the right upper quadrant (RUQ) view, (2) the left upper quadrant (LUQ) view, (3) the pelvic view and (4) the cardiac view (Fig. e3.1). The E-FAST includes anterior chest views to evaluate for pneumothorax. The RUQ view evaluates for fluid in the thorax (above the diaphragm) (Video e3.1), hepatorenal space (Morison pouch) and the paracolic gutter (inferior edge of the liver and right kidney) (Video e3.2), moving cephalad to caudad. The LUQ view, found slightly more superior and posterior than the RUQ, should mimic the RUQ views, but also include the subdiaphragmatic space, because free intraperitoneal fluid tends to accumulate here initially. The pelvis should be evaluated in the transverse and longitudinal planes, where fluid may be detected deep to the uterus (in females) or in the retrovesical space (in males) (Video e3.3). The cardiac evaluation can be performed in either the subcostal (or subxiphoid) or parasternal window (Video e3.4). Evaluation for pneumothorax uses a low or high-frequency transducer at a shallow depth, placed along the anterior chest wall and will be discussed in more detail in subsequent sections.

Pathology

Typically, free fluid is anechoic, but it can have echogenicity if active extravasation, a blood clot, or bowel contents are present within the fluid. Compared with other fluid-filled structures in the abdomen and pelvis, peritoneal free fluid generally has sharp pointed edges and an irregular shape, whereas most visceral or vascular structures have intrinsically smooth oval or round contours. The volume of fluid required for a positive US study depends on the site of injury, sonographic window, and experience of the operator, but 250 mL or more is generally visible, and nearly 600 mL of fluid is required for a positive upper quadrant window. With pericardial fluid, once a certain volume is reached, the pressure in the pericardial space increases dramatically,

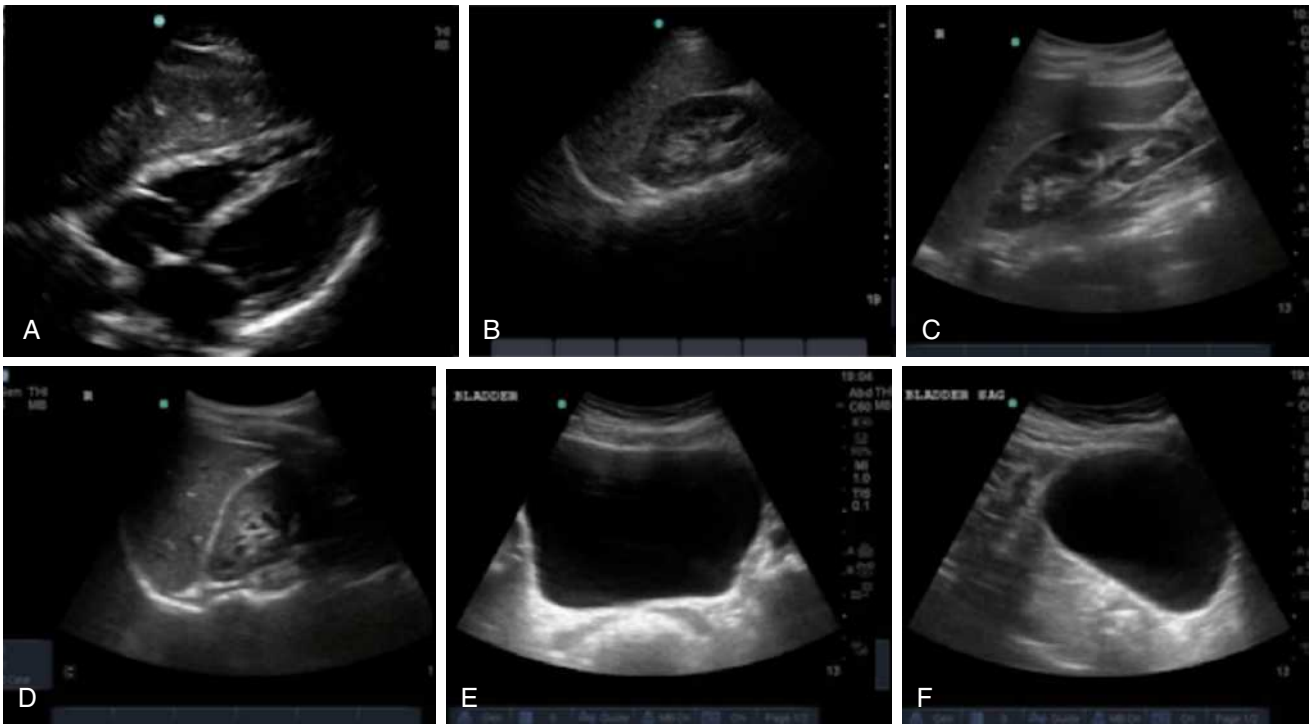

Fig. e3.1 Negative FAST images. (A) Subxiphoid view with no pericardial effusion. (B) Negative RUQ view showing the thorax and hepatorenal space without the paracolic gutter visualized. There is mirroring and loss of the spine, indicating a negative thorax. (C) Negative paracolic gutter area by the liver tip in the RUQ view. (D) LUQ view showing negative thorax, as in B, and splenorenal space. (E) Negative transverse bladder view. (F) Negative sagittal bladder view.

resulting in cardiac tamponade. Generally, at least 50 mL of fluid is required to cause hemodynamic compromise in a patient without prior pericardial inflammation (Fig. e3.2).

Special Considerations

In obstetric patients, abruption and fetal viability may necessitate an earlier operative course. FAST is unreliable for the detection of hemoperitoneum in patients with pelvic fractures. The detection of free fluid in an unstable patient with a pelvic fracture may be due to uroperitoneum from bladder injury rather than hemoperitoneum from vascular injury, clouding the decision for laparotomy versus pelvic embolization. In addition, retroperitoneal injuries to the genitourinary tract are not reliably assessed with the FAST examination. The FAST is further discussed in the "Pediatric Emergency Ultrasound" section.

Biliary

Biliary US, to detect gallstones and associated acute cholecystitis (AC), was one of the early applications of EUS and should be considered in patients with right upper quadrant pain, epigastric pain, jaundice, right flank pain, and sepsis without a clear source. Biliary US is fast and accurate, with a reported sensitivity of 87% to 94% and specificity of 82% to 96% in the detection of gallstones, comparable to radiologic US.[12,13] Despite the demonstrated high sensitivities and specificities for this examination, there remains a gap between this evidence and the decision making of surgical services, likely due to a lack of trust in biliary EUS.[14] Recent studies have questioned the benefit of measuring the CBD.[15]

Image Acquisition

The examination is performed with a low-frequency curved linear array or phased array transducer. Subcostal and intercostal windows will facilitate visualization of the gallbladder (GB), which should be evaluated in two orthogonal (perpendicular) planes (Fig. e3.3). Visualization and measurement of the common bile duct (CBD) remain part of the examination and should be performed.

Pathology

The diagnosis of cholelithiasis is made by identification of echogenic foci within the gallbladder lumen with associated shadowing. Other image patterns include stones with indistinct shadow, sludge, and the wall-echo-shadow (WES) sign seen in a gallbladder full of gallstones (Video e3.5). Although many sonographic findings can be seen with AC, including gallstones, dilated gallbladder, increased gallbladder wall thickness (>3 mm), sonographic Murphy sign, pericholecystic fluid, and CBD dilatation, gallstones are present in 95% to 99% of AC cases[16] (Fig. e3.4). A nonmobile stone in the gallbladder neck, confirmed in the left lateral decubitus position, is highly suggestive of eventual cholecystitis. A CBD larger than 6 mm in people younger than 60 years and larger than 10 mm in older patients may indicate choledocholithiasis.

Urinary Tract Ultrasound

Renal and urinary tract EUS can detect hydronephrosis and/or urinary retention in patients with back, abdominal or groin pain. In addition, bladder US is useful for the detection of urinary retention, Foley catheter localization, and guidance during suprapubic aspiration or Foley placement. Recent studies have shown that emergency clinicians are capable of finding hydronephrosis with EUS on adults, infants, and children when compared to CTs and/or radiologists, and that use of US for this purpose reduces length of ED stay.[17-20]

Image Acquisition

Renal US includes orthogonal views of the kidneys, with an emphasis on visualization of the renal calyces/pelvis. The sonographic windows

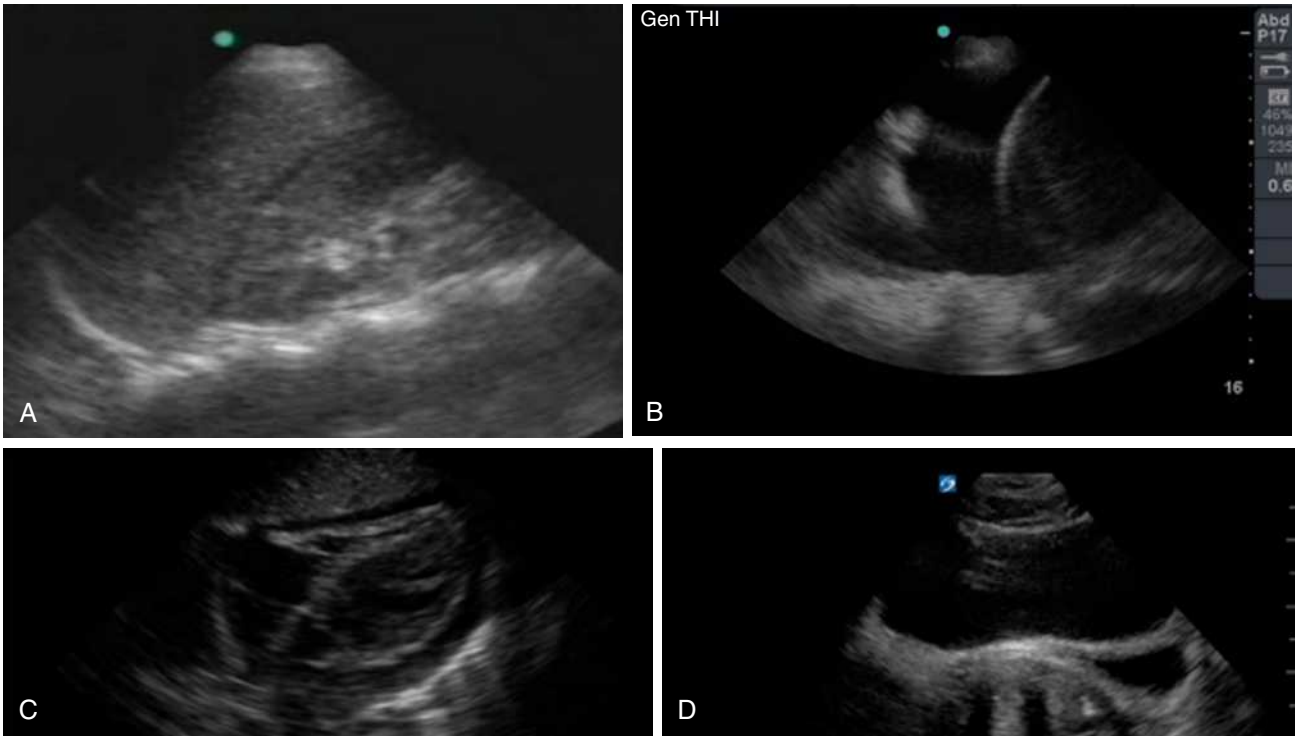

Fig. e3.2 Positive FAST images. (A) Positive RUQ view showing a thin stripe of fluid in the hepatorenal space. The thorax is negative and paracolic gutter not visualized. (B) Positive LUQ view showing a hemothorax and splenorenal space. There is loss of mirroring and continuation of the spine. (C) Subxiphoid view showing a pericardial effusion circumferentially. (D) Positive transverse bladder view with free fluid noted posterior to the bladder on the right of the image.

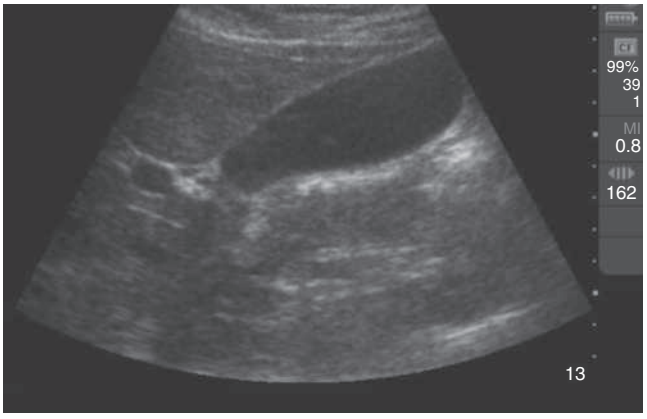

Fig. e3.3 Normal sagittal view of the gallbladder

Fig. e3.4 Sagittal gallbladder with signs of acute cholecystitis including stones with posterior shadowing, thickening of the wall anteriorly, and pericholecystic fluid seen within the wall of the gallbladder.

for the two kidneys are similar to those used in the trauma upper quadrant views. The bladder view is performed from the suprapubic window in transverse and sagittal planes. Ureteral jets can be assessed by placing color Doppler over the trigone of the bladder in the transverse view. Bladder volume calculations (Fig. e3.5) may be performed with on-machine calculators or by using the formula:

$$\text{Length} \times \text{width} \times \text{height} \times 0.72 = \text{volume}$$

Pathology

Hydronephrosis is characterized by dilation and anechoic fluid accumulation within the renal pelvis and calyces, ranging from mild to severe (Fig. e3.6). Renal and/or ureteral calculi may be identified as echogenic foci with associated shadowing and are usually located within the kidney (nonobstructive) or in the renal pelvis, proximal ureter, or uretero-vesicular junction. Color Doppler placed over the kidney can help differentiate mild hydronephrosis from the renal vasculature, as well as possibly accentuate any renal stones by producing the renal twinkle artifact.[21]

Abdominal Aorta

Emergency clinicians' use of EUS to detect an abdominal aortic aneurysms (AAA) in patients with flank, abdominal, groin, and/or back pain, with or without unexplained hypotension, has a sensitivity of 95% to 100% and specificity of nearly 100%.[22,23] Although intraperitoneal and/or retroperitoneal hemorrhage may be detected, abdominal US is insufficiently sensitive to exclude a leaking AAA and, therefore, CT

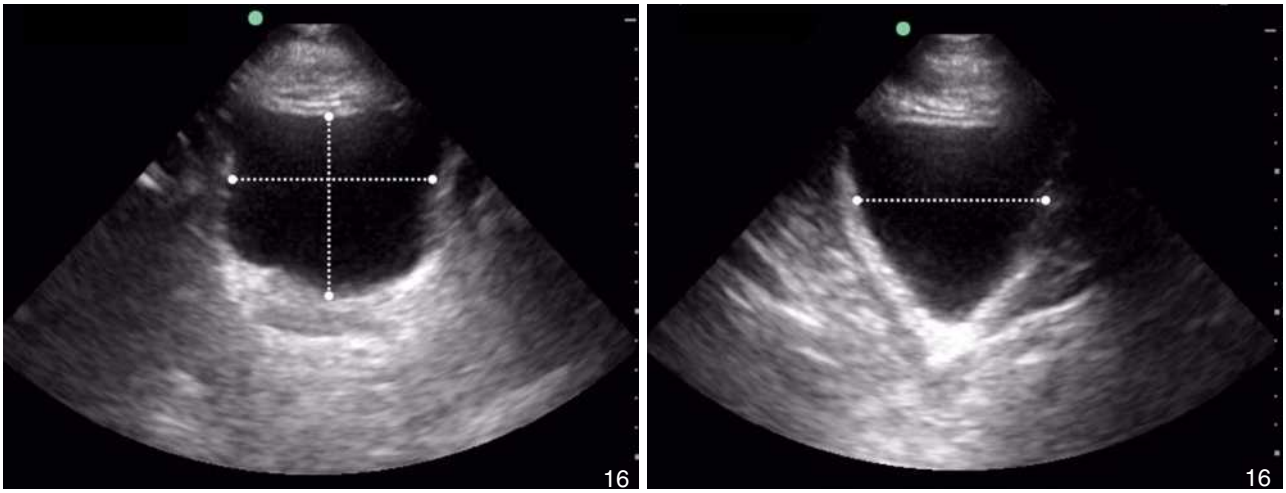

Fig. e3.5 Bladder volume measurements.

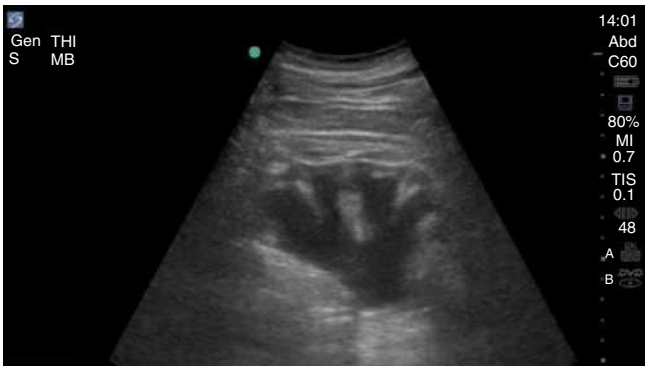

Fig. e3.6 Hydronephrosis with dilation of the calyces and renal pelvis of the kidney showing thinning of the cortex, signifying severe hydronephrosis.

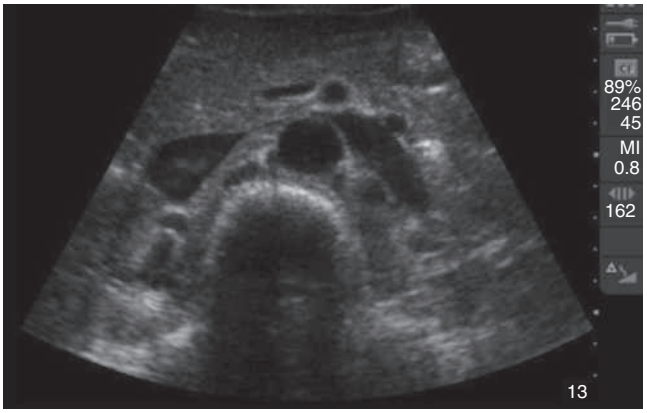

Fig. e3.7 Normal transverse view of the aorta.

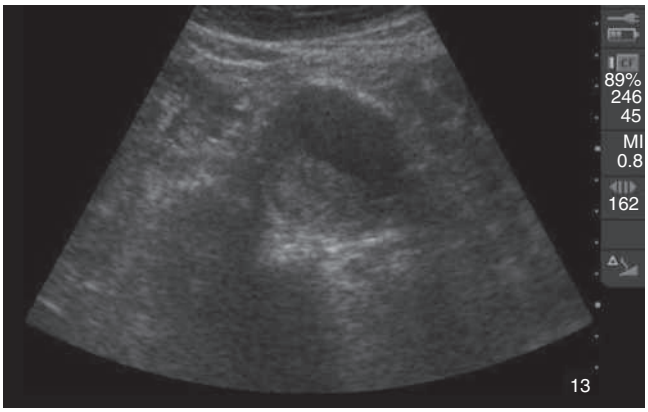

Fig. e3.8 Transverse view of a AAA with mural thrombus.

should be performed in patients with known or suspected aneurysms in whom the clinical picture suggests the possibility of rupture. Likewise, emergency US may demonstrate evidence of an aortic dissection, with sensitivities of 80% to 90% and specificity of 100%, but should not be used to exclude this potentially life-threatening diagnosis.[24]

Image Acquisition

Using a low-frequency transducer (curvilinear or phased array) and significant pressure to displace the overlying bowel gas, the aorta should be visualized from the subxiphoid region to the umbilicus (bifurcation) in both transverse and longitudinal planes. The transverse view should be obtained first to avoid the cylinder tangent error, which could falsely underestimate the size of the aorta (Fig. e3.7 and Video e3.6). Cross-sectional measurements should be taken of the aorta, outer wall to outer wall, including any mural thrombus that might be present. Aortic dissection may be detected by a combination of abdominal and cardiac scanning, with the addition of a suprasternal notch view to the traditional cardiac windows.

Pathology

An aortic diameter greater than 3 cm constitutes an abdominal aortic aneurysm, but risk of rupture increases with size and is rare with aneurysms smaller than 4.5 cm (Fig. e3.8 and Video e3.7). A linear echogenic flap, anywhere across the lumen of the aorta, is suggestive of aortic dissection and may be associated with a different Doppler flow pattern on either side of the flap (Fig. e3.9 and Video e3.8). The cardiac US examination may demonstrate an unexplained pericardial effusion, a dilated aortic root (>4 cm), aortic insufficiency, and/or a linear echogenic flap in the descending aorta.

Cardiac/Hemodynamic Assessment

Cardiac US enables rapid assessment for pericardial effusion, global left ventricular (LV) systolic function, and right ventricular (RV) enlargement, and may prove valuable in hemodynamic assessment and early detection of valvular or aortic emergencies. Indications for cardiac US include cardiac arrest, suspected pericardial effusion, trauma, chest

Fig. e3.9 Aortic dissection flap visualized on longitudinal view of the aorta.

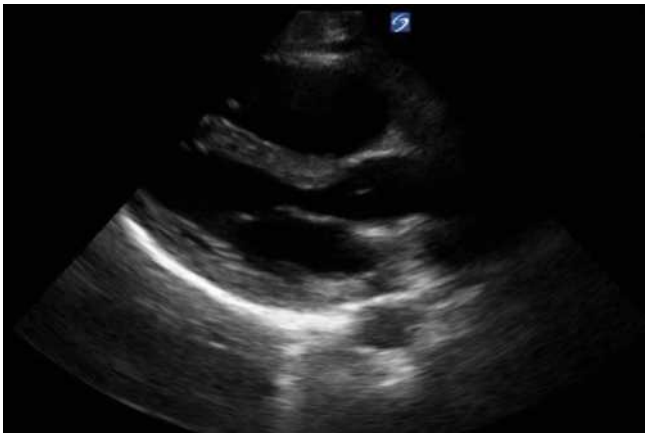

Fig. e3.10 Normal parasternal long-axis view of the heart.

pain, undifferentiated hypotension, or dyspnea. Cardiac US performed by emergency clinicians shows high accuracy in the detection of pericardial effusion, assessment of LV function, and evaluation of patients with undifferentiated shock. During cardiac arrest, US can be used to rapidly detect ventricular motion in asystole and pulseless electrical activity and confirm cardiac standstill.[25] Because advanced cardiac life support guidelines have suggested minimizing noncardiopulmonary resuscitation intervals, transesophageal echocardiography may prove even more useful in the periarrest patient.[26-28]

Image Acquisition

Cardiac US is performed through the transthoracic and transabdominal windows with the use of small curvilinear or phased array transducers. Typical views include the subcostal four-chamber view (subxiphoid), parasternal long-axis view (Fig. e3.10; see Video e3.4), parasternal short-axis view, and apical four-chamber view. The subcostal four-chamber view, as in the FAST, is ideal for assessment of pericardial effusion and useful during cardiac arrest because it does not interfere with chest compressions.[28] The long-axis subcostal view highlights the inferior vena cava (IVC) and can indicate volume status. The parasternal views are excellent windows for LV assessment. The apical four-chamber view is ideal for comparison of RV and LV sizes and function. Several US protocols have been developed to evaluate undifferentiated hypotension and can be used to narrow the differential diagnosis.

Fig. e3.11 Plethoric IVC showing where to take a measurement.

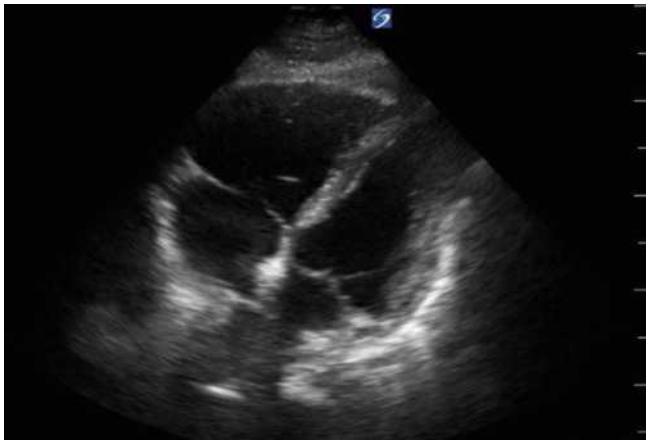

Fig. e3.12 Apical 4-chamber view of the heart with an enlarged RV.

Pathology

Pericardial fluid is typically anechoic, although it can contain internal echoes in cases of pericardial hemorrhage or infection. Large pericardial effusions are usually circumferential but can be loculated. As a result, assessment for pericardial effusion should include multiple views, when feasible, to confirm diagnosis and to avoid mistaking the epicardial fat pad for a pericardial effusion. Although cardiac tamponade is a clinical diagnosis, there are several suggestive echocardiographic features, including diastolic collapse of the RV (Video e3.9), loss of respiratory variation of the IVC (Fig. e3.11), and transvalvular flow velocity paradoxus.[29]

Assessment for global LV systolic function can be performed with visual estimation (Video e3.10) and/or assessment of E-point septal separation (EPSS).[30] EPSS is the distance between the anterior mitral valve leaflet and the ventricular septum measured using M-mode. A distance greater than 7 mm is abnormal, with larger measurements correlating to worsening systolic function. Emergency clinicians should recognize that accurate visual estimation of global LV systolic function requires experience and may prefer to categorize systolic function dichotomously as depressed or normal.

RV assessment is another useful tool for the emergency clinician when pulmonary embolism (PE) is high on the differential. With increasing right heart pressure, the RV dilates, squeezes poorly, and ultimately develops flattening of the interventricular septum, creating the "D" sign (Figs. e3.12, e3.13, and Video e3.11). The sparing of the RV apex is called the McConnell sign and is highly suggestive of PE.[31,32]

Airway/Thoracic Ultrasound

Thoracic US should be considered in patients with chest pain, dyspnea, and/or cough in whom the emergency clinician suspects pleural

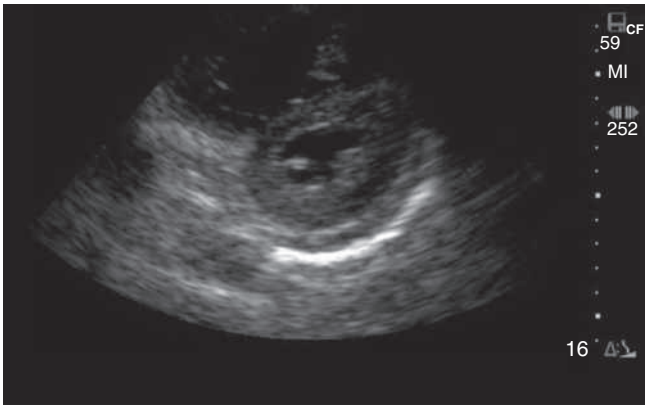

Fig. e3.13 Parasternal short axis view with "D" sign signifying increased RV pressure.

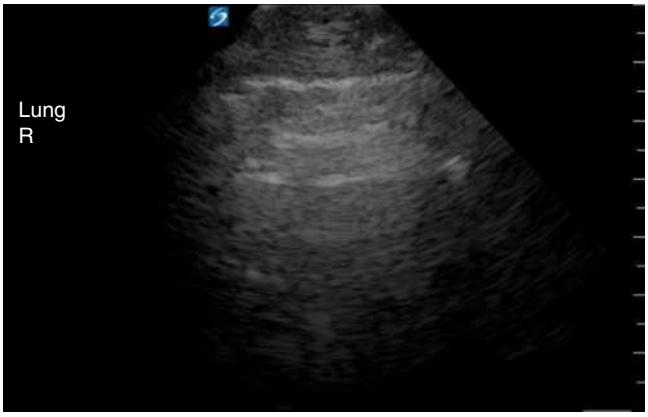

Fig. e3.14 A lines signifying normal lung.

effusion, pneumothorax, pneumonia or pulmonary edema. US evaluation of the acutely dyspneic patient has been associated with increased diagnostic accuracy as compared to traditional clinical examination, particularly for the identification of patients with a cardiogenic cause of acute dyspnea.[33] One study with a total of 1827 patients comparing lung US to chest x-ray showed US to be as specific and more sensitive than x-ray in identifying acute decompensated heart failure.[34]

Image Acquisition

Thoracic US is often performed with a low-frequency curvilinear array or phased array transducer, although visualization of lung sliding may be enhanced, if necessary, by the use of a high-frequency linear array transducer. The original BLUE (Bedside Lung Ultrasound in Emergency) protocol evaluated 4 areas on each hemithorax, but subsequent studies have looked at a number of protocols and additional areas of the anterior, lateral, and posterior thorax.[35] Lung sliding, a normal finding, is identified as the visceral and parietal pleura gliding against each other during normal respiration. A lines, horizontal equally spaced echogenic artifacts deep to the pleural line, are also a normal finding (Fig. e3.14).

Pathology

The visualization of lung sliding excludes the presence of a pneumothorax at that location on the patient's chest wall. Although M-mode and color Doppler techniques have been described as adjuncts to the evaluation of patients with suspected pneumothorax, neither is a necessary component of the examination. Absent lung sliding can result from a variety of causes in addition to pneumothorax, including pleural adhesions or consolidations, blebs, pleurodesis, partial or complete pneumonectomy, and contralateral mainstem bronchus intubation (Fig. e3.15). A lung point sign is identified at the border of the pneumothorax, where the image shows absent lung sliding until the lung moves into the interspace with respiration (Video e3.12).

Once the pleural line has been evaluated for sliding, then the determination of intraparenchymal fluid should be made. A lines indicate a dry lung, whereas B lines indicate the presence of fluid within the lung. B lines are vertical hyperechoic reverberation artifacts that arise from the pleura, move with respiration, extend off the screen without fading, and erase the normal A line pattern (Fig. e3.16). Normally found in small numbers in the dependent areas of the lung (atelectasis), the widespread distribution of B lines, typically 3 or more in one lung window, indicates increased interstitial and/or alveolar thickening due to fluid accumulation (edema) or scarring (fibrosis).[36,37] As the lung accumulates fluid with consolidation, such as a lobar pneumonia, it can appear echogenic, so-called liver-like (hepatization). When diagnosing pneumonia with lung US, the consolidation needs to be in contact with the pleura to be visible within an intercostal window.[38] Other signs can be seen with pneumonia, but dynamic air bronchograms, hyperechoic areas within bronchi that move with respiration, usually within the consolidated lung, are highly specific for alveolar consolidation.[39] As seen in the E-FAST examination, pleural fluid appears as an anechoic collection above the diaphragm, although internal echoes may be present in cases of chronic, infected, or loculated effusions.

Ultrasound in Early Pregnancy

Pelvic US by emergency clinicians is used to evaluate patients who are at risk for ectopic pregnancy. US is used to confirm intrauterine pregnancy in early pregnancy, which indirectly excludes ectopic pregnancy in most patients. Indications for sonographic evaluation include any symptoms or signs that raise concern for an ectopic pregnancy. EUS has reduced the morbidity of ectopic pregnancy by shortening the time to diagnosis and operating room treatment and has resulted in greater initial detection of abnormal pregnancy, reduced ED patient throughput times, and increased patient satisfaction.[40] The emergency clinician should not delay the US while waiting for laboratory test results and should take appropriate measures when concerning findings are noted. Approximately 25% of pregnant women will have first trimester bleeding and 11% (slightly higher with subchorionic hemorrhage and vaginal bleeding) will experience loss of pregnancy after a live intrauterine pregnancy has been visualized.[41] Emergency clinicians can also date pregnancies accurately by pelvic US with typical fetal biometry. Heterotopic pregnancies can occur spontaneously at a rate of 1 in 5000 but occur up to 1 to 3 in 100 in patients receiving assisted reproductive therapy (ART). As a result, confirmation of an intrauterine pregnancy may not sufficiently exclude the presence of a concomitant ectopic pregnancy in patients receiving ART, and emergency clinicians should perform comprehensive US evaluations in this patient population, when possible.[42]

Image Acquisition

Pelvic US is performed by a transabdominal or endovaginal technique and should be a systematic process. The transabdominal technique uses a low-frequency transabdominal transducer placed over the suprapubic area. Ideally, the patient should have a full bladder (an excellent sonographic window), but this may not be necessary if the uterus is large, or if the patient is thin. Advantages of the transabdominal technique include a wider field of view, detection of large pelvic masses or cysts, assessment of uterine lie, and greater depth of field. In the endovaginal technique, the transducer is placed in the vagina, ideally with a near-empty bladder. Endovaginal transducers are high frequency, providing excellent axial resolution but poor penetration of distant structures. Intrauterine yolk sac and fetal pole may be detected earlier, and ectopic pregnancies can be identified with more accuracy.

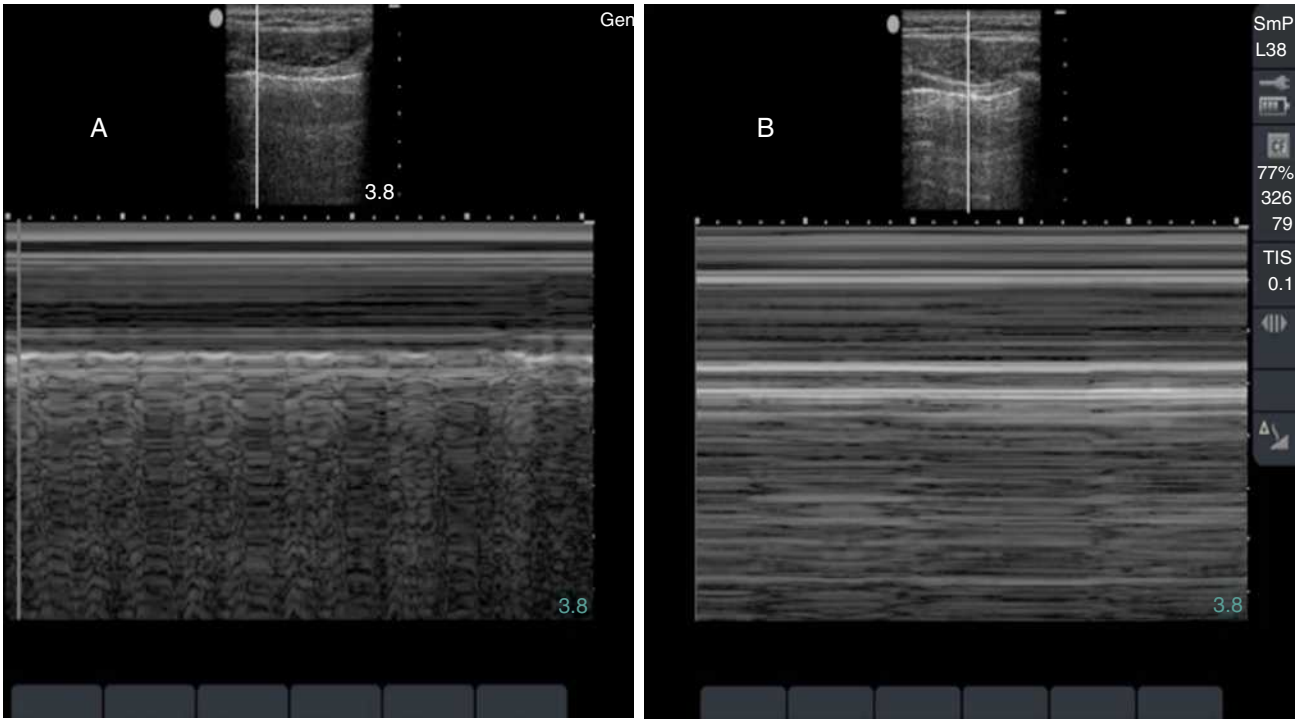

Fig. e3.15 M mode images of the lung. (A) Normal lung with "seashore" sign. (B) Pneumothorax with "stratosphere" or "barcode" sign.

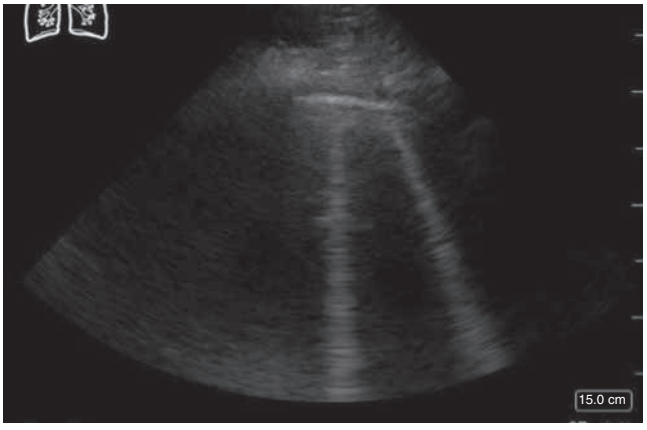

Fig. e3.16 B lines signifying fluid in the lungs

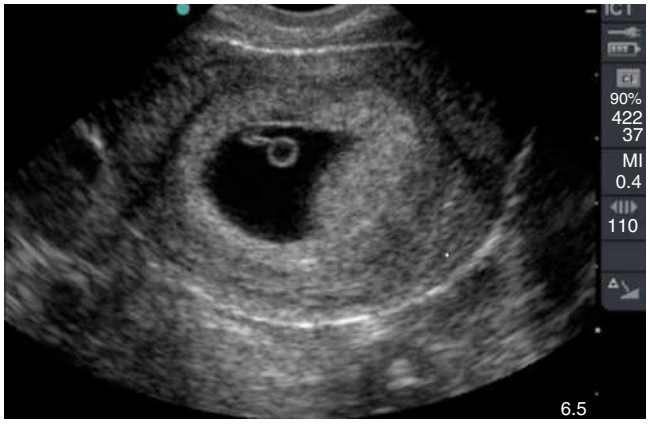

Fig. e3.17 Intrauterine pregnancy with yolk sac and fetal pole within the anechoic gestational sac.

Pathology

The diagnosis of intrauterine pregnancy is established when emergency clinicians confidently identify a gestational sac that contains a yolk sac and/or fetal pole located within the endometrium[43] (Fig. e3.17). Findings of an ectopic pregnancy include a chorionic ring or gestational sac containing a yolk sac or fetal pole outside the uterus or in an abnormal location in the uterus, such as the cornu or cervix (Fig. e3.18 and Video e3.13). Other findings may be subtle or nonspecific but should raise concerns, including adnexal masses, an empty uterus with a serum human chorionic gonadotropin (hCG) level above the discriminatory zone, or moderate to large amounts of free fluid.[44]

Deep Venous Thrombosis

EUS assessment for deep venous thrombosis (DVT) in patients with swollen or painful extremities has an accuracy from 89% to 96%, depending on operator experience. A large meta-analysis compared 2-point and 3-point US techniques in the emergency department and

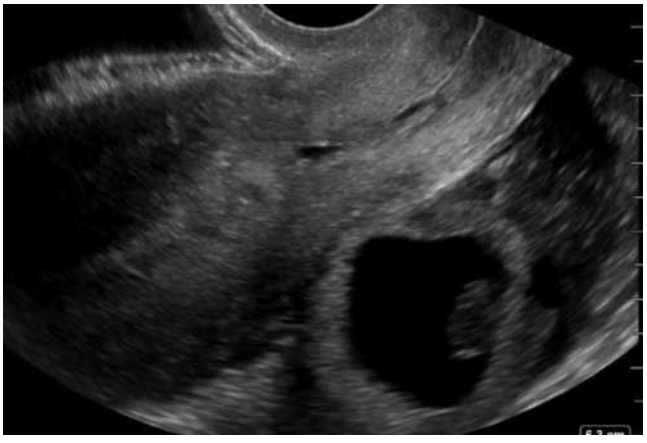

Fig. e3.18 Ectopic pregnancy seen posterior to the sagittal uterus with a fetal pole within the adnexa.

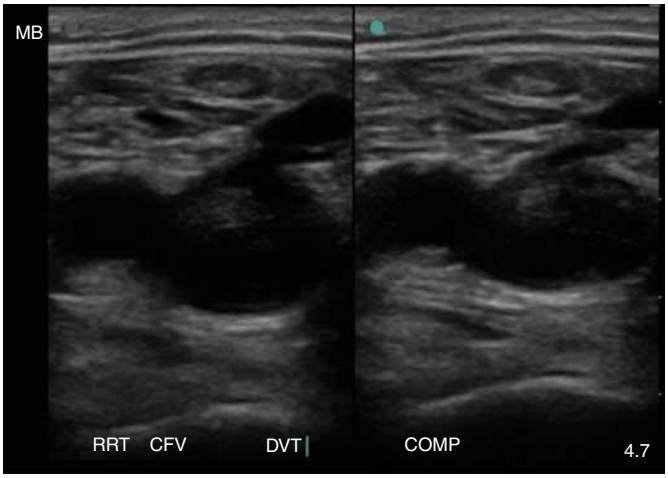

Fig. e3.19 Echogenic thrombus noted in the common femoral vein at the junction of the saphenous vein. The dual screen demonstrates lack of compressibility in the image on the right.

found similar sensitivities (2-point 91%, 3-point 90%) and specificities (2-point 98%, 3-point 95%).[45] A study comparing emergency physician–performed to radiology-performed US showed a substantial kappa coefficient of 0.83.[46]

Image Acquisition

Lower extremity venous compression US is typically performed with a high-frequency linear array transducer. The two-zone technique involves evaluating and compressing the common femoral vein from the saphenofemoral junction through the bifurcation of the femoral vein and the popliteal vein through its trifurcation. The three-zone technique adds the femoral vein from its origin through the distal thigh.[47] Evaluation of upper extremity veins is less commonly performed by emergency clinicians; Doppler US is required for the subclavian vein, which is not compressible under the clavicle.

Pathology

The lack of compressibility is the hallmark of a deep venous thrombosis and direct visualization of echogenic thrombi is commonly seen (Fig. e3.19 and Videos e3.14 and e3.15).

Ocular Ultrasound

Ocular US is a useful modality for diagnosing retinal detachment, posterior vitreous detachment, vitreous hemorrhage, intraocular foreign body, dislocated lens, increased intracranial pressure (Fig. e3.20), and retro-orbital hemorrhage.[47-50] In addition, pupillary size and extraocular movements can be evaluated, even in the presence of facial swelling (Video e3.16).[51] The reported sensitivity of ocular US for retinal detachment by emergency clinicians is 92%, and the specificity is 91.4%.[49] Ocular US is contraindicated in the setting of known or suspected globe rupture.

Image Acquisition

Using a high-frequency linear array transducer, sterile gel, and a biofilm cover over the transducer or patient's closed eyelid, the anterior and posterior chambers (Fig. e3.21) can be evaluated by scanning through the globe in orthogonal planes with low- and high-gain settings. Stabilization of your hand on the patient's forehead or nose allows for control of the pressure applied to the globe. Use of the ocular machine preset will minimize the thermal bioeffects to the eye structures during the examination.[9]

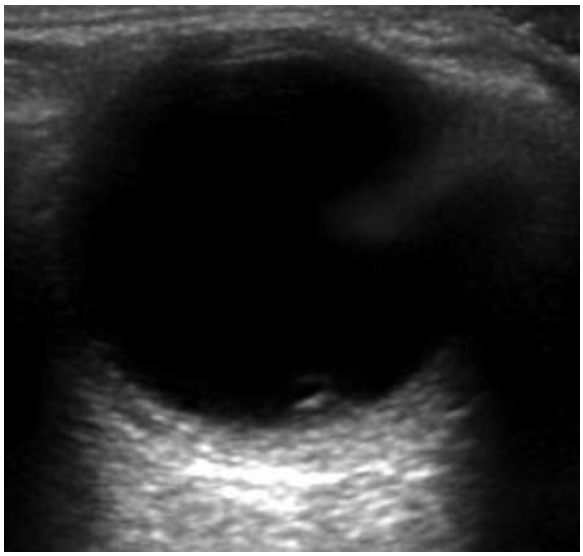

Fig. e3.20 Papilledema with swelling noted at the optic disc.

Fig. e3.21 Normal anterior and posterior chamber of the eye.

Pathology

Visualization of a linear structure in the anechoic posterior chamber indicates a retinal detachment (Fig. e3.22), as opposed to a vitreous detachment, if the flap does not cross the optic nerve but rather appears tethered to the edge (Video e3.17).[52] The diagnosis of ocular pathology may be facilitated through kinetic echography, which evaluates the chamber as the patient shifts the gaze in different directions (Video e3.18).

Soft Tissue Ultrasound

Soft tissue US is used to differentiate cellulitis from abscess, detect foreign bodies and hernias, and evaluate other pathologic processes, including masses, pseudoaneurysms, and glands. US can also differentiate peritonsillar abscess from cellulitis and can be used to guide peritonsillar aspiration. US has greater sensitivity and specificity than a clinical examination for the detection of soft tissue abscess.[53] According

Fig. e3.22 Retinal detachment with hyperechoic flap within the posterior chamber tethered to the optic nerve

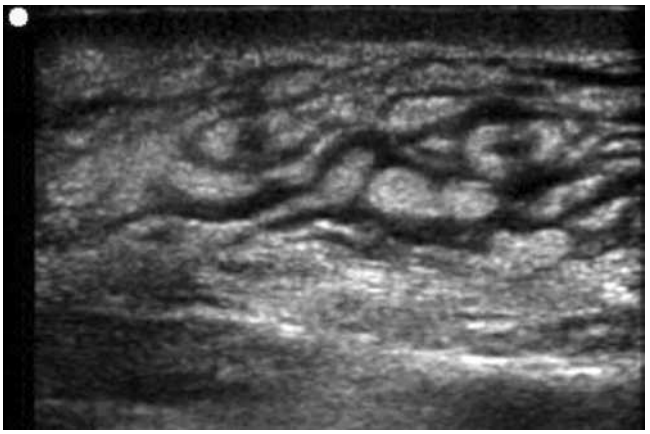

Fig. e3.23 Cellulitis with cobblestoning.

to a recent systematic review and meta-analysis of 8 articles, the use of US changed management for 17% to 56% of adult patients and 14% to 27% of children with clinical cellulitis, with an overall sensitivity of 95.5% and specificity of 80.3%.[54,55]

Image Acquisition

A high-frequency linear transducer is used to visualize the entire affected area in two orthogonal planes. Evaluation for peritonsillar abscess is best performed with the endocavitary transducer directly on the affected tonsil or with the linear transducer externally in an uncooperative child.

Pathology

Cellulitis or edema results in an echogenic pattern called cobblestoning (Fig. e3.23), as the fat lobules become separated by fluid. Abscesses are irregular, hypoechoic to anechoic collections, typically located within the subcutaneous layer (Fig. e3.24). US is diagnostic in cellulitis, abscess, and, in some case series, necrotizing fasciitis, as evidenced by gas and/or fluid within the tissue planes (Videos e3.19 and e3.20).[56,57] The detection of foreign bodies is characterized by variable echogenicity, with plastic, glass, and wooden objects shadowing distally and metallic objects creating highly reflective echogenicity and ring-down artifacts.

Musculoskeletal Ultrasound

Patients with suspected joint effusion, muscular, tendinous, or ligamentous injury may benefit from US-guided evaluation. EUS identification of tendon disruption is highly accurate in the knee extensors and Achilles tendon. EUS in the diagnosis of shoulder dislocation was found to be highly sensitive (99.1%) and specific (99.9%), with the potential to decrease time, radiation exposure, and health care costs.[58] Evaluation of the rotator cuff requires considerable experience but offers accuracy that rivals that of magnetic resonance imaging. In a systematic review and meta-analysis evaluating EUS and long bone fractures, most studies reported sensitivities and specificities of 90% and above, with EUS demonstrating excellent performance in pediatric forearm fractures and adult ankle fractures.[59]

Image Acquisition

Musculoskeletal US is performed with a high-frequency linear array transducer and imaging in two orthogonal planes. US detection of tendon and muscle injury is often assisted by movement of the limb and comparison of the contralateral side. Water bath techniques or standoff pads provide a better acoustic window for shallow tissue, such as digits.

Pathology

Joint effusions can be anechoic or echogenic, depending on type and age. Tendons and their anisotropic longitudinal fibrils can be visualized near joints, with pathologic tears appearing as a discontinuity of the tendon (Video e3.21). Muscles are hypoechoic, striated, and have echogenic borders with tears and hemorrhages appearing as interruptions of this normal pattern. The characteristic echogenic appearance of bony cortex with associated shadowing is used to identify normal bone and its contour. Fractures are seen as a defect in the bony cortex (Fig. e3.25).

Bowel Ultrasound

The use of bedside US for the evaluation of appendicitis, small bowel obstruction (SBO), and other bowel disease has been an area of increasing interest over the past decade and is now a core application. SBO EUS in the emergency department demonstrates a sensitivity of 88% and specificity of 54%, with small-bowel dilation greater than or equal to 25 mm (Fig. e3.26) and abnormal peristalsis the more sensitive parameters, whereas intraperitoneal free fluid, bowel wall edema, and transition point are more specific findings (Video e3.22).[60] EUS for appendicitis (Fig. e3.27) has shown equivocal accuracy, and therefore should not be the rule-out test or considered sufficient to stand alone. The use of US for diverticulitis, intussusception, volvulus, pneumoperitoneum, and hernias has also been described.

Pediatric Emergency Ultrasound

In 2019, expert guidelines were published specifically for pediatric emergency medicine as a result of mounting evidence confirming the benefits of EUS in children.[61] Although most US examinations have proven helpful in the pediatric population, the FAST examination seemingly has become less useful. The FAST examination in children is specific (91.4%), but the sensitivity is only 27.8% and rarely impacts management.[62] Furthermore, in a study of 925 hemodynamically stable children, the FAST compared to standard care showed no improvement of care, including use of resources, missed intra-abdominal injuries, hospital charges, and length of stay.[63] FAST may be of benefit to triage hypotensive children, but may not reflect the need for surgical intervention.[64]

Specific pediatric abdominal applications including intussusception, appendicitis, and pyloric stenosis have proven useful in the emergency department. After a short training session, pediatric emergency physicians were able to make the diagnosis of intussusception as accurately as radiologists, with a sensitivity and specificity approaching 100%.[64] EUS can make the diagnosis of acute appendicitis with higher accuracy in children than in adults, but should not be the final imaging modality if not detected.[65]

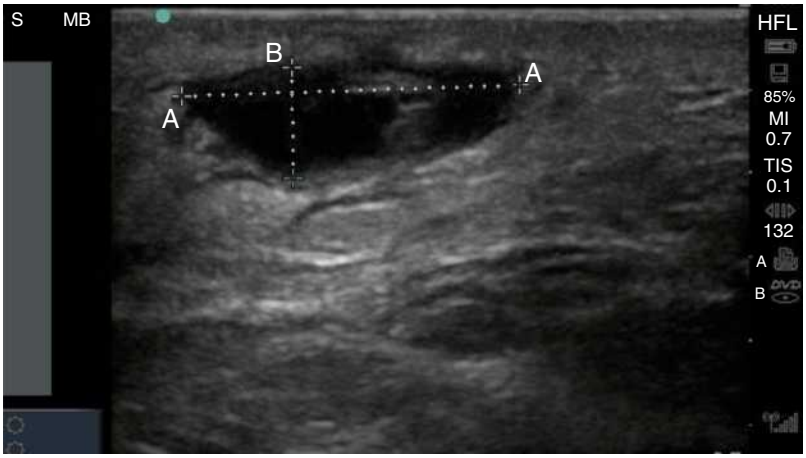

Fig. e3.24 Abscess showing measurement.

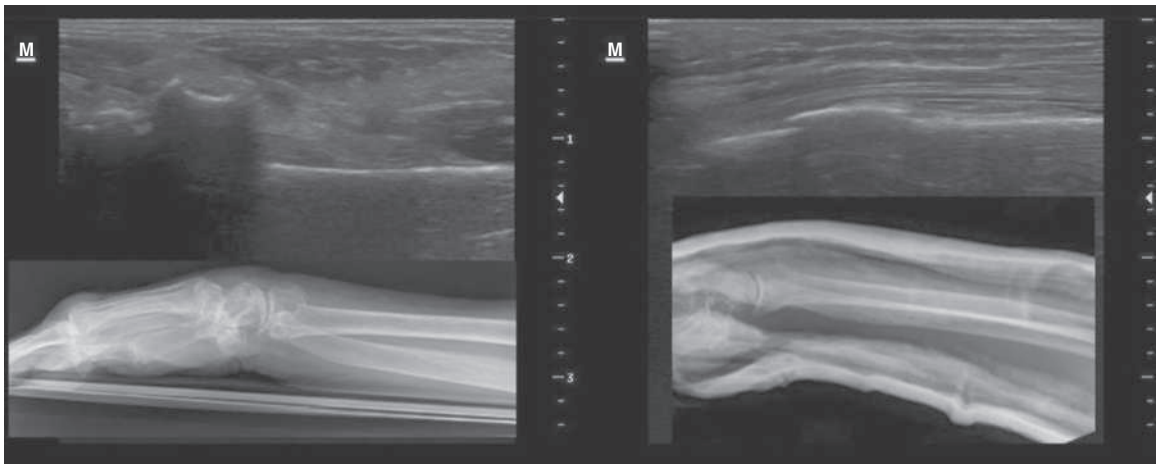

Fig. e3.25 Distal radius fracture before (*left*) and after (*right*) reduction.

Fig. e3.26 SBO with dilated bowel.

Other pediatric indications including fracture diagnosis and reduction have been shown to be highly sensitive and specific.[66] Both fracture and lung US have the potential benefit of decreased radiation exposure, length of stay, and cost. As with most US examinations, the usefulness of lung US is operator dependent but was shown to have good diagnostic accuracy in a meta-analysis on pediatric pneumonia, even in the hands of nonexperts.[67] Milliner et al. noted each lung zone should be visualized in sagittal and transverse orientation, as omission of either orientation could potentially miss pneumonia.[68] Lung US can also diagnose bronchiolitis.

Ultrasound for Procedural Guidance

In 2001, in response to the Institute of Medicine report *To Err Is Human,* the Agency for Healthcare Research and Quality (AHRQ) sanctioned a report on actions that may improve patient safety, recommending US guidance for internal jugular central line insertion, which was reiterated in the revised 2013 report.[69] Since the original report, the use of US for procedural guidance has expanded for many emergency procedures (Table e3.2) and is advocated for error reduction. Procedural guidance can be static or dynamic. Static guidance suggests that US has been placed over the anatomic area, and the area has been marked after noting angle and distance information. Dynamic guidance describes procedures performed with real-time US visualization of the needle entering the anatomic area, which is preferred and has demonstrated higher gains in safety and quality.[70,71]

Vascular Access Procedures

There are two common approaches to vein cannulation: out-of-plane, in which the vein is imaged in short axis and appears as a circular structure on the screen, and in-plane (Fig. e3.28), in which the vein is imaged in long axis and appears as a tubular structure traversing the width of the screen. Although the out-of-plane approach is more popular with novices, the in-plane approach may be safer in experienced hands, due to the continuous visualization of the needle tip during the entire procedure. In addition, an oblique axis in-plane technique has been described, where the vessels are imaged

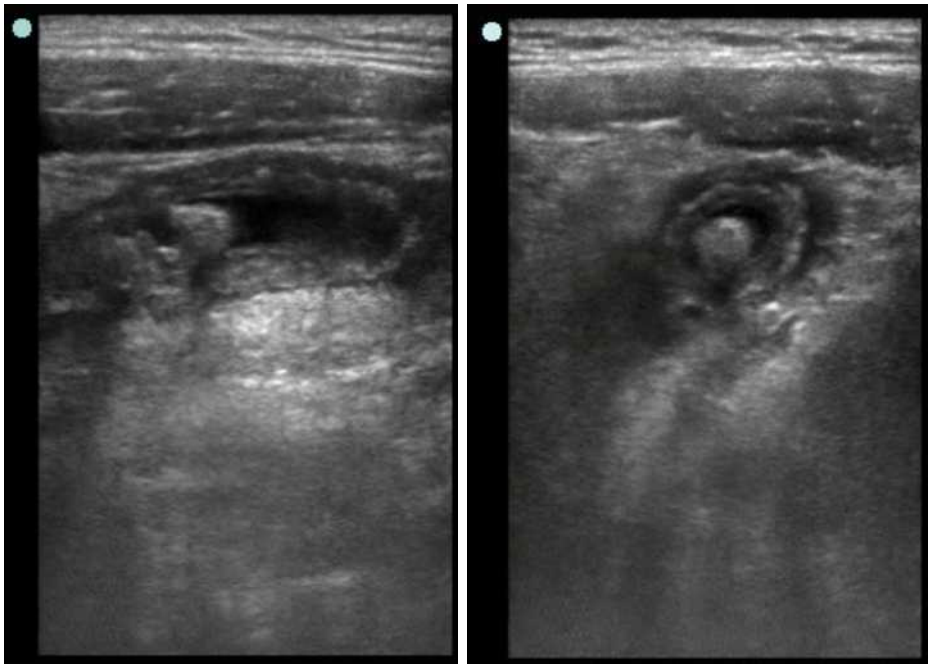

Fig. e3.27 Appendicitis with appendicolith.

TABLE E3.2 **Ultrasound-Guided Emergency Procedures**

Ultrasound	Procedure
Vascular access	Central venous access Internal jugular vein Subclavian vein Femoral vein Peripheral vein Intraosseous needle Arterial cannulation

Urinary bladder	Suprapubic aspiration and cystostomy Foley guidance
Neurologic	Lumbar puncture

at an oblique angle while the needle is inserted in plane. While the oblique axis may have a higher first-needle-pass success rate than the in-plane or longitudinal axis and fewer complications than the

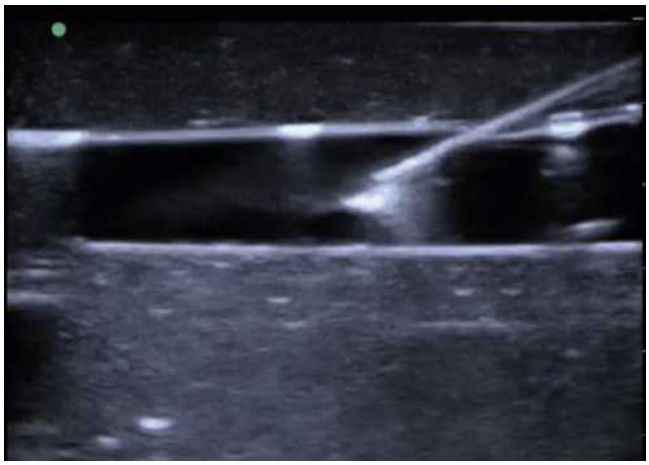

Fig. e3.28 In-plane approach to vascular access.

out-of-plane or short axis, the majority of studies comparing the three approaches found insufficient evidence to recommend one approach over the other.[72-74]

US guidance enables the emergency clinician to assess the internal jugular (IJ) for overlap with the carotid artery, vessel diameter, and presence of luminal clot or vessel obliteration. In the ED, US-guided IJ cannulation (Fig. e3.29) is associated with decreased time to vessel penetration and improved success in the difficult access patient, improved overall and first-attempt success rates, reduced time to insertion, and reduced complication rate.[74-76] US does not prevent posterior vein wall penetration, as reported in case reports and simulated models.

Emergency clinicians can also insert peripheral intravenous (IV) catheters successfully in patients with difficult access using emergency US, demonstrating a marked reduction in the need for central venous catheter placement in ED patients with poor IV access.[75] Veins that are large in width or at moderate depth (<1.6 cm) have a higher success rate. Nurses and ED technicians have also been taught to use US for peripheral venous guidance.[76] Arterial access has shown the same success.

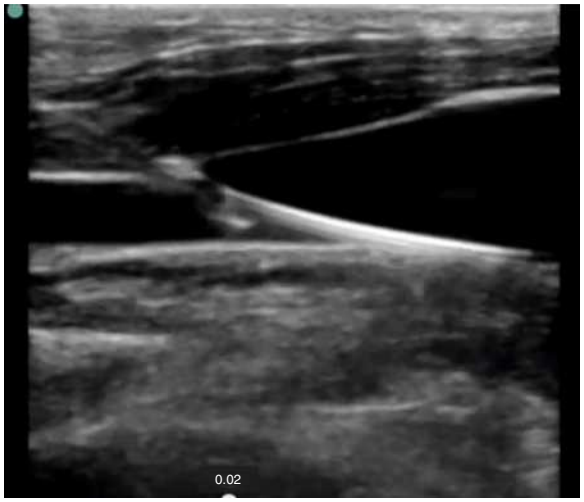

Fig. e3.29 Echogenic guidewire visualized in long-axis view of internal jugular vein.

Fig. e3.30 Sciatic nerve block using in-plane approach.

Drainage Procedures

US can facilitate procedures such as paracentesis, thoracentesis, pericardiocentesis, and arthrocentesis by confirming the presence and amount of fluid, as well as its relative location to key anatomic structures. As previously discussed, a static or dynamic approach can be used; however, the dynamic approach is favored. In paracentesis, US is useful for identifying the deepest location of ascites and presence of obstructing bowel loops or superficial vascular structures. Thoracentesis is assisted by considering the diaphragm as the most inferior anatomic landmark to avoid solid organ injury, as well as locating the lung and thereby reducing the rate of pneumothorax and tube thoracostomy. Pericardiocentesis also can be facilitated by visualizing the best window—subcostal, apical, or parasternal long—and needle guidance into the pericardial space, lessening the likelihood of cardiac puncture. Moreover, US can help guide the needle for most joint aspirations.

Localization Procedures

US guided procedures to localize nerves, intravertebral spaces and transvenous pacer placement can improve procedural success. US-guided nerve blocks (Fig. e3.30) confirm needle placement adjacent to the target nerve and allow the anesthetic to be delivered safely and effectively around the nerve. In light of the opioid crisis in our country, nerve blocks have become more popular and can be used for headaches, abscess drainage, fractures, dislocations, priapism, foreign body removal, and laceration repairs. Regional anesthesia has been increasingly incorporated into standardized care protocols for geriatric orthopedic trauma with excellent success.[77] EUS can also be used to facilitate lumbar puncture by identification of the spinous processes in patients without palpable anatomic landmarks. The literature comparing US-guided lumbar punctures versus traditional, landmark-based lumbar punctures remains controversial but suggests an increase in success rates with its use on infants.[78-80] Cardiac US can also be used to guide placement of transvenous pacer wires and for pericardiocentesis. US facilitates placement by imaging the wires in real time as they pass through the tricuspid valve and approach the apex of the RV.[81]

Useful web-based resources for learning more about EUS are shown in Box e3.2.

CHAPTER E3: QUESTIONS AND ANSWERS

1 Which frequency range defines US?

a. Less than 0.2 Hz
b. Over 2 Hz
c. Over 200 Hz
d. Over 20,000 Hz

Answer: D. US is defined as sound with frequency over 20,000 Hz.

2 Which of the following performance characteristics is true for higher-frequency probes?

a. Deeper penetration, higher resolution
b. Deeper penetration, poorer resolution
c. Superficial penetration, higher resolution
d. Superficial penetration, poorer resolution

Answer: C. Higher-frequency probes sacrifice penetration (depth of scan) for improved resolution (image detail).

CHAPTER E3: QUESTIONS AND ANSWERS—cont'd

3 Which type of US has the best resolution when the probe is perpendicular to the object of interest?
- **a.** Doppler US
- **b.** Grayscale US

Answer: B. Grayscale or B-mode US produces best imaging when perpendicular to the area of interest, whereas Doppler US is best performed when the angle of insonation is <60 degrees.

4 Sensitivity is typically greater than specificity for FAST examination.
- **a.** True
- **b.** False

Answer: B. The FAST examination is typically more specific than sensitive.

5 Which of the following is the correct order of imaging for increasing the sensitivity of detecting a pneumothorax?
- **a.** Chest x-ray (CXR) > CT > US
- **b.** CT > CXR > US
- **c.** CT > US > CXR
- **d.** US > CT > CXR

Answer: C. CT is only slightly more sensitive than US at detecting pneumothorax, but US is significantly more sensitive than supine CXR.

The Geriatric Emergency Department

The Geriatric Emergency Department

Kevin Biese and Ula Hwang

KEY CONCEPTS

- The rapid increase in the number of older adults in the United States (US) and around the world, as well as the unsustainable costs of the current US health care system, mandates improved emergency care systems for these vulnerable patients.
- Older adults are at high risk of experiencing harm from busy, crowded emergency departments (ED). While in the ED, they may experience prolonged lengths of stay, iatrogenic infections, misdiagnosis, delirium, bedsores and other adverse consequences.
- Older adults who are discharged are at high risk of ED return visit, hospitalization, or death within three months. Because older adults admitted to the hospital are at high risk of adverse events, care transition programs are needed to reduce the risk of inpatient stays and improve post-ED care.
- The Geriatric ED Guidelines are an excellent resource to improve the physical and process design to better address the needs of older adults.
- The Geriatric ED Collaborative and Geriatric ED Accreditation programs are innovative programs that facilitate the implementation of better emergency care for older adults.

PRINCIPLES

Background/Foundations

The current model of care delivery in the Emergency Department (ED) is designed for rapid evaluation, treatment, and turnover of patients.[1] The layout is designed to maximize resources while improving throughput at the expense of privacy and comfort (e.g., hallway beds, lack of space for family and/or caregivers). Choices in materials favor cost savings and space conservation (e.g., fluorescent lighting, narrow mattresses, and vinyl flooring). The triage system is designed to rapidly identify patients needing immediate intervention and is guided by the principle that clinicians target a primary acute medical problem using an optimal treatment algorithm. A traditional ED visit ends with admission for necessary medical care or discharge because the acute needs of the patient have been met. Too often, little emphasis is placed on arranging post-ED follow-up care or ensuring patient comprehension of discharge instructions. Although this approach may work for younger patients, the current ED model presents a challenge in the management of elders. Moreover, the model undermines the ability of the ED to care optimally for older adults and complicates their transition to follow-up care and access to community-based resources.[2]

Unlike younger patients, older adults have atypical and complex presentations of disease and trauma. They often present with vague complaints, polypharmacy, age-specific multifactorial geriatric syndromes (e.g., falls and delirium), comorbid disease burdens, and functional and cognitive impairments. Older adults are more likely to receive a greater number of diagnostic tests and treatment regimens, have longer lengths of stay, and often have multiple hospital admissions. Finally, after an ED visit, elders are more likely to suffer from health and functional decline and worsened quality of life. Adverse outcomes after ED visits have patient care and cost ramifications, suggesting that improved models of integrated care may facilitate good outcomes and decrease costs.

Advances in health education, pharmacotherapy, and health-related technology, have resulted in an increase in life expectancy. Accordingly, 20% of the US population, totaling more than 77 million people, will be aged 65 years and older in 2030, outnumbering the number of children for the first time in US history.[3] Of particular significance, the most rapidly growing segment of the population is 85 years and older, which is projected to increase by 129%, from 6.4 million in 2016 to 14.6 million in 2040.[4]

The 2013 RAND Report (https://www.rand.org/pubs/research_reports/RR280.html), evaluated the evolving role of hospital EDs in the US health care system. It found that EDs are increasingly used for complex evaluations. Emergency clinicians are the primary decision makers for half of all hospital admissions. ED admissions of Medicare patients are growing faster than any other US patient group, with 6 of 10 patients admitted through the ED. Furthermore, recent estimates indicate there is more than 1 ED visit for every 2 older adults in the US annually.[5] EDs increasingly see older patients with multiple health care needs due to convenience, perception of increased quality of care, and lack of rapid access to primary care providers. Because of the increasing number of elders and the outsized role EDs play in their medical care, it is necessary for ED design and structure to evolve and meet the challenge.

SPECIFIC DISORDERS/ISSUES

Geriatric Emergency Department Guidelines

In response to this growing need, an interdisciplinary group of professional specialties, societies, and organizations developed the Geriatric ED (GED) Guidelines, which were published in 2014. The guidelines consist of 40 specific recommendations in 6 general categories: (1) staffing and administration; (2) equipment and supplies; (3) education; (4) policies, procedures, and protocols; (5) follow-up and transitions of care; and (6) quality improvement measures.[6]

Staffing and Administration

The staffing and administration of the GED should be comprised of a multidisciplinary team of care providers who have specific geriatric training and education to focus on high-quality geriatric care. These include a GED medical director, GED nurse manager, staff physicians and nurses, and medical staff specialists (including a geriatric consultation service) who can provide accessibility to ancillary services (e.g., social workers, geriatric case managers, pharmacists, physical and occupational therapists). The goal is the establishment of dedicated ED

and in-hospital staff that is linked and coordinated with local outpatient resources.

Equipment and Supplies

The development of a GED should adapt the physical space with structural modifications and introduce and utilize equipment and supplies designed for the safe, comfortable, and effective evaluation and management of geriatric patients while decreasing iatrogenic complications. Enhancements that address issues of mobility, comfort, safety, and behavioral needs (including memory cues and sensory perception of vision and hearing) are desirable.

Suggested furniture improvements include reclining examination chairs that facilitate safe transferring, thick and soft gurney mattresses (or if feasible, pressure-redistributing foam mattresses) designed to decrease the risk of pressure ulcers.[7] Recent studies indicate higher-specification foam mattresses are associated with fewer pressure ulcers compared to the standard foam mattresses commonly found in the ED. Upholstery choices would preferably be soft, moisture-proof, easy to clean, and designed to protect fragile skin while retaining the ability to reduce contamination by hospital-associated pathogens. Special equipment for GEDs should include blanket warmers, nonslip fall mats, bedside commodes, walking aids and devices, hearing aids, and condom catheters to reduce the risk of catheter-associated urinary tract infections.

Visual orientation improvements include soft lighting, with a combination of ambient and indirect lighting, designed to increase overall lighting while reducing glare. Patients should have control of the lighting in their respective rooms. Light dimmers are inexpensive and easy to add to existing rooms. Exposure to natural light is also desired because it has been shown to improve recovery times and decrease the risk of agitated delirium.[8]

Color and pattern choices for facilities and structures should be made with an understanding of the vision and perception changes that accompany aging. Warm, light-colored walls (yellows and oranges) with a matte finish are preferable. Blues and greens are difficult to differentiate for many older patients. Rather than employing monochromatic schemes, colors should contrast between horizontal and vertical surfaces. Sharp, dominant contrast patterns may be disorienting and hinder mobility.[6]

Acoustic orientation improvements will provide better communication and decreased levels of anxiety and delirium. Private rooms and the use of sound-absorbing materials (e.g., curtains, ceiling tiles) are preferred to reduce background noise and increase patient privacy. Portable hearing assist devices are helpful. Reduction in overhead paging and machine noise should be a targeted goal. Use of music reduces anxiety in older ED patients, along with reductions in heart rate and blood pressure. Enhanced signage can improve communication and understanding.

A limited number of Geriatric EDs, such as the Gary and Mary West Senior Emergency Care Unit in La Jolla, California, have been fortunate to build new and exemplary facilities. The vast majority of hospitals will have to utilize existing space; however, innovative design and technologies can be implemented to promote geriatric-friendly environments.

Education

Interdisciplinary staff education is a key component to the implementation and success of a GED program. Residency program curricula, ED staff training, and continuing medical education should incorporate the established geriatric emergency medicine core competencies and provide specialty-specific training. This training should focus on contemporary, research-based, geriatric-specific material, with regular assessment for interdisciplinary core competencies. A variety of instructional platforms can be used and tailored to the learners and their needs. The GED guidelines recommend the inclusion of core geriatric emergency content outlined in Box e4.1.

BOX E4.1 Geriatric Education Guideline Content

- Atypical presentations of disease
- Trauma, including falls and hip fracture
- Cognitive and behavioral disorders
- Modifications of emergent interventions for older patients
- Medication management
- Transitions of care and referrals to services
- Pain management and palliative care
- Effects of comorbid conditions
- Functional impairments and disorders
- Management of diseases peculiar to the geriatric adult
  - Abdominal pain
  - Weakness and dizziness
  - Iatrogenic injuries
  - Cross-cultural issues involving older patients in the emergency setting
  - Elder abuse and neglect
  - Ethical issues, including advance directives

Policies, Procedures, and Protocols

Specific policies, procedures, and protocol initiatives are integral to the systematization of evidence-based clinical care for older adults. They are designed to facilitate the screening and assessment of geriatric patients for added needs, patient safety, and post-ED adverse outcomes. Additionally, they provide a framework to validate ED screening tools. These tools help ensure a programmatic approach to interdisciplinary care as well as guide a feasible approach to screening for frailty and additional more comprehensive geriatric assessment (Fig. e4.1 and Table e4.1).

Early research regarding the clinical impact of GEDs is growing. One multisite study of three GEDs found geriatric-specific interventions with a transitional care nurse were associated with reduced risk of hospital admissions during the ED visit (4.7% to 16.5% reduction across 3 sites), up to a 13.8% reduced risk of admission within 30 days following an ED visit,[9] and even reduced 30-day hospital readmissions (10.1% to 17.3% reduction at 2 sites).[10] Physical therapy consults in the ED have been shown to reduce fall-related revisits to the ED within 30 days.[11] These programs also reduce total costs of care.[11a]

Follow-Up and Transition of Care

Geriatric patients are particularly vulnerable to the deleterious consequences of hospitalization, including nosocomial infections, functional decline, increased rates of delirium, and iatrogenic complications.[12] Accordingly, reducing hospitalizations by providing safer discharge and outpatient follow-up is preferable whenever possible.

The GED should establish discharge protocols that provide clear communication of relevant information to patients, their families, and outpatient care providers, including primary care providers, specialty clinics, and nursing homes. A well-designed discharge process will account for elder needs (e.g., large-font instructions and utilization of teach-back strategies when possible) and should include a clear outpatient follow-up plan. To facilitate ongoing care, collaboration with community resources is established to provide home health services, equipment, and home safety assessment. Outpatient follow-up via telephone, telemedicine, texting, or direct contact is necessary. The GED

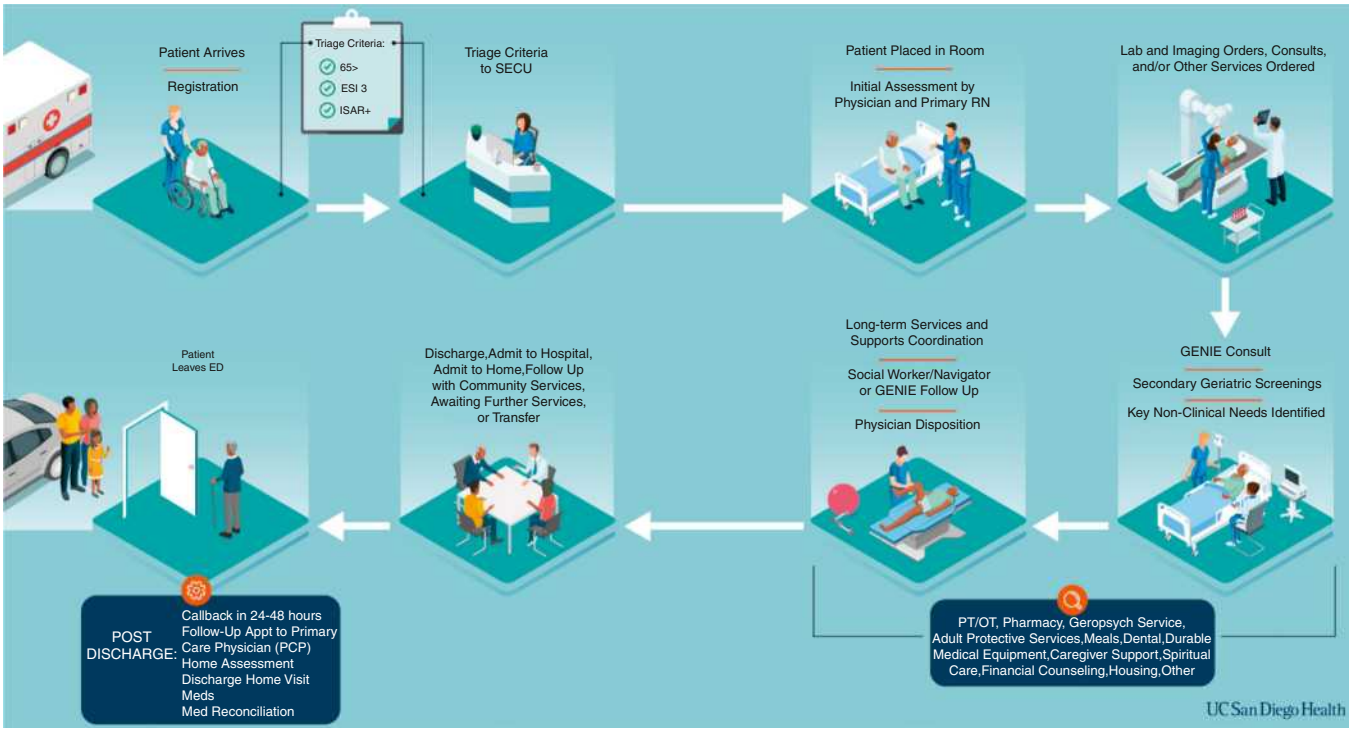

Fig. e4.1 Flowchart clinical workflow from the Gary and Mary West Senior Emergency Care Unit illustrating the programmatic approach to interdisciplinary care including integration of physical therapy, case management, social work, and pharmacy as well as to guide a feasible approach to screening for frailty and additional more comprehensive geriatric assessment.

- SECU eligibility determined by triage RN
- Age
- ISAR+
- ESI 3
- If qualify, GENIE Consult ordered automatically
- GENIE completes secondary screening
- Specialized service consults ordered

should use established relationships with community resources to facilitate short-term or long-term placement of the patient in a nursing home or rehabilitation facility when discharge back to the community is not possible but hospitalization is not needed.

Quality Improvement Measures

As with all care enhancement programs, it is important to track the impact of intervention implementation. Accurate tracking of care improvements in the GED, such as delirium screening or decreasing the number of patients in hallway beds, will ensure meaningful changes in care delivery. Accordingly, we recommend regular reporting through the use of a clinical "dashboard."

Geriatric Emergency Department Collaborative and Geriatric Emergency Department Accreditation

The GED guidelines were catalyzed and bolstered by the emergence of 2 initiatives. First, is the Geriatric Emergency Department Collaborative (GEDC), which is a network of geriatric EDs supported by the John A. Hartford Foundation and the West Health Institute. Its mission is to transform, catalyze, and evaluate the impact of best practices in Geriatric Emergency Care (https://gedcollaborative.com/). The GEDC offers educational programs and resources to assist GED implementation. Furthermore, the GEDC is organizing infrastructure to study the impact of evolving practices in geriatric emergency medicine.

Second, in 2018, ACEP launched the Geriatric Emergency Department Accreditation (GEDA) program (https://www.acep.org/geda/). The GEDA program accredits EDs at different levels based on steps that an ED takes to optimize care for older adults. As of March 2020, there were over 130 accredited geriatric EDs in over 25 states and 3 nations. Overall, the GEDA program has generated needed momentum to engage and motivate hospital leadership in resourcing the transformation to optimal geriatric emergency care.

CONCLUSION

Though geriatric EDs, and evidence validating their benefit, are still in the early stages of development, GEDs are likely to grow in number. Elders fare poorly in many traditional EDs and do so at a relatively high cost, especially if they are admitted to the hospital. Creating an ED environment that is designed with frail, older adults in mind will improve processes that better identify and target geriatric syndromes, chronic medical conditions, and psychosocial stressors. It will then connect these patients with outpatient care and social support critical to delivering high-value care and optimal recovery. Emergency physicians alone cannot accomplish these complicated tasks. Interdisciplinary teams, working together to facilitate integrated medical care and social support will also be necessary.

Although caring for medically and socially frail adults may not be the historical role EDs filled in the past, changing demographics and the complex nature of our health care system ensure that an increasing

number of older patients will come to the ED for medical care. Emergency medicine, with the assistance of programs like the Geriatric Emergency Department Collaborative and Geriatric Emergency Department Accreditation, will lead the charge to improved unscheduled, acute care for this vulnerable population.

CHAPTER E4: QUESTIONS AND ANSWERS

1. For which of the following outcomes are hospitalized elders at increased risk?
   a. Infections
   b. Delirium
   c. Functional decline
   d. Iatrogenic injuries
   e. All of the above

Answer: E. Geriatric patients are particularly vulnerable to the deleterious consequences of hospitalization, including nosocomial infections, functional decline, increased rates of delirium, and iatrogenic complications.

2. The Geriatric ED (GED) Guidelines developed by ACEP, SAEM, AGS, and ENA make recommendations in all of the following areas except:
   a. Education and patient care protocols
   b. Proper technique for central line placement
   c. Quality improvement measures
   d. Staffing, supplies, and administration
   e. Follow-up and transitions of care

Answer: B. The GED guidelines consist of 40 specific recommendations in six general categories: (1) staffing and administration; (2) equipment and supplies; (3) education; (4) policies, procedures, and protocols; (5) follow-up and transitions of care; and (6) quality-improvement measures.

3. The GED guidelines recommend elder-specific educational content in all of the following areas except:
   a. Atypical presentations of disease
   b. Cognitive and behavioral disorders
   c. Psychotherapy for adjustment disorders
   d. Pain management and palliative care
   e. Medication management

Answer: C. See Box e4.1.

4. ED consultation from which of the following interdisciplinary services has been shown to decrease the likelihood of an elder returning to the ED with a fall within 30 days?
   a. Pharmacy
   b. Social work
   c. Case management
   d. Physical therapy
   e. Occupational therapy

Answer: D. Physical therapy. Although all of the above interdisciplinary services likely improve care for older adults in the ED, being evaluated by a physical therapist in the ED after a fall is associated with lower likelihood of returning to an ED with another fall within 30 days.

5. Which of the following core content areas is not a component of geriatric emergency medicine education?
   a. Elderly trauma, including falls and hip fracture
   b. Myocardial infarction
   c. Cognitive and behavioral disorders
   d. Medication management
   e. Transitions of care

Answer: B. Although myocardial infarction is a condition commonly suffered by older adults, knowledge of myocardial infarction is not in and of itself geriatric emergency medicine education. Geriatric emergency medicine education involves geriatric syndromes, conditions underlying the acute presentation of disease such as polypharmacy or frailty, and management of conditions that are different for older adults than younger adults.

End of Life

Ashley Shreves and Tammie E. Quest

KEY CONCEPTS

- Palliative care is physical, spiritual, psychological, and social support provided to patients and families at any stage of serious illness.
- Palliative care teams are specialized interdisciplinary teams that should be involved early in the course of illness.
- Hospice care is a care system for patients and families with a prognosis of 6 months or less if the disease runs its usual course; referral from the emergency department (ED) may be indicated.
- Patients at the end of life often follow one of four terminal illness trajectories: sudden death, organ failure, cancer, or frailty. Awareness about these trajectories facilitates decision making.
- Outcomes are very poor for patients with advanced age or illness and cardiac arrest or respiratory failure requiring mechanical ventilation. Decision support tools should be incorporated into shared decision making.
- Goals-of-care conversations that outline patient and family hopes and expectations of interventions should be attempted in the ED.
- Emergency clinicians should make recommendations for care plans, interventions, and treatment courses based on prognosis, goals of care, and expected benefits of meeting the identified goals of care.
- Interpretation of an existing advance care plan or receipt of a prehospital order (e.g., POLST—***P***hysician ***O***rders for ***L***ife-***S***ustaining ***T***herapy) should factor into ED treatment plans in the context of the patient's illness trajectory.
- Symptom management (e.g., dyspnea, pain, delirium, agitation, secretions) is critical at the end of life.

FOUNDATIONS

The Institute of Medicine's 2014 report, *Dying in America,* highlights that patients nearing the end of life often experience multiple transitions between health care settings leading to fragmented care, inadequate symptom management, and demands on family members in terms of caregiver responsibilities. Traditional medical models of care have left both patients and caregivers with unmet needs, and this has translated into poor end-of-life experiences for many. There is additional concern that poor communication and lack of advance care planning have meant that some patients receive invasive, burdensome treatment near the end of life, inconsistent with their goals and values. The cost of this discordant care has been well documented, with 20% of Medicare dollars being spent on patients in the last year of life.[1] There has been renewed focus on improving the quality of end-of-life (EOL) care, primarily through the integration of palliative care principles throughout the health care system.

Patients living with a serious or terminal illness visit the emergency department (ED) often because these patients commonly experience medical crises. Emergency clinicians are skilled in the use of life-prolonging interventions; however, for patients with an advanced or terminal disease, such interventions may lead to unnecessary suffering and unwanted prolongation of the end of life. The emphasis on efficiency and early recognition and treatment of pathways common at the end of life, such as sepsis, lead to further challenges. These and other mismatches in the emergency clinician's skill set may lead to barriers in patient-centered EOL care. Accordingly, attention has been given to improving the quality of palliative and EOL care provided in the ED.

Palliative Care

Overview

According to The World Health Organization, palliative care is "…an approach that improves the quality of life of patients (adults and children) and their families who are facing problems associated with life-threatening illness. It prevents and relieves suffering through the early identification, correct assessment and treatment of pain and other problems, whether physical, psychosocial or spiritual."

Palliative care is usually provided by an interdisciplinary team of experts that offers comprehensive care and support systems for patients with a serious illness, including but not limited to those at the end of life. The focus of palliative care is to improve the quality of life for these patients and their family members. Expert symptom management and advanced communication skills focused on aligning patient goals and treatments are the two most critical components that palliative care teams bring to the care of patients with serious illness. Patients can receive active disease-focused treatment (e.g., cancer patients undergoing chemotherapy) while concurrently receiving palliative care. Palliative management is provided to inpatients through consultation, and home-based services and outpatient clinics are increasingly available. Palliative care has been shown to improve patient and caregiver quality of life, reduce depression, decrease the aggressiveness of EOL care, increase advance directive completion, decrease hospitalizations and length of stay, and reduce overall costs.[2]

Palliative Care in the Emergency Department

In 2006, the American Board of Emergency Medicine joined with nine other specialty boards to cosponsor the American Board of Hospice and Palliative Medicine. In 2013, the American College of Emergency Physicians published, as part of the Choosing Wisely Campaign, the recommendation that emergency clinicians should engage patients who present to the ED with chronic or terminal illnesses, and their families, in conversations about palliative care and hospice services. This alliance has recognized the real need for emergency clinicians to address the wide range of interventions and management decisions that are relevant at the end of life. The integration of emergency medicine and palliative medicine has stimulated educational efforts to define the scope of ED-based palliative care and curriculum design.

Early referral from the ED to hospice and palliative care services can benefit select patients, resulting in improved quality of life. There has been an explosive growth in palliative care programs over the last decade, making the availability of palliative medicine consults more routine. Regardless of subspecialty availability, there is a basic palliative care skill set that can be incorporated into the emergency clinician's practice. Communication skills can facilitate difficult conversations related to patient goals and wishes regarding the use of invasive therapies like intubation and CPR, how to interpret and apply advance directives, the basics of prognostication, and how to provide EOL symptom management for the most commonly encountered symptoms such as dyspnea and pain. The national Education in Palliative and End-of-Life Care for Emergency Medicine (EPEC-EM) curriculum has been designed to provide training and skills needed to be successful in this arena. Over the last decade, there has been an increased focus on the practical and operational aspects of palliative care delivery in the ED setting. Key questions include not just the "what" but the "how" to provide optimal palliative care. Identifying the right patient and the appropriate level of intervention needed has been the focus of much of the research.

Hospice Care

Overview

Hospice care is a type of palliative care available to patients with a terminal disease and an expected prognosis of 6 months or less if the disease runs its usual course. The hospice movement, which started in England in the 1950s, initially sought to provide a haven of medical care for persons dying of cancer. Home and inpatient hospice programs now exist throughout the United States (US) and are funded through Medicare.

Currently, hospice care is provided for an expanded spectrum of end-stage illnesses, including, but not limited to, cancer, organ failure, and neurologic diseases such as dementia, ALS, and stroke. Hospice care includes a set of services provided in the home, free-standing inpatient facility, hospital, or nursing home. Some hospice agencies use wards or units within the hospital setting, and others use beds dispersed throughout the hospital; some use both. Hospice services are delivered by an interdisciplinary team. All patients enrolled in hospice care have a supervising physician who authorizes the medical plan of care. Hospice field teams may consist of physicians, registered nurses, case managers, certified nursing assistants, social workers, chaplains, and volunteers. When a patient is receiving hospice care, the patient and surrogates agree that the goal is to maximize quality of life, with a focus on symptom management and relief of suffering, and that any services the hospice is expected to pay for must have prior approval of the hospice. If the hospice authorizes transfer to an ED for care, the hospice will usually cover all ED services. If a patient unilaterally decides to seek emergency services without partnering with the hospice, the patient may be at risk of losing hospice services because the hospice agency is the care plan manager.

Election of hospice care is not synonymous with "do not treat." Patients receiving hospice care can be treated for infections, receive artificial nutrition and hydration, undergo palliative invasive interventions aimed at improving quality of life, or receive palliative disease-directed therapy. These interventions need to be assessed and recommended based on the goals of care assessment. Depending on the admitting diagnosis, however, patients may or may not have to forgo certain treatments upon enrollment. For example, cancer patients are generally required to stop chemotherapeutic agents, whereas furosemide and even dobutamine infusions may be covered for patients with heart failure.

Individuals are considered for hospice care when they meet disease-specific prognostic criteria and have goals that are consistent with the hospice philosophy of care. Because the focus is on quality of life and disease management in the home setting, patients planning on returning to the ED or hospital in the event of a medical crisis are not ideal candidates for enrollment. For patients eligible for hospice but unable to enroll because of inconsistent goals or a desire to pursue disease-modifying treatments like chemotherapy, palliative care consultation can bridge the gap by providing excellent symptom management, psychosocial support, and assistance with goal setting and advance care planning. Home and inpatient hospice programs now exist throughout the United States and are funded through Medicare, Medicaid, and private insurers. Over time, there has been a small but steady increase in hospice utilization by Medicare recipients, with almost half of Medicare decedents accessing hospice in 2017.[3] The median time from enrollment to death is 24 days, often leaving insufficient time for many of the services that hospice can offer.

Hospice and the Emergency Department

Patients enrolled in hospice care utilize the ED significantly less than nonhospice patients at the end of life.[4] Still, hospice patients do present to the ED for a variety of reasons, including panic regarding decline, uncontrolled symptoms, inability or lack of the hospice agency to respond to needs, desire of the patient or family to seek additional opinions regarding care, and concern regarding the care provided by the hospice agency (often a concern regarding the use of medications). Under the US hospice benefit, the hospice agency is the patient's total care manager for anything related to the hospice diagnosis. The hospice should be notified if the patient receives care in the ED. If the hospice authorizes transfer to an ED for care, the hospice will usually cover all ED services. If a patient unilaterally decides to seek emergency services without partnering with the hospice, the patient may be at risk of losing hospice services because the hospice agency is the care plan manager.

An ED visit does not mean that the patient no longer desires hospice care. Although patients and families are instructed to call hospice before going to the hospital, this does not always occur. Patients and caregivers might tell clinicians that they do not understand hospice care or may express concerns that the hospice agency is not providing enough interventions. It can be difficult for some patients and families to accept the comfort care philosophy of hospice; hospice care may be equated with giving up, and patients and caregivers may fear that they will die quickly if enrolled. Despite patient or caregiver perceptions, hospice services may be able to meet their evolving needs, including antibiotics, artificial nutrition, hydration, arrangement of palliative procedures, and palliative radiation or cancer-directed therapy.

Hospice enrollment directly from the ED has been increasingly described and promoted (Box e5.1). The emergency physician can certify that the patient has a terminal disease and write hospice admitting orders. Because of the 24/7 nature of hospice care, all hospice agencies typically have on-call staff that can be reached at all hours; many of them can respond to the needs of the ED for emergent admissions. For some patients and families, the ability to avoid regular hospital admission and its associated risk of hospital death can be very meaningful. Increasingly, hospices have hospital-based services that are open to ED admission.

For actively dying patients with a limited prognosis of hours to days, or a high symptom burden requiring parenteral therapies, inpatient hospice is often the best option. There are regional variations in how patients can receive inpatient care, with some hospice agencies contracting for beds in acute care hospitals, and others having freestanding facilities. Transitions from ED to inpatient hospice are generally easier than a transition home with hospice care. While the latter is possible, it may take more planning and coordination, particularly on the part of caregivers, to be successful. Not surprisingly, caregivers rate the quality

BOX E5.1 Initiation of a Hospice Referral From the Emergency Department

1. Assess Medicare Hospice Benefit eligibility.
2. Discuss hospice as a disposition plan with the patient's physician. Contact the patient's personal physician and discuss the current condition, prognosis, and prior goals-of-care conversations. If you are considering hospice care, ask if the physician is willing to be the following physician for hospice services.
3. Assess whether the patient's goals are consistent with hospice care. Generally, this means a patient wants medical treatments and other support aimed at alleviating symptoms and maintaining quality of life without life prolongation.
4. Introduce hospice to the patient and family or surrogates.
   - Discuss the core aspects of hospice care and how these features can help the patient and family (e.g., 24/7 on-call assistance, home visits for symptom management, coordinated care with the patient's physician, emotional and spiritual or religious support).
   - Address concerns and clarify misconceptions.
   - Phrase your recommendation for hospice care in positive language, grounded in the patient's own care goals: "I think the best way to help you stay at home, avoid the hospital, and stay as fit as possible for whatever time you have left is to receive hospice care at your home…"
   - Discuss the location of hospice care. Usually, this is the patient's residence, such as a private home or long-term care facility. Direct admissions to hospice facilities can occur depending on bed availability and ability of local hospice agencies to arrange an immediate, direct facility admission. This is not available in all communities and requires a discussion with the hospice agency.
5. Make a referral and write orders. Call a hospice agency; anticipate these questions:
   - What is the terminal illness? Who will be the following physician (step 2)?
   - What equipment will be needed immediately (e.g., home oxygen)? Is there a caregiver at home?
   - Code status (patients cannot be denied hospice enrollment if full code; however, the hospice team will need to know if code status needs to be addressed further)
   - Questions you need to ask the hospice agency include the following:
     - How soon can you make an intake visit to the patient's home? Can you visit the patient immediately, even in the ED? (This is available in some communities.)
     - How should I coordinate filling of new prescriptions I want the patient to have?
   - Examples of ED-initiated hospice referral orders:
     - Evaluate and admit or enroll in hospice care.
     - Terminal diagnosis: _____.
     - Expected prognosis—terminal illness with less than 6-month survival likely if disease runs its normal expected course (or be more specific, if indicated).
     - Physician who will follow patient: _____.
6. Ensure patient or surrogate understanding and secure the plan. Communicate the plan following ED discharge; provide the name and contact number for the hospice agency.
7. What if hospice enrollment is appropriate, but cannot be arranged in a timely manner? If the patient can be cared for at home safely for 1 to 2 days without extra services, send her or him home with appropriate prescriptions and care instructions. In most communities, patients can be enrolled in hospice care within 24 to 48 hours, even on weekends. If they cannot be cared for safely at home, observation versus inpatient admission is likely necessary until a safe discharge plan can be established.

Adapted from Lamba S, Quest TE, Weissman DE: Initiating a hospice referral from the emergency department #247. *J Palliat Med*. 2011;14:1346-1347.

of EOL care higher when hospice is involved and when dying occurs outside of the hospital setting which underscores the need for hospice transitions to be considered from the ED.[5]

CORE ASPECTS OF PALLIATIVE CARE IN THE EMERGENCY DEPARTMENT

End-of-Life Trajectories and Prognostication

For a clinician to be comfortable with the care of serious illness, an understanding of end-of-life trajectories and the ability to formulate a prognosis is helpful. With modern medical advances, chronic diseases are present during the last years of life for most people. Depending on the type of underlying illness, 4 common patterns of decline have been observed in the last year of life[6] (Fig. e5.1). Sudden death (due to cardiac arrest, trauma, or other sudden event) occurs in only 15% of people. The other trajectories are more common and occur with roughly equal frequency. Understanding these trajectories enables one to contextualize the patient's acute visit, enhancing communication and medical decision making.

The disease most commonly associated with the terminal illness trajectory is cancer. Patients with cancer may remain independent and functional for some time but often experience a significant decline in overall health as death nears. The palliative performance scale is the most studied prognostication tool in this population, incorporating the patient's ability to perform activities of daily life (ADLs), level of consciousness, and oral intake[7] (Table e5.1). In cohorts of patients with

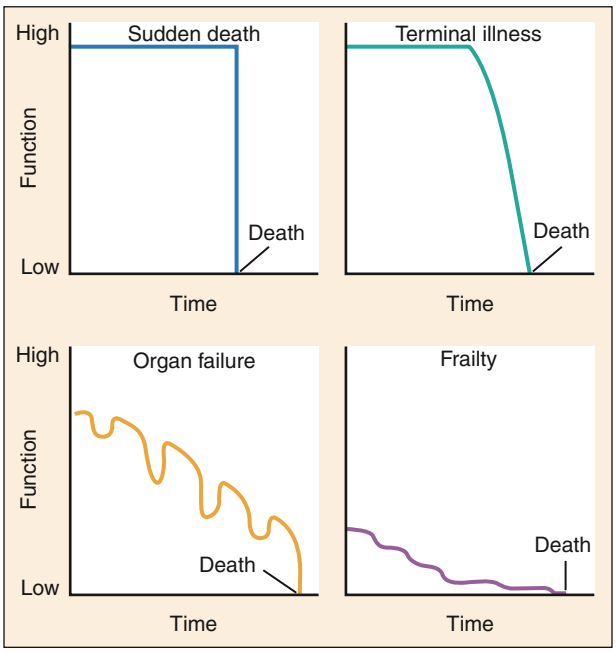

Fig. e5.1 Theoretic trajectories of dying. (From: Lunney JR, Lynn J, Hogan C. Profiles of older Medicare decedents. *J Am Geriatr Soc*. 2002;50:1108-1112.)

TABLE E5.1 Palliative Performance Scale

PPS Level	Ambulation	Activity and Evidence of Disease	Self-Care	Intake	Consciousness level
100%	Full	Normal activity and work No evidence of disease	Full	Normal	Full
90%	Full	Normal activity and work Some evidence of disease	Full	Normal	Full
80%	Full	Normal activity with effort Some evidence of disease	Full	Normal or reduced	Full
70%	Reduced	Unable to do normal job/work Significant disease	Full	Normal or reduced	Full
60%	Reduced	Unable to do hobby/housework Significant disease	Occasional assistance necessary	Normal or reduced	Full or confusion
50%	Mainly sit/lie	Unable to do any work Extensive disease	Considerable assistance required	Normal or reduced	Full or confusion
40%	Mainly in bed	Unable to do most activity Extensive disease	Mainly assistance	Normal or reduced	Full or drowsy ± confusion
30%	Total bedbound	Unable to do most activity Extensive disease	Total care	Normal or reduced	Full or drowsy ± confusion
20%	Total bedbound	Unable to do most activity Extensive disease	Total care	Minimal to sips	Full or drowsy ± confusion
10%	Total bedbound	Unable to do most activity Extensive disease	Total care	Mouth care only	Drowsy or coma ± confusion
0 (Death)					

a terminal illness, a score of less than 50% correlates with a prognosis of weeks, not months. In cases of organ failure (e.g., COPD, heart failure, liver failure, other progressive, serious medical diseases), gradual decline is punctuated by intermittent exacerbations, followed by dramatic and often surprising recoveries. In the first minutes to hours of decompensation, it can be difficult for the clinician to predict whether the patient is going to recover. This prognostic uncertainty can complicate goals-of-care discussions, often resulting in a time-limited trial of critical care in this population. The fourth trajectory of gradual decline, or frailty, is associated with some form of dementia in 50% of affected persons and a lingering course that can extend for many years, stressing and wearing out caregivers and other support systems as a decline in functional abilities progresses. Caregivers may have difficulty appreciating the severity of the patient's condition because they have gradually accommodated the patient's cognitive and functional decline. In the case of dementia, caregivers are not always educated about the expected complications of end-stage disease, including feeding/nutrition problems and severe infections, and may need assistance understanding that these problems are expected and a sign that their loved one is nearing the end of life. Proxy decision-makers with a more accurate understanding of prognosis are less likely to choose burdensome interventions for their loved one in the last 6 months of life.[8]

It can be helpful to have even more specific, concrete prognostic information about ED patients to guide decision making. Recently, the "surprise question," which has been well-studied in other settings, has been investigated as a potential prognostic tool in the ED. The emergency clinician is trained to ask, "Would I be surprised if this patient died in (weeks, months, a year)?" In a cohort of ED patients with advanced cancer, an Eastern Cooperative Oncology Group (ECOG) performance status of 3 to 4 (patient spending > 50% of waking hours in bed or completely disabled) and the emergency physician being "not surprised" if the patient died within the year correlated with a median survival of 3 months.[9] In an unselected population of older ED patients, when the surprise question was used to predict 1-month mortality, the test did not perform as well, with a sensitivity of 20% and a specificity of 93%.[10] Regardless, this tool may be increasingly incorporated into the ED admission workflow as a trigger for allocating appropriate resources, such as early palliative care consultations, to vulnerable patients.

Common Procedures and Interventions Faced at the End of Life

Intubation and Mechanical Ventilation

In terms of prognostication, a particular area of interest for emergency clinicians surrounds the initiation of mechanical ventilation. An ED intubation generally commits the patient to a course of critical care, with all its potential burdens. Although the benefits outweigh the risks in most patients, in those with a terminal illness or advanced age mechanical ventilation may simply prolong the dying process and lead to a highly medicalized death. Recent studies have suggested a morbidity and mortality burden in ED patients with advanced age and respiratory failure resulting in intubation.[11] In a large observational study, 43% of those age 85 to 89 years died during their inpatient stay while for those age 90 years and older, half died and a substantial proportion of survivors ended up in a nursing home setting.[11] The presence of certain comorbidities increases mortality even further, with admission diagnosis of sepsis, stroke or intracranial hemorrhage associated with unfavorable outcomes.[12]

Cardiac Arrest

Patients with a serious or terminal illness who experience a cardiac arrest have even more dismal outcomes. In one study of patients with advanced cancer and an in-hospital cardiac arrest, only 7% survived to discharge.[13] A recent study demonstrates that patients with advanced age and out-of-hospital cardiac arrest have particularly bad outcomes.[14] Of the 107 nursing home patients included, 0 survived to hospital discharge. A clinical decision rule called GO-FAR (Good Outcome Following Attempted Resuscitation) has been derived and

externally validated to predict patients who will both survive an arrest and do so with favorable neurologic outcomes.[15] Multiple variables such as age, comorbidities, and lab values are used to generate a score that then predicts the patients' likelihood for intact neurologic survival. This clinical score is included on MD-CALC so providers can rapidly and accurately calculate the score at the bedside. A 75-year-old patient with advanced cancer, septic shock, and pneumonia, for instance, would have a calculated GO-FAR score of 25, which would translate to a less than 1% chance of survival with minimal neurologic disability, should that patient experience a cardiac arrest. This kind of prognostic data can inform shared decision making with patients and families deliberating over code status determination.

Advance Care Planning and Advance Directives

Overview

Advance care planning is the process whereby people plan for future health states, anticipating a time when they will not be able to speak for themselves. It honors the ethical principle of patient autonomy. Advance care planning is a process and evolves over time for a given patient. For some, it can be as simple as a conversation with loved ones about their wishes should they find themselves in certain health states. In the ED, the future health state may change quickly over minutes or hours.

For others, where days, weeks, months, or years may pass before their health declines, advance care planning is a more formal process, leading to documentation of wishes in the form of advance directives. Examples of frequently encountered advance directives include a living will, a health care power of attorney or health care proxy form, and a POLST (Physician Orders for List-Sustaining Treatment) document (Fig. e5.2). Not surprisingly, the ED is where many of these discussions and directives are put into action. In cancer patients, early discussions about end-of-life care are associated with lower costs in the last month of life, lower likelihood of hospital, ICU, and ED use, and greater use of hospice.[16] A substantial portion of ED patients have engaged in advance care planning, and between a quarter to half have completed advance directives, underscoring the need for the emergency clinician to understand how to interpret and apply these at the bedside. Unfortunately, substantial barriers exist in allowing emergency providers access to these critical documents. Advance directives often do not transition with patients across care settings and even when documentation exists within the electronic medical record, providers are often unsure how to access the information. A recent study found little association between the preferences documented in a POLST advance directive and treatment intensity delivered in ED patients, and this may be partly explained by the fact that few providers ever accessed the POLST during the patient's episode of care.[17]

All states allow for patients to appoint a legal surrogate decision-maker, usually termed a health care power of attorney or health care proxy. This person does not have to be a family member and only assumes control of medical decision making when the patient loses decisional capacity. The proxy takes priority over all natural surrogates (typically ordered spouse, adult children, parent, then siblings). All states have some legal guidance regarding surrogacy when no advance directive exists. Individual state laws should be researched when a patient has no advance directive and no surrogate appointed by a legal document.

Patients near the end of life transition frequently between care settings. The same invasive treatments are considered for most, including intubation/mechanical ventilation, CPR, artificial nutrition, artificial hydration, and antibiotics. The POLST program, which originated in Oregon in 1991, grew out of a desire to ensure that patients' wishes regarding these frequently considered interventions could be easily communicated in an emergency, with significant implications for first responders and emergency clinicians. Unlike the living will, which gives broad and vague suggestions about EOL wishes, the POLST document actually translates patient preferences into a portable medical order set, because it is signed and completed by a physician. POLST programs are developed at the state level, and most states currently either have or are developing a POLST program. Behind the DNR form, emergency clinicians rate the POLST as the most useful advance directive, because it provides concrete guidance about how to care for the patient.[18] Although some providers have expressed concern about their medicolegal risk in relation to following POLST orders that are subsequently found to be in conflict with family preferences, many states offer specific legal immunity in relation to following POLST orders and if not, one is protected by common law: There has not been a single malpractice case borne out of this scenario.[19] As with all advance directives, they do not apply in the patient with decisional capacity so a patient is capable of revoking their own POLST orders.

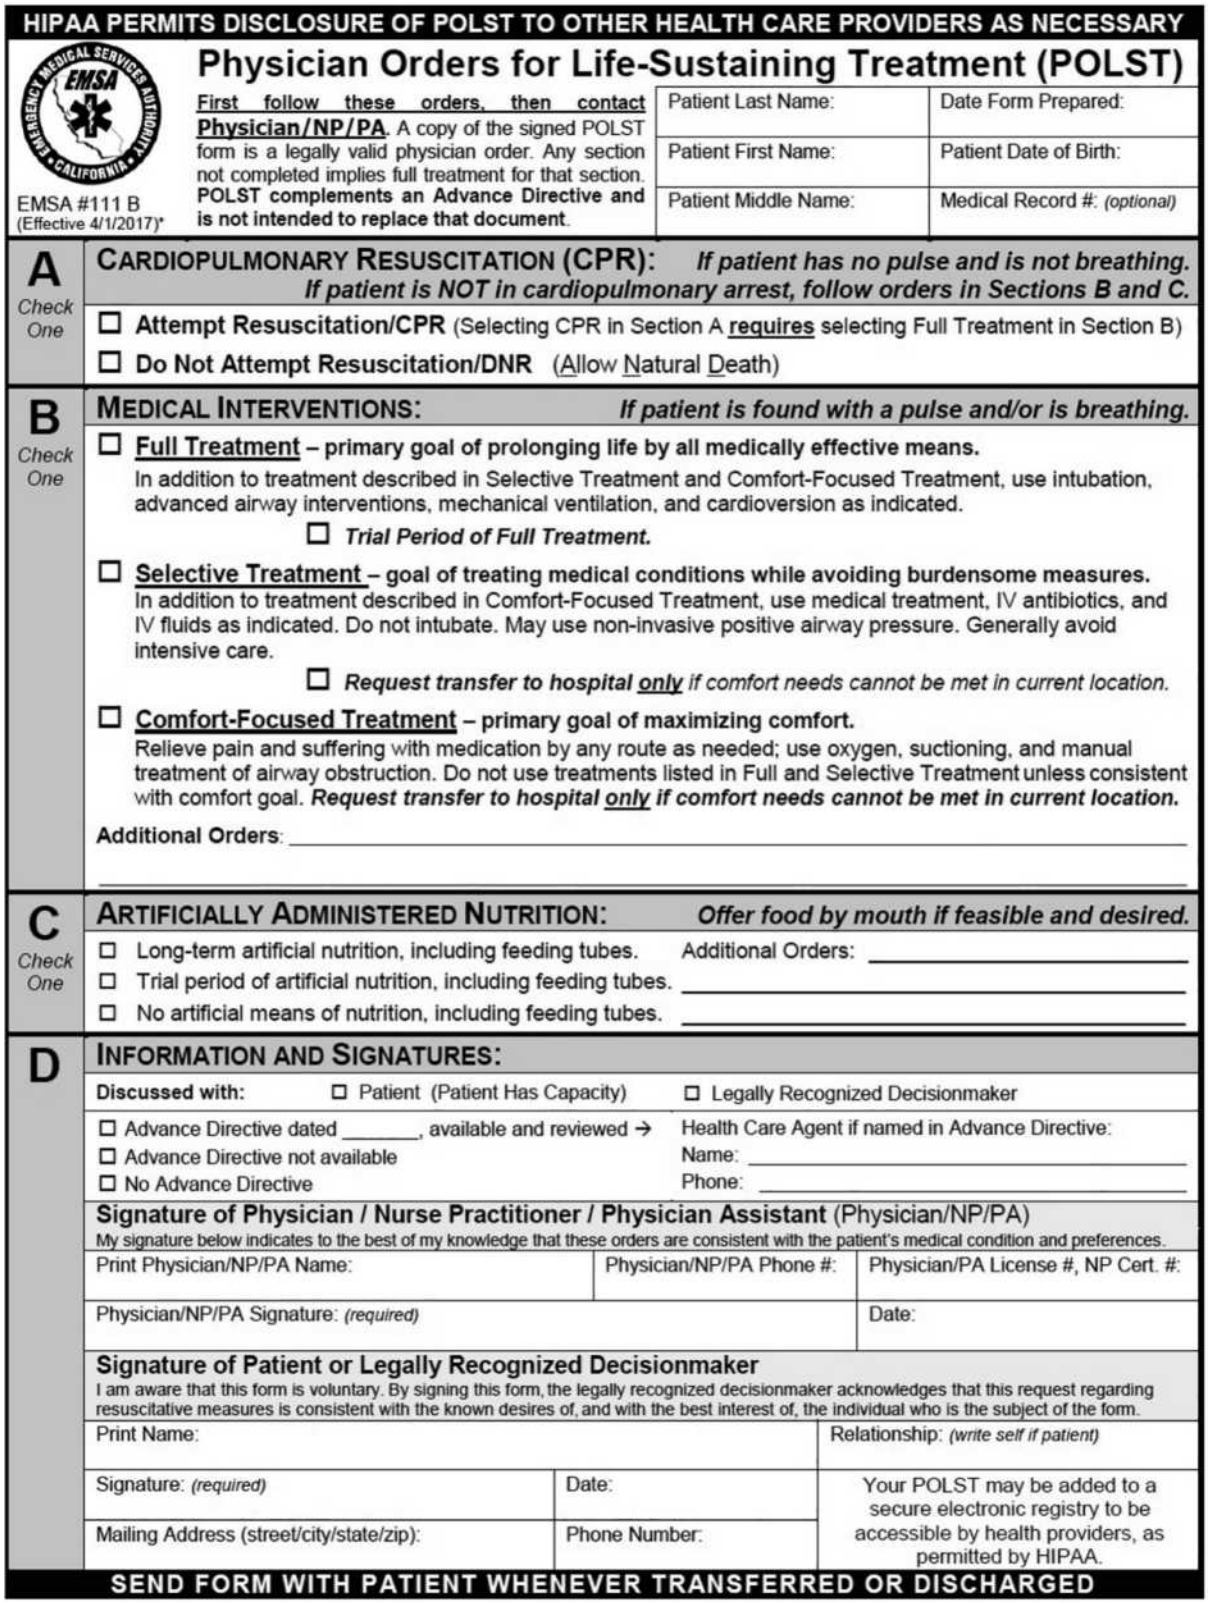
Do not resuscitate (DNR) and do not intubate (DNI) orders may exist alone or as part of the POLST. Although the interpretation of a DNR order may vary across states and hospitals, this generally refers to the use of ACLS protocols in the setting of a full cardiopulmonary arrest. In patients who are DNR, no interventions are applied at the time of death. There is confusion about whether the presence of a DNR order precludes the use of mechanical ventilation in patients in respiratory distress or failure. While the meaning of DNR may vary across settings, the clinician should not presume that a DNR order necessarily means the patient is DNI. For instance, it is reasonable to imagine a COPD patient who would be willing to undergo a time-limited trial of mechanical ventilation but would not want an attempted resuscitation in the setting of a cardiac arrest. Furthermore, DNR orders have a very narrow application, and they should not influence other types of care that patients receive at the EOL, though studies suggest they do.[20]

Goals-of-Care Discussions

An ED visit alone does not imply that patients or caregivers want all interventions at the end of life. Patients near the EOL use the ED for a variety of reasons, including but not limited to, overwhelming symptoms, uncertainty about prognosis, easy availability, and caregiver burnout. A core skill in managing patients near the end of life is the ability to assess and establish goals of care. In a true emergency, where the patient lacks capacity and there is no legal surrogate or advance care plan, such conversations take a back seat to resuscitation interventions. Most patients with a serious illness, however, present with enough time to establish goals of care before invasive interventions are required. Because these conversations can feel daunting, particularly when discussing the withholding and withdrawing of potentially life-sustaining interventions, a systematic and structured approach has been suggested.[21]

Emergency providers often want immediate answers about whether interventions such as intubation and CPR will be desired, but discussions about interventions that are not embedded in a larger conversation about prognosis and goals can be problematic; choices made may be driven by poor health literacy, misinformation, or strong emotions, rather than truly reflecting the patient's values and priorities. For this reason, conversations about goals of care are more successful when a "roadmap" is used; one example is the REMAP tool that was developed by the VitalTalk group, which stands for Reframe, Expect emotion, Map out patient goals, Align with goals, Propose a plan.[22]

In the ED, however, a preliminary step includes probing patients and caregivers for their understanding of the medical situation. "What have the doctors told you about your cancer, condition, etc.?" can be a helpful introduction. If there are considerable gaps between patient



HIPAA PERMITS DISCLOSURE OF POLST TO OTHER HEALTH CARE PROVIDERS AS NECESSARY

Physician Orders for Life-Sustaining Treatment (POLST)

EMSA #111 B
(Effective 4/1/2017)*

First follow these orders, then contact Physician/NP/PA. A copy of the signed POLST form is a legally valid physician order. Any section not completed implies full treatment for that section. **POLST complements an Advance Directive and is not intended to replace that document.**

Patient Last Name:	Date Form Prepared:
Patient First Name:	Patient Date of Birth:
Patient Middle Name:	Medical Record #: *(optional)*

A — Check One

CARDIOPULMONARY RESUSCITATION (CPR): ***If patient has no pulse and is not breathing. If patient is NOT in cardiopulmonary arrest, follow orders in Sections B and C.***

- ☐ **Attempt Resuscitation/CPR** (Selecting CPR in Section A **requires** selecting Full Treatment in Section B)
- ☐ **Do Not Attempt Resuscitation/DNR** (Allow Natural Death)

B — Check One

MEDICAL INTERVENTIONS: ***If patient is found with a pulse and/or is breathing.***

- ☐ **Full Treatment – primary goal of prolonging life by all medically effective means.**
  In addition to treatment described in Selective Treatment and Comfort-Focused Treatment, use intubation, advanced airway interventions, mechanical ventilation, and cardioversion as indicated.
  - ☐ ***Trial Period of Full Treatment.***
- ☐ **Selective Treatment – goal of treating medical conditions while avoiding burdensome measures.**
  In addition to treatment described in Comfort-Focused Treatment, use medical treatment, IV antibiotics, and IV fluids as indicated. Do not intubate. May use non-invasive positive airway pressure. Generally avoid intensive care.
  - ☐ ***Request transfer to hospital only if comfort needs cannot be met in current location.***
- ☐ **Comfort-Focused Treatment – primary goal of maximizing comfort.**
  Relieve pain and suffering with medication by any route as needed; use oxygen, suctioning, and manual treatment of airway obstruction. Do not use treatments listed in Full and Selective Treatment unless consistent with comfort goal. ***Request transfer to hospital only if comfort needs cannot be met in current location.***

Additional Orders: _____

C — Check One

ARTIFICIALLY ADMINISTERED NUTRITION: ***Offer food by mouth if feasible and desired.***

- ☐ Long-term artificial nutrition, including feeding tubes. Additional Orders: _____
- ☐ Trial period of artificial nutrition, including feeding tubes. _____
- ☐ No artificial means of nutrition, including feeding tubes. _____

understanding and clinical reality, these need to be addressed before moving forward with the remainder of the conversation. If patient or family expectations have already been communicated yet seem at odds with the clinical reality, a "hope for the best, plan for the worst" introductory phrase can be useful: "I see you're hopeful that she will get better. I'm hoping for that, too. Given how sick she is, I'm worried about her. I wonder if we can hope for the best, while also making a plan for how best to take care of her if she doesn't get better?"

Next, the provider delivers a headline that "reframes" the situation for the patient and caregiver. Most critical in this step is minimizing the

TABLE E5.2 NURSE Mnemonic for Providing Empathy

Nurse	Example
Name the emotion	"You seem very disappointed." "I can see you are in shock."
Understand	"I can only imagine how hard this has been for all of you."
Show Respect	"You have been a wonderful advocate/caregiver for your dad."
Express Support	"We will continue to help all of you on this journey."
Explore	"I heard you say you don't believe the information the oncologist gave you. Tell me more about that."

use of jargon. "I'm worried we're in a different place," "I'm worried that time is short," "I'm worried that she is dying," and "I'm worried we may not be able to turn this situation around" are examples of concise but clear messages. More concrete data like "All of her organs are failing" may also be used. "Expect emotion" is the next step in REMAP but strong emotional responses can occur at any point in the discussion. Emotional responses can occur before cognitive ones, though, and need to be recognized and addressed before patients and families can move forward with decision making. The NURSE mnemonic is a useful tool in enabling the provider to articulate empathy (Table e5.2). It stands for *N*ame the emotion, *U*nderstand the emotion, showing *R*espect, provide *S*upportive statements, and *E*xplore what's behind the emotion.

Next, the patient's and/or family's goals and values are "mapped out." "What would your mom tell us is most important to her right now?" and "When you think about the future, what are you hoping for?" can be helpful exploration questions. It can be appropriate here to ask if the patient ever engaged family in discussions about their EOL wishes or preferences regarding the use of invasive treatments. To communicate "alignment," the provider could say "I'm hearing that what's most important to you is *x, y, z*."

Last, a medical plan is "proposed" that takes into account the patient and family goals, the clinical scenario and expected prognosis, and the best interest of the patient. Providers should start with a big-picture suggestion first, followed by concrete recommendations. "Based on what I'm hearing, I think we should refocus all of our efforts on maximizing her comfort and supporting her through a natural dying process" would be appropriate when comfort-focused treatment represents the best care plan. There is often an expectation that certain interventions, like CPR, will be directly addressed. "When her breathing and heart stop, I don't recommend that we intervene. I don't think it would be helpful to use machines or other measures to try to prolong her life. Instead, we will focus on allowing her to have a natural death."

Depending on the patient and family, it may be necessary to be more explicit about code status by saying something like, "I will let the medical team know we've made this decision by entering a Do Not Resuscitate order in her chart." Phrases like "Do you want us to do everything?" or "Does she want to be resuscitated?" should be avoided for two reasons. First, the way the questions are framed implies that performing these interventions would be reasonable and successful, which is rarely the case at the EOL. Second, families do not understand what the provider means when using the term "everything" and "resuscitated" nor do they understand the consequences of these medical interventions.

For some patients and families, open-ended questions can be overwhelming and questions about values and goals met with uncertainty. In this situation, it can be useful to give concrete examples of three distinct treatment pathways—invasive, noninvasive, and comfort—from which patients and families can then select. "Some people in this scenario would say that they would want to live as long as possible and would want all measures used to keep them alive, even if there was some suffering associated with that and only a small chance the treatments would work. Other people would say that they would want a chance to live longer if there were simple problems that were easily treatable with things like IV fluids and antibiotics but that if their condition worsened despite these interventions, they would not want to escalate to more invasive treatments like life support. Still, others say that at this point in their illness, they want to focus on comfort exclusively and do not want their life prolonged unnecessarily. All three of these pathways are reasonable. If your mom could speak to us, which would she say makes the most sense for her?"

Emergency providers should clearly and compassionately discuss these important yet sensitive topics while recognizing that some patients and families may choose interventions that seem incongruous with their best interest. Not all patients and families are prepared for EOL decision making, and conflict or strong emotions may pose an insurmountable barrier to moving forward with a discussion. Still, others may hold certain cultural or religious beliefs that are at odds with plans that promote comfort over longevity. Although emergency clinicians are not ethically obligated to deliver futile care, often the most practical way forward involves a negotiation in which life-sustaining interventions are delivered, possibly with certain limits in place. Generally, families and providers can reach an agreement about a care plan but this process may require time-intensive conversations that are beyond the scope of emergency provider practice. Palliative care consultations would be appropriate in such cases.

Common Symptoms Requiring Palliation Near the End of Life

Within the last days to weeks of life, patients may experience an increase in symptoms to include pain, shortness of breath, agitation, delirium, seizures, and terminal secretions. As the patient undergoes physiologic decline, renal failure is observed and expected; patients may become increasingly susceptible to toxicities from medications that are renally cleared. As a result, caregivers may bring patients to the ED for symptoms that seem unmanageable or distressing, with or without hospice care in place. The emergency clinician can contextualize these symptoms for caregivers by recognizing what a normal dying process entails, including progressive lack of food or water intake, lethargy, renal and cardiac dysfunction with abnormal vital signs, progressive inability to swallow, altered mental status, and incontinence.

Patients suffering from a disease that is not curable may still want and benefit from a variety of medical interventions as part of the plan of care, such as antibiotics for intercurrent infections, drainage of effusions that cause shortness of breath, wound care for decubitus ulcers, decompression of bowel obstructions, and pain management. The caregiver may encounter several unfamiliar principles when treating symptoms in someone near the end of life. One of the challenges for the emergency clinician is the treatment of symptoms rather than the underlying diagnosis, even though this often is the appropriate option in palliative care. The emergency clinician may have concerns about drugging patients or overtreating them, but these are mostly unwarranted. Worrying about unintended consequences may lead to underdosing of medications, leaving patients without desired relief.

Pain

Pain is a common complaint with terminal illness. Although typically considered in the setting of cancer, pain in the end-of-life phase is prevalent across many noncancer conditions, such as heart failure, COPD, and dementia. As patients become less mobile, they may suffer pain from contractures, wounds, or other conditions secondary to

the primary illness. Patients suffering from malignant pain may need continuous infusions of opioids to obtain relief or rapid titration protocols, as well as an adjustment of chronic doses of analgesics in the ED. Patients with advanced illness and pain may be tolerant to opioids and require high doses to achieve comfort.

Rapid opioid dose escalation is the most important intervention in cancer patients receiving opioids. An initial parenteral breakthrough dose for a terminal patient having a pain crisis should be 10% of their 24-hour opioid dose. From there, doubling the dose may be required until successful analgesia is achieved. With IV administration of morphine, serum levels peak in 5 to 15 minutes, so patients need to be reassessed and re-dosed promptly. Side effects from opioids should be anticipated. Rising serum levels of opioids may stimulate the chemotactic trigger zone, causing nausea. Constipation is a common effect of opioids, and tolerance to this symptom does not develop. Prevention is far easier than treatment, so a stimulant laxative should be part of all opioid prescriptions for malignant pain. The use of nonsteroidal antiinflammatory drugs may be helpful in potentiating the effects of opioids in cancer patients. A fentanyl patch may be a useful tool, especially if IV access is limited/challenging. However, if a patch is placed in the ED, oral or IV opioids should be administered for pain control as the patch takes 12 hours to onset and 24 hours to reach steady state.

Dyspnea

Dyspnea is a common symptom at the end of life. It is multifactorial and not defined by direct pathophysiology. Shortness of breath can be part of the last stages of COPD, cancer, or other advanced chronic diseases as patients become cachectic and immobile. Furthermore, the list of problems that can cause dyspnea is broad, including, but not limited to, anemia, infection, pulmonary embolism, myocardial infarction, pleural effusion, pneumonia, aspiration, and pulmonary edema. In patients presenting to the ED with dyspnea and a terminal illness, determining the underlying cause of the symptom may be less important than treating the symptom itself. Oxygen therapy is not harmful but may have limited effects because hypoxia and dyspnea do not always correlate at the EOL. The first-line therapy for dyspnea is opiates. A safe starting dose for the opiate naïve would be morphine 2 mg IV. Timing and escalation of dosing mirrors that are used in pain crises. Noninvasive ventilation and high-flow oxygen have a role in palliating dyspnea in select patients with an advanced illness, particularly in those hoping for improvement but wanting to avoid more invasive interventions.

Death in the ED

Death Notification and Breaking Bad News

As with discussing goals of care, a roadmap has been proposed by the VitalTalk consortium for breaking bad news—GUIDE—that can also be applied to death notification. GUIDE stands for *G*et ready (maximize the privacy of the setting, ensure the right people are in the room, make sure all the information is correct), *U*nderstand what the patient/family knows, *I*nform (starting with a headline, minimizing jargon), *D*emonstrate empathy, and *E*quip the patient or family for the next steps.

Emergency clinicians must be adept at communicating bad news to patients, family members, and caregivers. Death notification can be particularly challenging. How it is done may impact the family's subsequent course of grief and coping. Emergency clinicians have particular challenges in delivering bad news. They do not have ongoing relationships with their patients, and the bad news may be abrupt and unexpected. Feeling skilled in providing disclosures to families is key in managing external sources of provider stress.

Death notification often occurs after an unsuccessful resuscitation attempt. Sometimes the family has initiated the 911 call and recognized that their loved one had died at that time. On the other hand, a family summoned to the ED may have no idea that they are about to be informed that their loved one has been critically injured or has died. When giving the news, emergency clinicians should use a clear headline like, "He died," to be sure that there are no misunderstandings about the outcome being conveyed. A wide range of emotional responses should be anticipated, with expressions of anger and disbelief being common. Those at the scene should be assured that their responses to the emergency were appropriate, the medical care team did all that was possible, and the victim did not experience unnecessary discomfort.

When the notification is to an individual who is more than an hour away or otherwise unable to come to the ED physically to receive the bad news, the information needs to be disclosed by phone. If the first contact with survivors of an ED death is by telephone, it is recommended that the survivor be told to come to the ED, if at all possible. Although family members may ask or even demand to know if death has occurred, allowing some time for the assimilation of news by delaying information about the final outcome may be more helpful for the grieving process. Nonphysician staff may be used to summon survivors and can inform them that the patient has been involved in an accident or is seriously ill without signs of improvement.

The emergency clinician should make sure that the relative has someone present in the room if possible, ask them to be seated, and name the person involved. It is best to start with brief information about the circumstances and provide a warning that bad news is coming before breaking it. Even a few seconds of preparation in these circumstances can serve to partially attenuate the acute psychic pain. As indicated by the perceived response, the clinician may need to ask, "Are you able to talk for a few minutes?" Some individuals may be unwilling or unable to continue after they hear the initial news, and they should be given an "out," but a definite time to reconnect should be established (e.g., 10–15 minutes).

Viewing the Body

When a death has occurred, the family should be offered an opportunity to view the body. This may be the first exposure to the body for the survivors and can make an abstract and unreal notification more concrete. Although most survivors find viewing of the body helpful, no attempt should be made to force this on them, and a few are not comforted by seeing the deceased.

If possible, the body should be moved to a small room, preferably away from the main treatment area. Family members should be warned of what to expect, such as color and temperature changes, injuries or invasive premortem procedures, and the presence of endotracheal and intravenous (IV) tubing or other medical devices.

A staff member should remain in the room or within close range at all times. This contact allows the staff to help make the viewing an important and supportive aspect of the grieving process. Survivors should be allowed to remain with the body for as long as seems appropriate. When gross disfigurement has occurred, the viewers should be warned about this, and the body should be discreetly covered, when possible. Survivors may even find that helping to clean and prepare the body (particularly with a pediatric death), holding a loved one, or preparing for transport may allow a final expression of caring.

Family Presence During Resuscitation

It is increasingly common to invite a close family member to attend resuscitation attempts. Evidence has suggested that presence during procedures and resuscitations may be beneficial to surviving patients and family members who choose to stay, and they are not harmed by the experience.[23,24] Less consensus exists among providers, and they often express discomfort with the concept, with nurses expressing less

discomfort than physicians.[25] If resuscitation is to be witnessed by a family member, preferably a protocol is in place and a staff member who is dedicated to supporting that person should be present. Processes and procedures should allow for the ED team to work effectively but also allow families the option of observing resuscitation.

Field Death Pronouncement

Several physiologic circumstances have been identified in which out-of-hospital providers should not initiate or continue CPR because of uniformly poor outcomes and no benefit from intervention. American College of Emergency Physicians (ACEP) and American Heart Association (AHA) guidelines state that CPR should not be initiated in patients with nontraumatic cardiac arrest and signs of irreversible death, such as decapitation, dependent lividity, or rigor mortis.[26] Furthermore, the presence of a valid advance directive like a POLST or out-of-hospital DNR that indicates an attempted resuscitation is not desired, should lead to field death pronouncement. ACEP policy recommends discontinuation of resuscitation in the out-of-hospital setting if the patient remains in asystole or wide-complex pulseless bradycardia after a trial of adequate resuscitation, including CPR, intubation, medications, defibrillation, and pacing. The National Association of EMS Physicians supports this approach. Termination of resuscitation efforts in nontraumatic cardiac arrest patients should be made in agreement with online medical direction and predicated on access to witnesses or family, provider comfort with death notification and grief counseling, and safety and logistic considerations. If questions arise about resuscitation, CPR and advanced cardiac life support measures should be initiated and the patient transported. It can be easier and is ethically more sound to withdraw care in the ED than to withhold care at the scene.

CHAPTER E5: QUESTIONS AND ANSWERS

1. The primary focus of palliative care is to
   a. transition dying patients to hospice.
   b. administer morphine to terminally ill patients.
   c. improve the quality of life of patients living with serious illnesses.
   d. facilitate the withdrawal of life-sustaining treatments in terminally ill patients.

Answer: C.

2. Emergency providers commonly discuss the issue of code status with their patients. In terms of prognosis after a cardiac arrest,
   a. a recent study of nursing home patients experiencing cardiac arrest found high rates of survival to hospital discharge.
   b. there are no good data, so providers should rely on their gestalt when counseling patients and families about code status determination.
   c. a clinical decision rule called GO-FAR has been validated and can give providers predictions for neurologically intact survival in individual patients using variables from their clinical data.
   d. older patients and those with a terminal illness fare surprisingly well.

Answer: C.

3. An 80-year-old patient with stage IV pancreatic cancer, enrolled in hospice, presents to the ED in respiratory distress. His vital signs are HR 120, RR 30, O_2 saturation 85% on RA and 100% on NRB, BP 100/50. He lives at home with his family and has been relatively stable and asymptomatic until today. The emergency provider should do all of the following, EXCEPT
   a. assume that because the patient called 911, his goals are to focus on life prolongation and that he would want to be intubated.
   b. notify the patient's hospice provider that the patient is in the ED and obtain more history about recent events.
   c. gather clinical data, review advance directives, and then engage the patient and/or family in a conversation about goals of care.
   d. consider administering low-dose morphine to alleviate the patient's dyspnea.

Answer: A.

4. Which of the following is expected to be the least likely cause of death for adults in the United States?
   a. Cancer
   b. Cardiovascular disease
   c. Heart disease
   d. Trauma

Answer: D. According to the Center for Disease Control, accidents are the third leading cause of death in the United States. (http://www.cdc.gov/nchs/fastats/leading-causes-of-death.htm.)

5. In a nondeath disclosure setting, deliverance of bad news should start with which of the following approaches?
   a. Allowing the patient to react to the news
   b. Asking the patient if he or she wants to know
   c. Making sure you keep the conversation going to provide comfort and thereby dull the emotional impact of the news
   d. Your knowledge of the complete medical implications and ramifications of the news

Answer: B. Respectful disclosure of difficult news includes assessing the readiness and willingness of the patient to receive the news.

6. Mr. Jones is a 54-year-old man currently receiving hospice care at home for advanced colon cancer. His wife calls 911 when he becomes unresponsive. On presentation to the ED, his vital signs are blood pressure, 60/40 mm Hg; heart rate, 140 beats/min; temperature, 39.6°C (103.3°F); respiratory rate, 12 breaths/min. He is moaning with a facial grimace. His wife, who is the legal decision maker, is at the bedside. Which of the following represents the best course of action?
   a. Initiate sepsis protocol, begin treatment for pain, and call the palliative care service.
   b. Initiate sepsis protocol, page the hospice nurse, and speak to his wife regarding goals of care.
   c. Page the hospice nurse, begin treatment for pain, and speak to his wife regarding the goals of care.
   d. Page the hospice nurse and speak to his wife regarding the goals of care.

Answer: C. Under the hospice benefit, the hospice agency is the care manager. The patient has lost capacity and his wife is his decision maker and she should be consulted regarding goals. Pain and non-pain symptoms should be addressed while other actions are being taken.

7. Mrs. Smith is a 68-year-old woman with advanced heart failure who presents in cardiogenic shock with multiple previous admissions that state that she is currently optimized with all available therapies. You decide to initiate hospice care from the ED. Which of the following do you do next?
   a. Call the hospice liaison on call for the ED to speak with her family regarding their options.
   b. Call the palliative care service to discuss hospice care with the patient and her family.
   c. Conduct a goals-of-care discussion with the patient and her family.
   d. Discuss the benefits of hospice care that would allow the patient to stay at home with her family.

Answer: C. Central to the discussion of hospice care is an assessment of the goals of care focused on care that addresses the distress of the illness and not the reversal of the primary illness.

8. In performing a death disclosure, which of the following statements represents best practice when communicating news of death?
   a. "Your loved one didn't make it."
   b. "Your loved one has died."
   c. "Your loved one has gone to a better place."
   d. "Your loved one has passed on."

Answer: B. It is not recommended to use euphemisms or unclear statements to communicate news of death because this can cause confusion and ambiguity for the receiver of the news.

9. Mr. Stone is a 27-year-old man with glioblastoma multiforme. He has completed radiation treatment and is on oral chemotherapy. Over the last week, he has become progressively weaker and is now in bed. He is no longer speaking and is dropping things. He is taking sips of clear liquids and coughs after swallowing. Which of the following is the strongest predictor of his death?
   a. Aspiration risk
   b. CT scan that shows progression
   c. Deterioration of speech
   d. Functional status

Answer: D. The palliative performance scale is the most studied prognostication tool for patients with terminal illness. It incorporates the patient's ability to perform activities of daily living (ADLs), level of consciousness, and oral intake[7] (see Table e5.1). In cohorts of patients with a terminal illness, a score of < 50% correlates with a prognosis of weeks, not months.

10. Mr. Samuels is a 46-year-old man with severe breathlessness and anxiety due to advanced chronic obstructive pulmonary disease. His vital signs are temperature, 36.8°C (98.2°F); blood pressure, 110/60 mm Hg; heart rate, 115 beats/min; respiratory rate, 34 breaths/min; oxygen saturation, 98% on room air. He is visibly anxious and reports dizziness and dyspnea. Which of the following is the best initial treatment?

a. IV fluids
b. Lorazepam
c. Morphine
d. Oxygen

Answer: C. In the absence of hypoxia, morphine has been shown to relieve the sensation of breathlessness. Benzodiazepines have not been shown to relieve breathlessness and may increase side effects.

Bioethics

Kenneth V. Iserson and Carlton E. Heine

KEY CONCEPTS

- Bioethics is a method of using values and moral principles to come to defendable decisions for ethical dilemmas. In emergency medicine, many ethical dilemmas often go unrecognized.
- Ethical dilemmas arise from conflicts between multiple good options or multiple bad options, not between good and bad choices.
- Values come from a variety of sources: community, culture, religion, and family. The values driving medical decisions should be the patient's values.
- Basic ethical principles include autonomy, beneficence, nonmaleficence, justice, and confidentiality.
- Consent requires decision-making capacity or appropriate surrogate decision makers.
- Not only religious but also family, cultural, and other values contribute to patients' medical care decisions. Without asking, it is impossible to know what decision a specific person would make.
- Patient autonomy recognizes an adult person's right to accept or to reject recommendations for medical care, even to the extent of refusing all care, if that person has appropriate decision-making capacity.

FOUNDATIONS

The medical care we provide today bears little resemblance to what was available when the first edition of this book was published. What has not advanced as far or as fast is our system for deciding, morally and fairly, what treatments should be provided. Scientific development has outpaced our social and ethical framework and often leaves clinicians struggling with moral dilemmas about the appropriateness of tests and procedures. This chapter is an introduction to our current tools for helping emergency clinicians approach ethical, rather than medical, dilemmas.

Bioethics, a subset of ethics, is the application of values and moral rules to find reasoned and defensible solutions to actual or anticipated moral dilemmas facing clinicians. The moral precepts that underpin ethical decisions are derived from a variety of sources, including individual, cultural, and community value systems. Unlike the law, which is relatively rigid and can lag years or even decades behind modern developments, particularly in the case of scientific and medical issues, bioethical constructs allow greater flexibility in decision making. Emergency clinicians are often called on to identify a patient's personal, cultural, religious, or community values and to balance these values with their own personal and professional ethos. A working knowledge of bioethics greatly enhances the emergency clinician's ability to make reasonable, ethical decisions in the limited time frame common to the practice of emergency medicine.

In contrast to professional etiquette, which relates to standards governing the relationships and interactions between providers, bioethics deals with relationships between providers and patients, providers and society, and society and patients. Issues within the realm of professional etiquette include billing, referrals, advertising, competition, conflicts of interest, professional courtesy, and employment and supervision of auxiliary personnel. These are quite different from bioethics' concerns of basic moral values and patient-centered issues. Although the two areas occasionally overlap, each relies on different standards, values, and problem-solving methods.

Ethics and Emergency Medicine

In emergency medicine, the focus is inevitably on the inherent "medical" nature of each case; therefore, it should come as no surprise that ethical dilemmas often go unrecognized. Emergency clinicians may also misperceive ethics as embodying the dictates of secular or religious law or as a discipline that describes irresolvable issues.

This chapter addresses several ethical issues in emergency medicine. What follows are brief discussions of the relation of law to bioethics; bioethical values and principles; moral imperatives in emergency medicine; ethical oaths and codes; applying bioethics to clinical situations; bioethical dilemmas in emergency medicine; a rapid decision-making model for ethical dilemmas; advance directives; the relationship between consent, decision-making capacity, and surrogate decision makers; ethical issues in resuscitation; and ethical issues in public policy.

SPECIFIC ISSUES

Bioethics and the Law

Emergency clinicians often look to the law for answers to thorny dilemmas. Yet, except in the rare cases of "black-letter law," wherein specific actions are delineated, these issues are best served by turning to bioethical reasoning and using bioethics consultations. It is said that good ethics makes good law but that good law does not necessarily make good ethics. Societal values are incorporated both within the law and within ethical principles and decisions. Laws are rules of conduct established by legislatures, administrative agencies, courts, or other governing bodies. They often vary from locale to locale and are enforceable only in the jurisdiction where they prevail. By contrast, ethics is more universal within a culture, incorporating the broad values and beliefs of correct conduct. The primary differences between law and bioethics are shown in Table e6.1.

Modern bioethics developed because the law often has remained silent or inconsistent on matters vital to the biomedical community. The rapid increase in biotechnology, the failure of both the legal system and legislatures to deal with new and pressing issues,

and the increased liability crisis drove the medical community to seek answers to the difficult questions that practitioners must work through on a daily basis.

Bioethical principles are not static and may evolve as societies change. The same evolution occurs within the law. For example, elective abortion, once illegal in most United States (US) jurisdictions, is now legal in most circumstances and jurisdictions. Likewise, not all basic ethical principles have universal support, just as the values implicit in many legal changes have divided US society.

Rights and Duties

Without a duty to act, there can be no rights. Both a moral and a logical connection exist between the rights and the duties of individuals; one cannot exist in the absence of the other. In general, a duty is an action required by the rights of others, the law, a higher authority, or one's conscience. This obligation to act can be based on an individual's personal values, professional position, or other commitments. For the physician, this duty to act is a role responsibility, at least specifically as a physician and possibly always. The role-duty link occurs whenever a person occupies a distinctive place or office in a social organization to which specific duties are attached to provide for the welfare of others or to advance in some specific way the aims or purposes of the organization. In this circumstance, performance is predicated not on a guarantee of compensation but rather on a concern for another person's welfare. The emergency clinician has not only such a moral duty but, because of the Emergency Medical Treatment and Active Labor Act (EMTALA), also a legal duty.

Significant overlap can exist between legal and ethical decision making. Frequently, there is concurrence on basic issues. On occasion, clarity within the law can lead to clearer thinking in bioethics, and vice versa. Both law and bioethics, for example, use the term *rights,* as in "patients' rights" and "the right to die." This term is often used to advance an ethical argument about medical care and is frequently misunderstood or applied erroneously. A legal right is a demand that a person can make on another person, embodied by *in personam* rights, or against the state for recognition and enforcement of this demand. Most rights involved in bioethical discussions are *in rem* rights. These most often are negative rights, because they entail someone else's duty to refrain from doing something. A common source of ethical conflict is between "active rights," the right to act or not act as one chooses, and "passive rights," the right to not be acted on by others in certain ways.

Values

Values are the standards by which human behavior is judged. Values are learned, usually at an early age, through indoctrination into the birth culture, from observing behavior, and through secular (including professional) and religious education. Although many of these learned values overlap, each source often claims moral superiority over the others, whether the values are generic and cultural, legal norms, religious and philosophical traditions, or professional principles. Societal institutions incorporate and promulgate values, often attempting to solidify old values even in a changing society. In a pluralistic society, clinicians treat people with multiple and differing value systems, so they must be sensitive to alternative beliefs and traditions. This section discusses the role of religious, patient, institutional, and professional values, including professional oaths and codes specific to emergency medicine.

Society's Values

Organized religions see themselves as keepers of society's values. Even though various religions may appear dissimilar, most hold the golden rule, "Do unto others as you would have them do unto you," as a basic tenet. Problems surface in trying to apply religion-based rules to specific bioethical situations. For example, although "Do not kill" generally is accepted, the activities that constitute killing, active or passive euthanasia, or merely reasonable medical care vary with the interpretation of the world's religions as they do with the interpretations of various philosophers. As members of a democracy with significant populations practicing multiple religions, emergency clinicians should behave in a manner consistent with each patient's values. The most basic underlying question is: What is the patient's desired outcome for medical care?

Not only religious but also family, cultural, and other values contribute to patients' medical care decisions. Without asking, it is impossible to know what decision a specific person would make. An important point is that religion influences modern secular bioethics, which uses many religion-originated decision-making methods, arguments, and ideals. In addition, clinicians' personal spirituality may allow them to relate better to patients and families in crisis.

Patient Values and Ethical Decisions

A key to making bedside ethical decisions is knowing the patient's values. Many people cannot answer the question: What are your values? However, physicians can get an operational answer by asking patients what they see as their goal of medical therapy and why they want specific interventions. The responses represent concrete expressions of patient values. In patients who are too young or are deemed incompetent to express their values, it may be necessary for physicians either to make general assumptions about what a normal person would want in a specific situation or to rely on surrogate decision making. But with patients who can reason and communicate, care should be taken to discover what they hold as their own, uncoerced values.

Although each individual is entitled and perhaps even required to have a personal system of values, certain values have become generally accepted by the medical community, the courts, legislatures, and society at large. Autonomy and individual dignity, for example, are two such values; they have been considered fundamental and often are given overriding importance, especially in many Western societies. Although some groups disagree about each of these values, this dissension has not affected their application to medical care.

BOX E6.1 Commonly Accepted Societal and Bioethical Values

Autonomy: Self-determination. A person's ability to make personal decisions, including those affecting personal medical care. Autonomy is the opposite of paternalism.

Beneficence: Doing good. A duty to confer benefits. Production of benefit.

Confidentiality: The presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient's permission.

Distributive justice: Fairness in the allocation of resources and obligations. This value is the basis of and is incorporated into society-wide health care policies.

Nonmaleficence: Not doing harm, prevention of harm, and removal of harmful conditions.

Personal integrity: Adhering to one's own reasoned and defensible set of values and moral standards.

FUNDAMENTAL BIOETHICAL PRINCIPLES

Nonmaleficence and Autonomy

The basic tenet that all medical students are taught is nonmaleficence: "First, do no harm." This credo, often stated in Latin, *primum non nocere,* derives from the recognition that physicians can harm as well as help. With the physician's fallibility recognized, patient autonomy is and has been for several decades the overriding professional and societal bioethical value. Autonomy recognizes an adult person's right to accept or to reject recommendations for medical care, even to the extent of refusing all care, if that person has appropriate decision-making capacity. It is the counterweight to the medical profession's long-practiced paternalism (or parentalism), wherein the practitioner determines what is "good" for the patient, regardless of whether the patient agrees. Coupled with paternalism is coercion, the threat or use of violence to influence behavior or choice. The authority figure in a white coat combined with implied or explicit threats remains a potent force for counteracting patients' wishes. The thrust of modern bioethics is to respect patients by honoring their autonomy (Box e6.1).

Beneficence

At the patient's bedside, beneficence (doing good) and confidentiality (holding information in confidence) have been long-held and nearly universal tenets of the medical profession. Similarly, personal integrity (the adherence to one's own moral and professional standards) is basic to thinking and acting ethically.

Justice

The concept of comparative or distributive justice suggests that a society's comparable individuals and groups should share similarly in the society's benefits and burdens. Many society-wide decisions affecting thoughts and actions about the allocation of limited health care resources are based on this principle. Although it is important for physicians to be careful stewards of health care resources to maximize benefits, it is not appropriate for clinicians to limit or to terminate care on a case-by-case basis as an extrapolation of the perceived need to limit health care expenditures. Distributive justice is a social policy concept rather than a clinical model for individual physician/patient decisions.

Truth-Telling

Personal integrity involves adhering to one's own reasoned and defensible set of values and moral standards and is basic to ethical thought and action. Integrity includes a controversial value within the medical community: truth-telling. Some people think that the patient has the right to know the truth, no matter what the circumstances, and have championed absolute honesty. Yet many of these same people, when patients themselves, have been appalled by their physician's lack of sensitivity in relating unfavorable medical news. In this context, being honest does not mean being brutal; the truth is best tempered with a modicum of compassion.

Physicians accept a lack of truth-telling, depending on the circumstances. When patient harm may result from failing to disclose the truth, such as happened in the infamous Tuskegee experiments, in which treatment was knowingly withheld from Black men with syphilis, it is not only immoral but also probably illegal to withhold the information. Likewise, when failure to disclose information is strictly for the clinician's benefit, such as not telling a patient about a dismal prognosis or a medical error, the clinician's behavior suggests serious ethical and legal deficits. The issues become murkier when truth-telling, or lack thereof, involves a third party, such as a sex partner who has been exposed to an infectious disease.

Confidentiality Versus Privacy

Stemming at least from the time of Hippocrates, confidentiality is the presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient's permission. Health care workers have an obligation (duty) to maintain patient confidentiality. On occasion, the law, especially public health statutes, may conflict with this principle, because they require physicians to report specific diseases, injuries and injury mechanisms, and deaths. The Health Insurance Portability and Accountability Act (HIPPA) of 1996, a US federal law designed to protect patient information, however, takes the principle of confidentiality to the extreme, often resulting, paradoxically, in greater difficulty in obtaining crucial information needed to treat emergency department (ED) patients.

Privacy, which is often confused with confidentiality, is the right of patients to enough physical and auditory isolation so that they cannot be seen or heard by others during interactions with medical personnel. ED overcrowding, patient and staff safety issues, and ED design limit patient privacy in many cases.

The increasing use of telemedicine to render advice and to guide procedures at remote sites also places a strain on both patient privacy and confidentiality. Suggested ethical guidelines for such practices can facilitate the use of these new technologies without sacrificing either patient rights or physician duties.[1]

MEDICAL AND MORAL IMPERATIVES IN EMERGENCY MEDICINE

Professional Values

Emergency clinicians, in both the out-of-hospital and ED environments, operate with four imperatives: (1) to save lives when possible, (2) to relieve pain and suffering, (3) to comfort patients and families, and (4) to protect staff and patients from injury. All but the last of these are common imperatives of most other clinicians as well, although saving lives may occur more often and more dramatically in emergency medicine settings.

Safety: A Unique Value

The last imperative, safety, is nearly unique to emergency medicine. In both the out-of-hospital and ED settings, clinicians often encounter dangerous situations in which the environment, the patient, a friend, or a family member poses a threat. Violence against emergency care workers is well documented and unfortunately common. The ED routinely

deals with psychotic and intoxicated patients and patients injured in human-on-human attacks, and those involved are often under extreme stress. Although most try to accommodate basic patient rights, clinicians' priority must be their own safety and the safety of their coworkers. This priority does not imply that clinicians should ignore patient safety but only that they should first ensure their own safety if they or their colleagues are at risk. When involved in or directing out-of-hospital activities, especially those related to wilderness medicine, safety and security will usually supersede most other considerations.[1]

CODIFYING PROFESSIONAL VALUES: ETHICAL OATHS AND CODES

In the abstract, bioethical principles often appear simple. However, clinicians adhere not only to basic bioethical principles but also, at least tacitly, to several professional, religious, and social organizations' ethical oaths, codes, and statements. This complexity can create a confusing array of potentially conflicting bioethical imperatives. Because bioethical principles seem to be neither universal nor universally applied, the most patient-centered principles that normally hold sway.

Organizational and Institutional Values

Institutions, including health care facilities and professional organizations, have their own value systems. Health care facilities, although relatively well standardized under the requirements of regulatory bodies and government agencies, often have specific value-related missions. Religiously oriented or affiliated institutions may be the most obvious of these, but charitable, for-profit, and academic institutions also have specific role-related values. The values of professional organizations often are set forth in their ethical codes.

Professional Codes

Through the years, the medical profession has codified its ethics more rigorously than any other professional group, incorporating many standard bioethics principles into its ethical codes and oaths. For generations, the existing part of the Hippocratic Oath set the ethical standard for the medical profession. Yet its precepts clash with modern bioethical thinking, and many subsequent professional codes have included what may best be termed *economic guidelines* and *professional etiquette,* along with ethical precepts. Emergency clinician professional values have been incorporated into organization codes, such as the American College of Emergency Physicians' (ACEP) Code of Ethics, and into a more personal oath developed by the Society for Academic Emergency Medicine.

Most modern ethical codes do not require a higher level of duty or commitment for members than the same basic moral behavior that is expected of society at large. In fact, many of the ethical issues that would seem to be important to medical specialties usually are not addressed in their codes. Even when topics of interprofessional interactions are excluded, existing medical professional codes differ markedly. All, however, try to give a "bottom line"—that is, minimally acceptable—course of action.

APPLYING BIOETHICS

Emergency Clinician/Patient Relationship

The emergency clinician has a markedly different relationship with patients from that of other health practitioners, especially those providing primary care (Table e6.2). Emergency clinicians care for patients who are unfamiliar to them and to the institution. Practitioners who either know their patients or who care for them in less acute settings often have the time and the mechanisms to make sound ethical decisions, but emergency clinicians have more limited options. A suggested method for rapid, ethical decision-making in the ED setting is outlined in Figure e6.1 and discussed in a later section.

TABLE E6.2 Relative Differences Between Emergency Practice and Primary Care Practice

Emergency Department Setting	Primary Care Setting
Patient is often brought in by ambulance, police, or family.	Patient chooses to enter medical care system.
Patient does not choose physician.	Patient chooses physician.
ED personnel should gain patient's trust.	Physicians and nurses already enjoy patient's confidence and trust.
ED personnel do not know the patient, family, or their values.	Physicians and nurses often already know the patient, family, and their values.
Patient experiences an acute change in health status.	Patient has chronic medical problems.
Anxiety, pain, alcohol, and altered mental status are common.	Anxiety, pain, alcohol, and altered mental status are less common.
Decisions are made quickly.	There is usually time for reflection and deliberation.
Physician makes decisions independently.	Physician has greater opportunity to consult with patient, family, other physicians, ethics committees, lawyers, courts, and ethicists.
Physician represents institution and medical staff.	Physician represents self or medical group.
Work environment is open and less controlled.	Work environment is private and controlled.
ED personnel frequently have a stressful work schedule.	Work schedule often is set or canceled by physician.

ED, Emergency department.

Recognizing Ethical Problems

Although physicians like to reduce all clinical situations to "medical problems," today's increasingly complex medical environment often produces problems that are inexorably intertwined with fundamental bioethical dilemmas. Some are obvious, but many are more difficult to recognize.

Prioritizing Conflicting Principles

Once such dilemmas are recognized, applying bioethical principles to clinical situations can be confusing. When two or more seemingly equivalent principles or values seem to compel different actions, a bioethical dilemma exists. This situation is often described as being "damned if you do and damned if you don't," in which any potential action appears, on first reflection, to be an option between two seemingly equivalent goods or evils. In the following real case, taken from the book *Ethics in Emergency Medicine,* the attending physician can be said to be on the horns of a dilemma (involving two prickly but seemingly equal choices): although only two options for action may be available, both options involve several conflicting bioethical principles.[2]

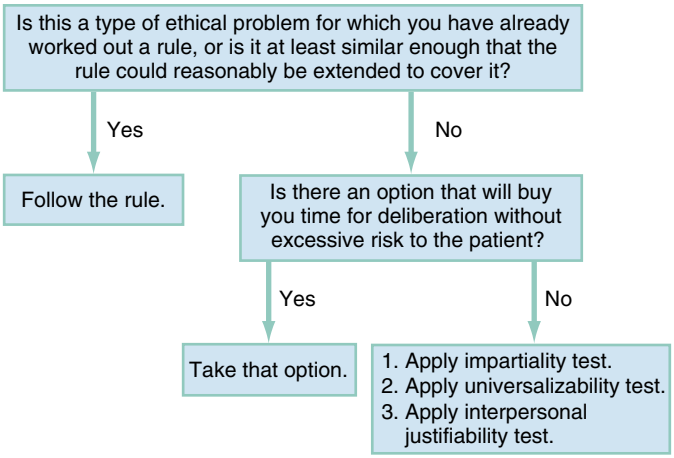

Fig. e6.1 A rapid approach to ethical problems in the emergency department (ED). (Modified from: Iserson KV. An approach to ethical problems in emergency medicine. In: Iserson KV, Sanders AB, Mathieu D. Ethics in Emergency Medicine, ed 2. Tucson, AZ: Galen Press, 1995.)

Case Example: Conflicting Bioethical Principles

A 60-year-old man stabbed himself in the abdomen because of intractable pain from terminal pancreatic cancer, unrelieved by any medical therapy. A well-meaning friend, who happened to be in the house when the event occurred, called the paramedics, who brought him to the ED. Although the man will obviously bleed to death if he is not given aggressive care, neither the patient, who is still alert and oriented, nor his wife, who is present, wants any treatment other than pain control. A review of his chart confirms that his physicians are at a loss as to how to alleviate his pain and that he is expected to die within the next several weeks. The physician believes in respecting a patient's autonomy yet usually questions patients' decision-making capacity when they attempt suicide. Such patients' actions seem to raise the question of whether they have a right or an ability to be autonomous. This physician also believes strongly in beneficence—helping those in need, relieving pain, and saving lives when possible. Beneficence suggests two alternative courses of action: palliative care or therapeutic intervention. Merely using analgesics and other comfort measures will abet a suicide; initiating medical and surgical interventions will prolong a dying process that the physician's colleagues have found to be unresponsive to even palliative treatment. Which value takes precedence: patient autonomy or beneficence? If beneficence predominates, should it be aimed toward relieving suffering, prolonging life, or a third option that could include both? Bioethics deals with problems that are neither black nor white—only gray.

MEDICAL IMPERATIVES AND BIOETHICAL DILEMMAS

Clinicians have their own ethical values, as do professional organizations and health care institutions. Conscience clauses permit clinicians to "opt out" when they believe that they have a moral conflict with professionally, institutionally, or legally required actions. These conflicts, which may have a religious, philosophical, or practical basis, pose a barrier to use of the normal ethical decision-making algorithm. When such conflicts exist, it is morally and legally acceptable, within certain constraints, for the physician to follow a course of action based on his or her own value system. The constraint generally requires that timely and adequate medical care be provided for the patient, which may be particularly difficult to achieve in emergency medicine. When conflicts over values exist, however, it is essential for the practitioner to recognize the patient's identity, dignity, and autonomy to avoid the error of blindly imposing personal values on another.

Professional Value Conflicts

The imperative to save lives causes the most conflict between emergency clinicians and other clinicians. Emergency clinicians recognize that some of the intubations and resuscitations that they perform will be unwanted by patients or surrogates. Nearly all emergency clinicians have on occasion been berated by an irate intensivist or private practitioner for resuscitating a patient "who should not have been resuscitated." Nevertheless, the lifesaving imperative begins when the ambulance is called.

One classic dilemma is that posed by the exsanguinating adult patient, awake and still with medical decision-making capacity, who explicitly refuses to accept any blood or blood products based on religious beliefs. The physician, with a professional duty and moral commitment to preserve life, does not agree with the patient's decision. Yet society (through the benchmark of court decisions) has repeatedly sided with the patient. In this case, the patient's autonomy and right to practice his or her religion are recognized as the overriding values. The case becomes less clear when the patient does not have decision-making capacity, is a minor, or appears to be under external pressure to make a life-threatening decision.

Other examples of ethical problems and conflicts in emergency medical care include uncertainty about resuscitation efforts, especially when patients and families may not want such efforts; teaching, particularly in critical situations, or using procedures performed on the newly deceased; emergency medical service (EMS) control, when administrative rules and good patient care conflict; helping others when one's own life may be placed at risk; and patient access, such as limited financial and personnel resources in the face of obvious patient need. Even if these problems do not fit into the classic form of a dilemma, they may be recognized as bioethical problems, because they require the clinician to make a choice between two (or more) accepted values.

RAPID ETHICAL DECISION-MAKING MODEL

The rapid ethical decision-making method of ethical case analysis, described in Figure e6.1, is designed as a way of avoiding an ethically incorrect course of action for the emergency clinician needing to act rapidly in the face of an ethical dilemma. A decision based on a known precedent—the first step—is the most productive way to use this method. However, such decision-making requires advanced planning, in-depth reading, and thought regarding ethical problems. Just as with the indications for any emergency procedure, emergency clinicians should at the very least be prepared with a course of action for the most common ethical dilemmas they may face in the ED.

Even the prepared clinician, however, can encounter cases without relevant known precedents. With no precedent to rely on and no way to "buy time," the practitioner should select a possible course of action and test it for ethical validity. In such instances, three tests—the impartiality test, the universalizability test, and the interpersonal justifiability test—can be used. The *impartiality test* asks whether the practitioner would accept this action if he or she were in the patient's place. In essence, this is a form of the golden rule. The *universalizability test* asks whether the practitioner would be comfortable having all practitioners perform this action in all relevantly similar circumstances. This involves generalizing the action to all colleagues and then asking whether a rule for the contemplated behavior is reasonable. The *interpersonal justifiability test* asks whether the practitioner can supply good reasons to others for the action. Will peers, superiors, or the public

be satisfied with the answers? If the answer to the question posed in each of the three tests is affirmative, the practitioner has identified a reasonable probability that the proposed action falls within the scope of ethically acceptable actions.

ADVANCE DIRECTIVES

The ethical principle of patient autonomy is the foundation for a range of documents that outline what care a patient wishes to receive if he or she is no longer able or competent to directly communicate those values. The term *advance directive* describes several types of legal and quasi-legal documents. Advance directives usually are written to avoid prolongation of an inevitable, often painful or nonsentient dying process. However, they can also be used to instruct surrogates and the patient's medical team to "do everything" whenever possible. Advance directives include the living will, durable power of attorney for health care, prehospital advance directive (Box e6.2), and mental health advance directive. Do not attempt resuscitation (DNAR), do not hospitalize, and out-of-hospital DNAR orders are not considered to be advance directives but rather are physician orders, because they are not patient or surrogate initiated. All play a role in emergency medicine.

Critically ill or injured emergency department or prehospital patients, who lack decision-making capacity, sometimes present with a nonstandard advance directive, such as a "Do Not Resuscitate" tattoo or medallion. Emergency clinicians must immediately address the question of whether to withhold treatment based on what may or may not be a legally valid patient directive. When faced with nonstandard directives, physicians can follow them, ignore them, or simply use them as an additional piece of information about the individual's wishes.[2] (Advance directives, DNR orders, and other end-of-life considerations are discussed in Chapter e5.)

CONSENT, DECISION-MAKING CAPACITY, AND SURROGATE DECISION MAKERS

Respect for patients, the basis for patient autonomy, requires that adults consent before undergoing medical interventions. To give consent, they must retain decision-making capacity. When patients cannot make their own health care decisions, others need to make such decisions for them. In such situations, three questions arise:

- What does "consent" mean in the ED?
- How can clinicians determine when patients lack such capability?
- Who then makes the decision?

Consent

Patients can provide three forms of consent: presumed, implied, and informed. Many patients may provide all three types of consent at different times during a single ED visit. Because clinicians use all three types of consent in EDs, and all are ethically and legally valid, clarifying the differences between them is in order.

The concept of *presumed consent* most commonly applies when patients are informed of what will occur and do not refuse treatment. They allow themselves to be rolled on a gurney to the radiology suite to have a urethral catheter placed, and they remain still while being sutured. The more dramatic ED scenario involving presumed consent is the arrival of moribund patients with grave, often unstable conditions

BOX E6.2 Guidelines for Development of an Out-of-Hospital Advance Directive Policy

Policy Scope

To ensure maximum coherence and compliance, a comprehensive out-of-hospital DNAR policy should be endorsed by the widest possible jurisdiction, comprising local, regional, and state agencies and the medical community, including the EMS governing body. Whenever feasible, legislative support for such a policy should be sought.

Policy Guidelines

1. Note the established fact that current basic and advanced life support interventions may not be appropriate or beneficial in certain clinical settings.
   - Develop a means to educate the public about the appropriate use of 911 after expected deaths.
   - Establish the fact that comfort care and palliative care are affirmative actions for patients with DNAR orders. These appropriate interventions, including hospice and respite care, do not require EMS activation, and often can be arranged by calling the patient's physician in anticipation of death.
   - Develop a means to educate health care workers on topics of advance directives, including information on local out-of-hospital DNARs, community hospice alternatives, and bereavement services.
2. Establish consensus on the ideal identification device for DNAR directives to ensure continuity of care across settings.
3. Reiterate that initial resuscitative attempts usually are indicated when the patient's wishes are not known.
4. Define the conditions under which an out-of-hospital DNAR order can be considered, including its use in long-term care settings and in the emergency department (ED).
5. Define which patients have the decisional capacity to agree to a DNAR order and whether surrogates can sign such orders.
6. Establish a mechanism to determine the precedence of various directives, including living will, durable power of attorney for health care, and out-of-hospital advance directive (i.e., DNAR order).
7. Develop a statutory prioritized list of surrogates to be used when there are no advance directives and the patient's decisional capacity is impaired.
8. Consider language acknowledging the growing home hospice movement as it concerns children and incorporate provisions for document use in minors.
9. Establish that the decision not to attempt resuscitation must be an informed decision made by the patient or the surrogate.
10. Identify the information that should be contained in the DNAR order and the authority that will be responsible for development of such a mechanism.
11. Identify the clinical procedures that are to be provided and those withheld in the adherence to the DNAR order or specify the authority that will verify adherence.
12. Define the exact way the DNAR order is to be followed, including the role of online medical direction. Each system should ensure that a communication path to access online medical direction is immediately available, when necessary.
13. Establish legal immunity provisions for those who implement DNAR orders in good faith.
14. Establish data collection and protocol evaluation to perform periodic operational assessments.
15. Identify permissible exceptions to compliance with DNAR out-of-hospital directives. For example:
    - The patient can revoke a written directive at any time.
    - The EMS personnel can cancel the out-of-hospital DNAR order if there are doubts about the document's validity.

DNAR, Do not attempt resuscitation; *EMS,* emergency medical service.Adapted from: Schears RM, Marco CA, Iserson KV. "Do-not-attempt-resuscitation" (DNAR) policy in the out-of-hospital setting. *Ann Emerg Med.* 2004;44:68.

for which a reasonable person would be expected to want treatment. In those cases, clinicians "presume" that rational patients would want treatment. A question that must be raised, however, is whether those patients would want interventions even in the absence of a reasonable chance for meaningful (from the patient's standpoint) survival.

Implied consent is operative when patients actively cooperate with the procedure, such as when they extend the arm for phlebotomy or lift the blouse so that leads can be placed for electrocardiography. Working under presumed or implied consent does not signify absence of patients' concern about the procedure or its complications. Rather, patients may (1) believe they know enough about the procedure to permit it or to cooperate with it without further questioning, (2) be in a condition (e.g., unconscious) in which they are unable to communicate, or (3) feel too afraid (e.g., of the clinician or hospital authority) or uncomfortable (e.g., because of a language barrier) to ask.

Informed consent assumes that a patient who has decision-making capacity (e.g., has been given all pertinent facts about the risks and benefits of a particular procedure) understands the risks and benefits and voluntarily agrees to undergo the procedure. Even if a patient with decisional capacity does not ask about a complex or potentially dangerous procedure, the clinician is obligated to provide information about the associated risks and benefits, unless the patient specifically asks not to be told. In those cases, the patient should be asked if he or she would like a relative or friend present in the ED to be told. This person need not be the patient's surrogate, but may later help explain what occurred to the patient.

Informed consent relates to both law and ethics. Respect for patients' wishes is the requirement's ethical bulwark; statute and common law provide the legal rationale. Clinicians have a professional and moral obligation to provide their patients with the information necessary to make informed decisions. Communicating honestly with patients so that they may participate in decision making is a recent rather than historical imperative. Based on respect for patients, this cooperative physician/patient relationship reverses the paternalism that, since Hippocratic times, has guided physician interactions with patients.

Virtually all states, either in statute or by common law, now require physicians to inform patients about treatment choices and the associated risks and benefits. The legal standard for the information provided is either the community standard (also known as the *professional community standard* or the *reasonable physician standard*) or the materiality standard (also known as the *reasonable* or *prudent* or *subjective patient standard*). The former asks: What would a prudent physician in the same community, with the same background, training, and experience, have disclosed to a patient in the same or similar situation? The latter asks: What would a reasonable patient in the same or similar situation need to know to make an appropriate decision?

Note that great variability exists in the legal requirements. For example, although most of the nation's EDs require informed consent for many regional anesthetic blocks, closed fracture reductions, abscess incision and drainage, lumbar punctures ("spinal taps"), injection of radiocontrast agents and radionuclides for radiography, and nonemergency thoracostomy (chest tube placement), Texas statutes eliminate any requirement to disclose the specific risks or hazards before these procedures are performed.

Decision-Making Capacity

Many ethical dilemmas in emergency medical care dissolve on ascertaining the patient's decision-making capacity, often linked with consent to (or, more commonly, refusal of) a medical procedure. A basic canon of both ethics and law, as stated by Justice Benjamin Cardozo, is that "[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body."[3] These situations can often be clarified by an appreciation of what is meant by decision-making capacity and how it relates to consent.

Emergency clinicians must be prepared to decide quickly whether patients lack decision-making capacity. Although a lack of capacity is obvious in the unconscious or delirious patient, it often is less apparent when the patient remains verbal and at least somewhat coherent. Because such decisions in emergency situations are often time-sensitive, unlike in other medical venues, bioethics consultations may not be readily available.

In clinical practice, the word *competence* is often used to mean *capacity*. *Competence* is a legal term and can be determined only by the court. *Capacity* refers to a patient's ability to make decisions about accepting health care recommendations. Capacity is always decision-relative rather than global. Although an inebriated person can have the capacity to refuse to have a small laceration sutured, especially if there is evidence of prior refusal without remorse, the same person may not have the capacity to agree to an elective operation or to refuse to have an emergent lifesaving procedure or operation. To have adequate decision-making capacity in any circumstance, the person must understand the options, the consequences of acting on those options, and the costs and benefits of consequences in relation to a relatively stable framework of personal values and priorities (Box e6.3). Disagreement with the physician's recommendation is not in itself grounds for determination that the patient is incapable of making a decision. In fact, even refusal of lifesaving medical care may not prove the person incapable of making valid decisions if it is done based on firmly held religious beliefs, as in the case of a Jehovah's Witness patient who refuses a blood transfusion.

Surrogates

If patients lack the capacity to participate in some decisions about their care, surrogate decision makers should then become involved. In most locales, the patient's advance directive may designate surrogates, or such persons or agencies may be detailed in institutional policy or law. Surrogates often include spouses, adult children, parents (of adults), and others, including the attending physician. On occasion, bioethics committees or the courts will need to intervene to help determine the decision maker.

Children represent a special case. Persons younger than the age of majority (or unemancipated minors) are usually deemed incapable of making independent medical decisions, although they are often asked to give their assent to the decision, allowing them to "buy in" to their medical treatment plan. In many cases, in determining whether a child has decision-making capacity, the same rules as those that apply to adult capacity are used. The more serious the consequences, the more the capacity to understand the options, consequences, and values involved is required of children to make a decision.

BOX E6.3 Components of Decision-Making Capacity

- Knowledge of the options
- Awareness of consequences of each option
- Appreciation of personal costs and benefits of options in relation to relatively stable values and preferences[a]

[a]As part of the assessment for capacity, the patient should be asked about why he or she made a specific choice.

Modified from: Buchanan AE. The question of competence. In: Iserson KV, Sanders AB, Mathieu D. *Ethics in Emergency Medicine*, ed 2. Tucson, AZ: Galen Press; 1995.

In the relatively rare case in which a patient has a court-appointed guardian for health care decisions, the guardian's decisions supersede those of both the patient and any other surrogates. Even if a parent is present, it is not always clear that the adult is acting in the best interest of the child. In such cases, child protective services may need to become involved. Disagreements between parents may, in extreme cases, require the involvement of bioethics committees or the courts.

Family

Traditionally, and usually in practice, the family, in particular the spouse, acts as a surrogate decision maker when the patient does not have the capacity to make medical decisions. Yet even when there is a strong family tie, emotional or fiscal costs may sway the surrogate decision maker from certain courses of action the patient would wish to be taken.

Surrogates make decisions based on two distinct patterns: substituted judgment and best interests. *Substituted judgment* is used when there is an assumption that the surrogate knows enough about the patient's values to make a decision similar to that which the patient would make. It is not clear that anyone knows that much about a person to make decisions in every situation. Surrogates use the *best interest* standard when they do not know what the patient would want done in a particular situation, but, as in the case of Karen Ann Quinlan, in which life-prolonging measures were eventually discontinued against the wishes of some family members, they can use earlier statements and behavior to document the patient's values and then make a decision.[4] Some states may require explicit written directives for surrogates to follow. The best interest standard also applies in cases in which the patient has never had adequate decision-making capacity, as in the Saikewicz case, in which a court-appointed guardian for an elder who lacked decision-making capacity decided against treatment for leukemia after consultation with medical specialists because of a low likelihood of success in the face of debilitating side effects of treatment.[5] Unless there is already a court-appointed guardian, these situations often end up in court.

Surrogate Lists

If a patient lacks decision-making capacity and has no advance directive, many states stipulate that another person may automatically become the person's surrogate. In practice, this almost always means that the patient's spouse may act in that capacity. Some states now have a statutory surrogate list to simplify the process. The most extensive of such lists, which has worked well for more than two decades, specifies surrogates in the following order: spouse (not divorced or legally separated), a majority of the adult children who can be reasonably contacted, parents (of an adult), domestic partner, sibling, close friend, and attending physician, in consultation with a bioethics committee.

Bioethics Committees and Consultants

Multidisciplinary committees have been developed in most large hospitals to consult on cases with bioethical dilemmas and may also participate in surrogate decision making. These committees usually have three main functions. First, they coordinate education on bioethical issues involving clinical care for the committee members, hospital physicians and staff, patients, families, and the local community. Second, they help institute mandatory or suggested policies or guidelines for health care professionals regarding decision-making processes in problematic cases and resource allocation. Third, they consult prospectively and retrospectively on clinical cases and offer advice and conclusions to those directly involved, most often concerning the treatment or nontreatment of patients who lack decision-making capacity. Ethics committees usually do not act as the primary decision makers. Rather, the members serve as consultants, providing information, advising, and supporting the primary decision-making role of the patient/family/physician triad. A common consultation relates to urgent decisions about withholding, withdrawing, or continuing life-sustaining medical care. Ethics committees played a visible role in many institutions during the COVID-19 epidemic, as they sought to define Crisis Standard of Care in the event of shortages of ventilators and ICU beds. A large part of ethics committee work consists of clarifying the facts and fostering communication. In 1995, the Joint Commission (formerly the Joint Commission for the Accreditation of Healthcare Organizations [JCAHO]) began requiring hospitals to ensure that ethics committees perform their functions.

Emergency Clinicians

In the past, clinicians made unilateral decisions for their patients, regardless of whether the patients had the capacity to decide for themselves. This still occurs, of course, especially for the acute illnesses and unexpected injuries seen in EDs. If the patient's decision-making capacity is questioned in the ED, the clinician is often forced to make a decision without assistance. But when it is possible to buy time, clinicians should consult with colleagues and, if possible, the hospital's bioethics committee (see Fig. e6.1). When making unilateral decisions, clinicians should recognize that they are not omniscient. Prognoses are often incorrect and medical knowledge is finite.

Courts

The courts often act as the final adjudicators of disagreements over medical care. They appoint legal guardians and, in a few select cases, the set precedent that is followed as health law. The courts, however, usually are neither expeditious nor necessarily cognizant of bioethical principles. They are instructed only to follow the societal values codified in the law. Many courts have suggested that whenever possible, health care decisions should remain at the bedside rather than in legal chambers.

RESUSCITATION ETHICS

The most time-dependent of all activities, and arguably the best training periods in the ED, occur during resuscitations. The patients who require this care have implicitly been guaranteed that all appropriate medical knowledge and skill will be brought to bear in the attempt to save their lives. This implied promise leads to a dilemma. If the most proficient ED professional always leads the resuscitations and performs procedures, the patient will receive the maximum beneficence, as well as nonmaleficence, as expected. Yet restricting ED practice in this manner also deprives future patients of trained clinicians who could bestow the same beneficence.

This controversy has raged for many years. The appropriate balance seems to be that training in EDs can ethically proceed, as it does in other areas of medicine, if safeguards are provided in the form of onsite supervision by experienced clinicians to ascertain that the patients receive the best possible and most appropriate care. It also has been suggested that medical students and residents be certified for cognitive and procedural skills in a manner like that of other hospital physicians. This certification would enable faculty to know when trainees can perform resuscitations, as well as other medical procedures, on their own.

Rarely discussed, but a common practice in some teaching hospitals, has been the custom of allowing trainees with little skill or knowledge to learn and to practice procedures on those undergoing resuscitation only when a patient is deemed "unsalvageable." This practice does a disservice to the patient because prolongation of resuscitative attempts

solely for this purpose may lead to a clinical state that prolongs dying. It also harms the family and society by making them pay for unnecessary procedures. (It may actually be less problematic to practice and to teach once a patient is dead, because the patient cannot be harmed, and the family does not pay for these activities. See the Postmortem Teaching section later in this chapter.)

Futility

Emergency clinicians, nurses, and EMS personnel may, in some circumstances, believe that further medical interventions are "futile." Yet only three situations meet the most commonly accepted definition. The first such situation, which clinicians can identify in only a limited set of circumstances, is that in which the intervention is effective in less than 1% of identical cases, based on the medical literature. ED thoracotomy for blunt trauma is a well-documented example. Another common scenario with very low survival rates is that of the out-of-hospital cardiac arrest, either unwitnessed or in a patient who arrives from a long-term care facility. Individual clinicians should not rely on their own experiences to make such decisions, however, because they often are skewed owing to selective memory, limited numbers of similar cases, and other biases.

The second futile situation is physiologic futility, in which known anatomic or biochemical abnormalities will not permit successful medical interventions. Examples of such abnormalities generally accepted by EMS as reasons not to intervene or to provide transport to hospitals are rigor mortis (muscle contraction after death), algor mortis (lowering of body temperature after death), burns so severe that the victim is beyond recognition, and injuries incompatible with life (e.g., decapitation). These, along with prolonged normothermic resuscitative attempts without success or prolonged "downtime" with an isoelectric electrocardiogram and pulseless electrical activity, are the criteria often used to help determine whether EMS personnel can pronounce death on the scene. In these instances, EMS need not expend valuable resources in a futile resuscitative effort.

The third situation is that in which the proposed intervention will not achieve the patient's goals for medical therapy in accordance with the patient's values. Recognizing this instance, the ACEP asserts, physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient. Because this course of action is based on knowing the patient's values related to medical treatment, it is necessary to have talked with the patient in advance (rare in the ED setting), to have received surrogate-supplied information or decisions, or to have access to the medical record. The danger is that differences in values between caregivers and patients may lead to overtreatment or undertreatment. Communication, with use of a third party, if necessary, may help resolve these issues.

The futility concept should never be used to deny care to dying patients. Even terminal patients experience medical emergencies that require intervention. The goal is to ease pain and suffering. How that is accomplished depends on the patient, the medical condition causing discomfort, and the patient's value system.

Withholding Versus Withdrawal of Treatments

In emergency medicine, a significant difference *rightfully* exists between the withholding and the withdrawal of life-sustaining medical treatment. The justification for this distinction stems, in part, from the nature of the practice of emergency medicine and the unique way emergency clinicians apply many ethical principles. Because emergency clinicians often lack vital information about their patients' identities, medical conditions, and goals for medical treatment, withholding of emergency medical treatment is more problematic than is later withdrawal of unwanted or useless interventions. Owing to the nature of emergency medicine, in both out-of-hospital and ED settings, higher standards are required to withhold medical treatment than to withdraw it.[6]

Physicians should begin or continue resuscitation of those patients who arrive at the ED without enough evidence to determine that the resuscitation effort will be unsuccessful. The only reason to *withhold* cardiopulmonary resuscitation (CPR) is the availability of clear evidence, such as a standard advance directive, that the patient did not wish to have this done or of clinical evidence that further efforts would be futile. Without such information, the presumption must be to intervene.

Once the emergency clinician obtains information confirming a patient's wish not to be resuscitated or indicating a medical condition not amenable to resuscitation, resuscitative efforts and other medical treatment may appropriately be withdrawn. This information may be obtained from an advance directive, a patient surrogate, recent documentation in the medical chart, or EMS communication detailing the failed results of the ongoing resuscitative effort. With rare exceptions, such as after failed suicide attempts, resuscitative efforts should be withdrawn when information is provided either that the patient did not want such efforts or that the patient's medical condition precludes success.

Many factors influence the potential success of resuscitative efforts, including time to CPR, time to defibrillation, cause of the arrest, presence of comorbid illness, pre-arrest clinical status, and initial arrest rhythm. No combination of these factors, however, clearly predicts the outcome.

Three special situations should be noted:

- Cardiac arrest from blunt trauma is nearly uniformly fatal, so little benefit derives from performing chest compressions for an extended period after the airway is secured.
- When health care resources are limited (e.g., during disasters), available resources (e.g., time, personnel, and equipment) should be devoted to treatment of those patients with the greatest chance of benefiting. This principle may lead to withholding or more rapid discontinuation of resuscitative efforts than is standard in normal practice.
- It is unethical to prolong resuscitative efforts to practice or to teach procedures or to complete research protocols.

Palliative Care

Although lifesaving medical interventions may not be appropriate in all cases, emergency clinicians, whenever possible, should provide patients with palliative care. Terminally ill and fatally injured patients have the right to receive state-of-the-art palliative care. Palliation often includes analgesics and may include diuretics, sedation, oxygen, paracentesis or thoracentesis, and other medications or procedures to alleviate suffering. Medical personnel should never withdraw or withhold palliative care; only treatment should be withheld when it is appropriate. Although medical practitioners, surrogate decision makers, and sometimes patients find it emotionally easier to forgo new interventions than to withdraw ongoing treatment, no orders, policies, or directives should ever prevent emergency clinicians from alleviating discomfort.

The purpose of palliative interventions is not to prolong the dying process but rather, when death is inevitable, to make it as comfortable as possible for the patient. As patient advocates, emergency clinicians may need to "push" to have the patient admitted to a hospital, hospice, or nursing home or to get ancillary personnel (e.g., social workers, home health nurses) to intervene for the patient.

Notifying Survivors

Death, especially when it is sudden and unexpected, shocks and devastates family and friends. For them, it is a life-changing event, with every nuance burned into their memories. Moreover, although they may not consciously acknowledge it, such losses may deeply affect ED personnel, despite their almost constant exposure to life's disasters. This makes death notifications and dealing with the survivors both vitally important and extremely difficult. Emergency clinicians, who deal with sudden death on a regular basis, can gain considerable knowledge of and to hone their skills in how to care for the survivors, their newest patients.

Even though notification of survivors of a sudden and unexpected death is one of the most difficult parts of the job for emergency clinicians, they and other professionals whose job includes delivery of such news are rarely taught the skills necessary to perform this task. Notification of survivors is emotionally draining; 70% of emergency clinicians find death notifications to be personally difficult. Perhaps this is because only half received any type of death-notification education in medical school, and only one-third received any such training during residency.

On occasion, physicians give the job of death notification to residents, medical students, or nurses. Although all three groups should be present to learn the techniques involved, to have an opportunity to hear what is said, and to observe an attending physician showing sensitivity, they should not be left to do death notifications on their own. That is a form of professional abandonment and, in a teaching hospital, the worst form of student abuse.

Viewing Resuscitations

Traditionally, survivors have not been permitted to view resuscitation attempts. That attitude, however, is gradually giving way to a more enlightened view based, in part, on recognition that families gain enormous psychosocial benefits from being present during the resuscitation of loved ones.

The argument against allowing survivor onlookers has been that resuscitations often involve large teams, unclear communications, and team leaders who are unwilling or unable to make firm, timely, and rational decisions. Having family members present, the argument goes, introduces the possibility of an onlooker fainting or otherwise becoming another patient. Survivors frequently misinterpret the team's discussions or actions, and team members may feel uncomfortable having family members judge their actions.

Yet studies in both the US and Britain have shown that nearly all survivors who witnessed ED resuscitative efforts found the experience helpful. Seventy-six percent of survivors responded that their grieving was facilitated by having witnessed the resuscitation, and 64% thought that their presence was helpful to their dying family member. Psychological tests of survivors who witnessed resuscitation attempts, performed at 3 and 9 months after the event, showed that this group experienced fewer episodes of "intrusive imagery," such as flashbacks of the events leading to the death, compared with survivors not present at the resuscitation (relatives in the control group). They also had lower levels of anxiety, depression, posttraumatic avoidance behavior, and grief.

The American Heart Association (AHA) now endorses giving family members the opportunity to be present so long as the patient has not previously objected. This position stems from the benefits families can derive from their presence during resuscitation attempts, the lack of harmful effects on them from viewing these resuscitations, and their quasi-right to be there based on the nature of their relationship to the patient.

The presence of these survivors does not hinder the resuscitative efforts and often leads to quieter, more effective team efforts. Experience has shown that survivors who witness ED resuscitative attempts never question whether the team "tried hard enough," do not ask whether the person is *really* dead, and spend less time in the ED trying to come to terms with the death. In addition, survivors may thank the ED team for their efforts, a situation that rarely occurs under other circumstances, and the ED staff never has to "notify" survivors of the death.

The general procedure is as follows:

- Ask survivors if they want to view resuscitative efforts.
- If they do, give them a quick briefing about what they will see, and have a knowledgeable staff member, usually a chaplain, social worker, or ED nurse who can answer their questions, accompany them.
- Provide a chair for elders and allow survivors to leave and to reenter as they wish.
- Staff should attempt to cover as much of the patient as is compatible with effective resuscitative efforts.
- Team members should be advised that family is in the room.
- The survivors should be encouraged to talk to and touch the patient.
- Decisions to pronounce the patient dead, although often discussed with the family, generally are communicated in the format of advising them that "we must stop now." They should never be asked whether to stop the resuscitative effort; this is a medical decision.
- If the family is present when it is clear that resuscitative efforts should cease, the situation should be explained to the family before supportive measures are discontinued. This provides them with a chance to "say goodbye" before death is pronounced. Dedicated pediatric EDs and pediatric resuscitation units in general EDs have adopted these procedures more often than others.

Postmortem Teaching

A less commonly discussed aspect of emergency medicine education programs is the use of recently deceased patients to teach or to practice emergency procedural techniques, such as intubations and central line placement. Although whether this practice is ethical is a matter of controversy, a reasonable argument might be that if medical treatment could not save the patient, then the emergency clinician's responsibility is to hone skills for the next patient in need of expertise in resuscitative techniques. This is not to condone the desecration of a body. Rather, it suggests that because clinicians learned the techniques used during the attempted resuscitation on other dead or living patients, this (now dead) patient owes the next patient the same courtesy. No one would advocate practicing unneeded procedures on living patients, and many people argue against experimental use of animals. The religious or ethical beliefs of some ED personnel may make practicing or teaching of these procedures in such circumstances problematic.

Resuscitation Research

Physicians in a new and advancing specialty have an obligation to use research to advance the knowledge base from which they practice. In the United States, federally mandated institutional review boards (IRBs) must approve any research involving human subjects, including research in EDs and, possibly, in prehospital care. Increasingly, research ethics committees are being used to approve human subject research throughout the world. The IRBs try to guarantee that patients are asked to participate in research review and sign an adequate informed consent document. Yet, even if the patient is conscious, it is unclear whether truly free and informed consent can be given during a medical emergency. In both trauma and cardiac resuscitation

research, informed consent is, of course, not feasible. It is usually difficult, if not impossible, to obtain retrospective patient or, if appropriate, prospective surrogate consent. So as not to deny critically ill and injured patients the opportunity to participate in possibly beneficial research trials, the US Food and Drug Administration (FDA) and the Department of Health and Human Services (DHHS) issued regulations, which became effective in 1996, that allow "emergency research" without informed consent. These regulations contain extensive patient safeguards, including community consultation, public disclosure, and intensive oversight. Some have questioned whether they are too restrictive, particularly when applied to non-"life-threatening" situations in which there may be more than "minimal risk."[7]

The ethical and legal basis for these regulations is presumed consent: If the research is not harmful, and especially if it is potentially helpful, most "reasonable" patients would acquiesce to the research, given the basic values of good and evil (see Box e6.1). As routinely occurs in emergency medicine practice, persons suffering unexpected adverse events with a high probability of rapid death or serious morbidity generally demand that the physician deliver acute care interventions—immediately and without discourse. If there is a chance that the patient could benefit from a therapeutic course of action in such circumstances, most people would demand that it be used. Similar logic applies with acute care research, especially when accepted or standard therapy is futile and possibly when the investigators believe that equipoise (therapeutic equality) exists between the two tested forms of therapy. Protection for the patient in these cases rests with IRBs, which, among other considerations, must guard against the possibility of organ-specific success but failure to benefit the entire person, such as producing a patient in a persistent vegetative state after "successful" CPR.

Beyond IRB authorization for research is a moral responsibility for the individual researcher to ensure that the research protocol and its execution are ethical. This responsibility extends to the journals in which the research is published. Emergency medicine has an excellent record of ethical research, although a large percentage of human research studies published in the major emergency medicine journals fail to mention either IRB review or informed consent.

PUBLIC POLICY AND BIOETHICS

Restricted Access to Emergency Medical Care

Society has acknowledged its moral obligation to ensure that everyone has reasonable access to adequate health care. People's need for health care is unequally distributed and highly unpredictable. Few could afford this care if left to their own devices, so mechanisms are in place to share the risk.

The ethical dilemma for emergency clinicians comes in basically two forms: one precipitated by the institution in which the ED is housed and one by outside third-party payers. Some institutions have refused care to patients coming to the ED, sending some away for clinic appointments at a later time. Institutions also have pressured emergency clinicians to limit treatment, ancillary tests, or hospital admission for patients without the ability to pay. Although such limitation may seem patently immoral, another question should be asked: Is there a moral obligation to the community to keep the health care institution financially viable? Hospitals have closed their doors because of financial losses, and many hospitals, especially in inner-city areas, are on the verge of bankruptcy.

Some prepaid health maintenance organizations (HMOs) use "gatekeepers" to keep patients in need of emergency medical care away from immediate assistance at institutions other than the HMO parent hospital. Moreover, the HMO's income may depend on *not* hospitalizing patients, *not* using ancillary tests, and *not* permitting ED visits. Nevertheless, it is prudent and ethical for emergency clinicians to err on the side of providing for the patient's needs.

Morality of Triage Decisions

In the aftermath of a massive natural or human-made disaster, triage officers face difficult decisions about who will receive scarce lifesaving treatment and who will be left to die without treatment. Even in "routine" ED triage, decisions about who should receive treatment priority and who can wait for treatment may, at least occasionally, have life-and-death consequences.

Triage provides a method to distribute health care resources when patient needs exceed available resources. Triage operates along a continuum of decreasing resources, social order, and the resource-to-patient ratio. Arrival patterns, triage methods, and the applicable ethical basis for triage vary along this continuum.

Most triage systems are designed to serve the values of human life, human health, efficient use of resources, and fairness. Nevertheless, because of the variety of specific triage settings and goals, no single "correct" way to perform or to justify triage can be identified. Routine triage in the relatively resource-rich setting of the modern hospital ED, for example, focuses appropriately on maximizing benefits for each individual patient, giving treatment priority to patients whose needs are most urgent. In triage after a massive disaster, when not all individual needs for lifesaving care can be met, the focus may shift from an individual to a group perspective, and triage officers may seek to save as many lives as possible with the limited resources at their disposal. In special circumstances (e.g., times of war), military commanders may direct that triage systems devote scarce medical resources to achieve a nonmedical goal, namely, military victory. In situations of complete devastation, the lack of social order and minimal resources may make triage impossible.

Whether the choice of a triage system is justifiable depends on an evaluation of the specific system itself, its underlying values and principles, and the setting in which it is applied.

Physician Response to Risky Situations

Over the millennia, personal values have dictated whether a physician would remain with his or her patients during extreme or catastrophic circumstances. Physicians, even legends of medicine such as Galen, often fled to save their own lives. In the era of modern epidemics of unknown virulence and etiology, and the increasing frequency of natural disasters such as wildfires or earthquakes, it remains a personal moral decision, especially for emergency clinicians who are on the frontline of these medical assaults.

How will physicians respond when a catastrophe involving personal risk strikes? The moral backbone of medical professionals may be tested as health care providers weigh multiple factors to determine whether to stay and carry out their professional roles and duty to put the needs of their patients first, or to step back and decrease their personal risk.

With incomplete information, providers may make decisions based on heated emotions and panic rather than an accurate perception of risk. The decision to stay or to leave will ultimately depend on the individual practitioner's risk assessment and value system. Professional ethical statements about expected conduct establish important professional standards and norms, but each practitioner will interpret and apply them on the basis of his or her own situation and values. Recent historical precedent suggests that many physicians and other health care providers will dutifully care for the sick and needy, even at great risk to themselves. Although some emergency clinicians have worked in dangerous situations, most have not; nothing in day-to-day emergency medicine practice prepares emergency clinicians for the great

opportunities and challenges that accompany a pandemic. Emergency clinicians can, however, reflect on their professional and personal responsibilities in crisis situations, and public and private institutions can create plans for effective communication and care when a disaster strikes. If this can be achieved before the next pandemic or disaster that includes personal risk to clinicians, emergency clinicians—who are inevitably among those at highest risk—can be encouraged to "stay and fight."

Despite the language in numerous medical ethics codes, nothing, either morally or legally, requires a specific physician response to risk-prone situations from civilian clinicians; it remains a personal decision. The decision to remain in or to leave a risky health care situation will ultimately depend on the provider's own risk assessment and value system.[8]

"Proactive Ethics": How Can Emergency Clinicians Change the Rules?

In every medical system, practitioners find that they repeatedly face identical ethical dilemmas. The normal outcome is an incomplete and often unsatisfactory decision made by administrators, lawyers, bioethics committees, or others. "Proactive ethics" involves changing the rules under which we operate. Easier done in some settings than in others, the process requires that all "stakeholders," those with a vested interest in an equitable solution, first come to the table and reach a compromise. Such groups often will include physicians, nurses, EMS personnel, lawyers, religious authorities, and representatives of affected groups (e.g., an organization of elders in the case of issues involving the aged). Armed with this agreement or even sample legislation that they can present to politicians, it becomes easier to change laws or administrative rules to address recurrent ethical dilemmas. One such process led to a landmark out-of-hospital advance directive law, which markedly lessened unwanted EMS resuscitation attempts. It also led to an extensive statutory surrogate list and a simplified set of advance directives. Subsequently, physicians also spearheaded the similar, but less effective, Physician Orders for Life-Sustaining Treatment. Proactive ethics lies in the role of public policy—an arena in which emergency clinicians are well suited to play a pivotal role.

Audiovisual Recordings and Social Media Use

As the technology becomes more available to record and post online the activities of emergency department patients and staff, the ethical principles of privacy and confidentiality assume increasing importance. Emergency physicians commonly use social media for both personal and professional purposes. Perhaps due to the high prevalence of formal training about the professional use of social media, they generally seem to be aware of the negative aspects of posting inappropriate patient images and descriptions. Yet younger physicians seem to be less aware of the negative effects that posting personal information about their unprofessional activities can have on their medical license and hospital privileges.[9]

With proper protections, audiovisual recording in emergency departments can provide significant value to clinicians and patients. Recordings can help patients understand and recall vital parts of their ED experience and discharge instructions, add important visual data to the electronic medical record, and help to diagnose difficult cases in real time by crowdsourcing the information with many other physicians.

Health care institutions should provide HIPAA-compliant methods to securely store and transmit health care-sensitive recordings and establish protocols. Protocols should include both consent procedures their staff can use to record and distribute (print or electronic) audiovisual images and appropriate disciplinary measures for staff who violate them. Clinicians imaging patients in international settings should be guided by the same ethical norms as they are at their home institution."[10]

The most basic ethical guideline, responding to the need to preserve confidentiality and privacy, is to provide informed consent to patients or their surrogates, being sensitive to the patient-physician power differential. Importantly, any use of these images on social media must go beyond what is legal and avoid what has been termed "medutainment," providing images that nonprofessionals might see as prurient.[11]

A Global Perspective

Emergency clinicians ever more frequently respond to acute and chronic "humanitarian catastrophes," those conflicts and calamities generating both widespread human suffering and destructive events. While struggling to provide care in these difficult situations and sometimes to do simultaneous research, health care workers must also apply standard bioethical concepts with sensitivity to local mores. The ethics of providing health care in resource-challenged environments is a complex and confusing topic. It implies three related questions: What can we do with the resources on hand? Of all the things we can do, which ones should we do? How do we define standard of care? Resource-poor settings encompass multiple environments, cultures, scenarios, actors, and types of intervention.

Basic ethical principles apply in every culture within the context of their patient and community values. Cultural sensitivity suggests that ethical issues need to be approached with an awareness of local mores. Most commonly, these issues include the release of medical information; a patient or family's refusal of treatment; the determination of futility for patients with terminal conditions; and involvement with group, elder, or family decision-makers.[12]

Among the bioethical principles that directly apply to this work is that the humanitarian imperative comes first, meaning that action should be taken to prevent or alleviate human suffering arising out of disaster or conflict, and that nothing should override this principle. In addition, assistance is given regardless of the race, creed, or nationality of the recipients and without adverse distinction of any kind, with priorities based on need alone. This includes neither using offers of help to further government policy nor promoting political or religious views. Finally, physicians should be accountable, not only to the organizations with whom they work, but also to the local populations who they are there to help.[13,14]

CHAPTER E6: QUESTIONS AND ANSWERS

1. Which of the following statements regarding patient confidentiality is FALSE?
- **a.** It describes the patient's right to enough physical and auditory isolation so that they cannot be seen or heard by others during interactions with medical personnel.
- **b.** It imposes a duty on health care workers.
- **c.** It may conflict with the law, especially public health statutes.
- **d.** It presumes that what the patient tells the physician will not be revealed to any other person or institution without the patient's permission.

Answer: A. Although isolation of patients for confidentiality is a good goal, the limited space and hectic nature of an ED would sometimes prevent timely and quality care.

2. Which of the following can emergency clinicians always rely on for appropriate guidance when faced with ethical dilemmas?
- **a.** State laws and medical board policies
- **b.** The American College of Emergency Physicians' (ACEP) Code of Ethics
- **c.** The Hippocratic Oath
- **d.** None of the above

Answer: D. All these examples are great for guidance on ethical dilemmas, but none of them can "always" have guidance for every situation that can occur.

3. To have adequate decision-making capacity in any circumstance, a person must understand all of the following EXCEPT:
- **a.** The available options.
- **b.** The consequences of acting on those options.
- **c.** The costs and benefits of consequences in relation to a relatively stable framework of personal values and priorities.
- **d.** The court's decision about their competency.

Answer: D. To be deemed competent an individual must understand A, B, and C. Answer D is a legal issue and is not required for competency.

4. Which of the following statements regarding the withholding of treatment in the ED is TRUE?
- **a.** It legally differs from withdrawing treatment.
- **b.** It morally differs from withdrawing treatment.
- **c.** It requires clinical information that is often unavailable immediately.
- **d.** It should never be done.

Answer: C. In an emergency not all relevant information is available at the time important decisions must be made.

5. When using the "rapid approach to ethical problems in the emergency department (ED)" to decide on a course of action:
- **a.** Always consult with the bioethics committee/consultant before acting.
- **b.** Assume that each ethical problem in the ED requires a unique solution.
- **c.** Test your chosen action against your religious values.
- **d.** When practicable and safe for the patient, buy time to consult on possible options.

Answer: D. Ethical problems can often take some time to work out, but a rapid approach rarely has enough time for a formal ethics consult. Buying some time so a reasonable solution can be derived is often the best that can be done.

Emergency Medical Treatment and Labor Act and Medicolegal Issues

Robert A. Bitterman

KEY CONCEPTS

- The Emergency Medical Treatment and Labor Act (EMTALA) governs virtually every aspect of hospital-based emergency services.
  - Centers for Medicare and Medicaid Services (CMS) deems anyone on hospital property to have "come to the emergency department." Hospital property consists of the entire main hospital campus, including parking lots, sidewalks, and driveways, and any ambulance owned and operated by the hospital, even if the ambulance is not on hospital grounds.
  - Any person who comes to an ED requesting examination or treatment for a medical condition must be provided with an appropriate medical screening examination (MSE). The purpose of the MSE is to determine whether the patient has an emergency medical condition (EMC).
  - Presentation to the ED or on hospital property is not sufficient to trigger the hospital's duty to provide an MSE; a request for examination or treatment of a medical condition is also necessary. The request can be made by the patient or by anyone on behalf of the patient (e.g., EMS personnel, a police officer, or a babysitter, family member, or legal guardian).
  - CMS regulations require that the screening examination be done by "qualified medical personnel." Typically, the designation applies to physicians or advanced practice providers (nurse practitioners [NPs] or physician assistants [PAs]).
  - An appropriate MSE must be reasonably calculated to identify critical medical conditions and must be uniformly provided to all patients who present with substantially similar complaints.
  - Hospitals need to have a policy and practice for left-without-being-seen (LWBS) patients that adequately documents pertinent findings and protects the hospital from liability.
  - Medicare-participating hospitals that have specialized capabilities or facilities are required by EMTALA to accept appropriate transfers of patients who require such capabilities or facilities if the hospital has the capacity to treat the patient.
  - Once a hospital admits the patient in good faith as an inpatient for further treatment, the hospital's obligation under EMTALA ends.
- Emergency Consent for Procedures
  - The emergency clinician who proposes to undertake the procedure must be the one to obtain the patient's informed consent. The duty to obtain consent cannot be delegated.
  - Whenever emergency clinicians are in doubt about the legality of a situation related to consent, they should do and document what they believe to be in the patient's best interest. Delaying treatment in an emergency to obtain informed consent is a much more serious and common medicolegal problem than failure to obtain proper informed consent.
  - Consent for minors in the ED is a nonissue. Consent is a creature of state law; EMTALA preempts state law, and it requires the ED to provide an MSE and stabilizing treatment to all minors presenting to the ED.
  - A parent's right to freedom of religion (e.g., Jehovah's Witness) does not include the right to deny life-sustaining medical intervention for that person's children.
- Leave Against Medical Advice
  - Emergency clinicians should be cautious when patients the demonstrate intention to leave the ED against medical advice. The capacity to make reasonable medical decisions can easily be affected by alcohol, drugs, pain, or any number of medical conditions. Careful evaluation and documentation of the patient's decision-making capacity supports the decision to allow the patient to leave or to retain the patient against their will. The courts (and public opinion) tend to support clinicians who act in the best interests of the health and safety of their patients.

PRINCIPLES

Federal and state laws tightly control the practice of emergency medicine. The magnitude and complexity of the governing legal authority plus the significant penalties for noncompliance, such as criminal sanctions, civil lawsuits, civil monetary penalties, and exclusion from participation in Medicare and Medicaid, oblige emergency clinicians to have functional knowledge of these laws.

Federal law—the Emergency Medical Treatment and Labor Act (EMTALA)—governs how emergency clinicians must triage, register, examine, treat or stabilize, discharge or transfer, use hospital resources, and involve on-call medical staff expertise when caring for patients presenting to the emergency department (ED).[1] State laws further control the practice of emergency medicine through such issues as consent, reporting requirements, confidentiality requirements, forensic and police matters, civil commitments, and emergency medical service (EMS) statutes (Box e7.1).

SPECIFIC ISSUES—EMERGENCY MEDICAL TREATMENT AND LABOR ACT

EMTALA originally was enacted to prevent private hospitals from refusing to treat indigent patients with medical emergencies or transferring ("dumping") them in an unstable condition to public hospitals. Subsequent amendments to the law, government regulations, and court decisions greatly expanded the reach of EMTALA, such that the law now sets national standards for screening, stabilizing, and discharging or transferring ED patients.

Medical Screening Examination

Any person who comes to an ED requesting examination or treatment for a medical condition must be provided with an appropriate medical screening examination (MSE), regardless of immigration status, insurance status, or ability to pay.[1,2,3] The purpose of the MSE is to determine

BOX E7.1 Elements Hospitals and Emergency Clinicians Must Address to Ensure EMTALA Compliance

- Adopt (and enforce), and educate all appropriate staff on a hospital-wide EMTALA policy, as well as emergency department (ED)–specific policies.
- Define the hospital's standard ED medical screening examination (MSE) process, including identifying "dedicated emergency departments" and designated "qualified medical personnel" to perform the MSE, as defined by the government.
  - Establish the hospital's patient stabilization procedures and documentation.
  - Do not delay access to the MSE, stabilizing care, on-call physicians, or transfer on account of or to inquire about the patient's insurance status (EMTALA's "no-delay" provision).
  - Address the ED/outpatient registration procedures and payment collection systems.
  - Implement processes and procedures regarding patient refusal of the MSE, stabilizing treatment, or transfer.
  - Post required signs in areas used for MSEs, including the ED, labor and delivery, and psychiatric intake centers
- Implement an effective ED physician on-call system, with written duties and responsibilities.
- Create a process for receiving patient transfers and for transferring patients to other facilities.
  - Create a uniform system and "transfer packet" for transferring patients out of the hospital.
  - Create a system for accepting or rejecting patient transfers from other facilities.
  - Institute appropriate documentation requirements for ED medical records, a "central log" for patients presenting to the hospital, transfers, and on-call lists.
- Monitor and quality assurance review the hospital's EMTALA compliance.
- Draft a policy and procedure to report suspected EMTALA violations to the Centers for Medicare and Medicaid Services (CMS).
- Review the potential application of EMTALA to the hospital's outlying facilities, such as urgent care centers or ambulance/helicopter EMS services.
- Review disaster plans and public health emergency responses for EMTALA issues.
- Draft and use legally approved EMTALA forms to achieve/document compliance.

whether the patient has an emergency medical condition (EMC).[1] Mere presence in the ED or on hospital property does not trigger the hospital's duty to provide an MSE; a request for examination or treatment of a medical condition is also necessary. The request can be made by the patient or by anyone on behalf of the patient.[1,2,3] If a person is unable to speak to request care, hospital personnel may infer a request if the behavior suggests a need for examination or treatment.[2,3]

The Centers for Medicare and Medicaid Services (CMS) deems anyone on hospital property to have "come to the emergency department."[2,3] Hospital property consists of the entire main hospital campus, including parking lots, sidewalks, and driveways, and any ambulance owned and operated by the hospital, even if the ambulance is not on hospital grounds.[2] CMS then divides hospital property into dedicated EDs and all other property. A dedicated ED is a place that is held out to the public as providing unscheduled care for persons with EMCs, including typical hospital EDs, labor and delivery units, and psychiatric intake centers.[2,3] Urgent care centers generally do not have to comply with EMTALA.

CMS exempts on-campus areas that typically do not provide emergency care, such as physicians' offices, skilled nursing facilities, and nonmedical facilities, and off-campus ambulatory facilities such as medical office buildings and dialysis centers.[2]

Presentations to the hospital's dedicated ED require only a request for examination or treatment of a medical condition, whether or not an emergency medical condition is present. Presentations to non-ED parts of hospital property, however, require the request to be for an emergency condition before EMTALA applies.[2-4]

Emergency Medical Condition

EMTALA defines an EMC as acute symptoms of sufficient severity (including severe pain) such that the absence of immediate medical attention could reasonably be expected to result in (1) placing the health of the individual (or, with respect to a pregnant woman, the health of the woman or her unborn child) in serious jeopardy, (2) serious impairment to bodily functions, or (3) serious dysfunction of any bodily organ or part.[1] In the case of a pregnant woman who is having contractions, an EMC is defined as one in which there is inadequate time to effect a safe transfer to another hospital before delivery, or that transfer may pose a threat to the health or safety of the woman or the unborn child.[1]

If the MSE does not reveal an EMC, further care of that patient is not controlled by EMTALA, so the law's provisions governing stabilizing treatment, transfer of the patient, or involvement of on-call physicians cease to apply.[1,2,3] ED managers should ensure that there is a process in place for documentation of the completion of the MSE on every ED medical record including the presence or absence of an EMC.

Patients Brought by Emergency Medical Services to the Emergency Department

CMS deems a hospital's EMTALA obligation to begin the moment the patient "comes to the ED" and a request is made on behalf of the patient for examination or treatment of a medical condition, not when the hospital "accepts" the patient.[3] Sometimes, such as when there is an influx of multiple trauma victims, it is reasonable for the hospital to ask the EMS provider to stay with the patient until such time as ED staff becomes available to care for that person. However, CMS requires that "even if a hospital cannot immediately provide an MSE, it must still triage the individual's condition immediately upon arrival to ensure that an emergent intervention is not required and that the EMS provider staff can appropriately monitor the individual's condition."[3]

National Emergencies or Disasters

The Secretary of Health and Human Services can exempt hospitals from EMTALA during times of national or local disasters or terrorist acts, bioterrorist events, or pandemic infectious disease.[2,3] EMTALA still applies to individuals potentially exposed to Ebola virus, COVID-19, or other highly contagious diseases who present to the hospital's ED.[5]

Sexual Assault Cases

A person coming to the ED solely for the collection of evidence for a criminal investigation is not requesting examination or treatment for a medical condition, so no MSE is required. However, if the person complains of pain or injury or wants pregnancy or sexually transmitted disease prophylaxis, that person is requesting examination or treatment for a medical condition and must be provided with an MSE.[1-3]

Police-Requested Blood Alcohol Tests

When a police officer brings a patient to the ED requesting a blood alcohol test, an MSE should be performed to determine if a potentially

serious cause of abnormal mental status exists and normal patient consent provisions apply.[3] A patient who is deemed capable of decision making may refuse the MSE and request that only the blood be drawn. The refusal of the MSE is documented, along with the patient's decision-making ability, as for any other refusal of treatment or evaluation. If the patient is too intoxicated to make medical decisions, release from the ED should be delayed until the patient is capable of rational decision making. A physician or advanced practice provider should assess and document a patient's competence.

Health Care Providers Qualified to Perform the Medical Screening Examination

CMS regulations require that the screening examination be done by "qualified medical personnel" and that the hospital's governing body formally designate, in writing, who is a qualified person to perform medical screening on behalf of the hospital.[2] Typically, physicians and nurse practitioners (NPs) or "physician assistants (PAs) working independently or under the direction of an emergency physician" are designated as such. Triage by a nurse does not constitute an MSE, even for obvious nonemergent conditions.[2,3]

Ancillary Services as Part of the Medical Screening Examination

The law requires hospitals to provide the screening examination "within the capabilities of the hospital's emergency department, including ancillary services routinely available to the ED."[1] Accordingly, the scope of an MSE may range from a brief history and physical examination to an extensive evaluation including advanced imaging or procedures, such as a lumbar puncture. For example, if it takes a complete neurologic examination, CT scan, or lumbar puncture to decide whether a headache patient has a subarachnoid hemorrhage, then those procedures are considered part of the MSE. The hospital is obligated to use only the resources, such as ED ultrasound, ordinarily available to its ED.[1] This includes consultation, such as with an on-call surgeon, when needed to determine whether an EMC is present. If a rural hospital only has mobile magnetic resonance imaging (MRI) capability once per week, it is not required to provide MRI services the other 6 days per week to the ED.

Policies, Procedures, and Practice Guidelines

Each hospital determines its own standard screening policies and procedures. Hospital standards are individualized depending on ED and ancillary capabilities. A hospital satisfies the requirements of EMTALA if it conducts standard screening procedures, uniformly, for all patients with similar complaints and circumstances.[6]

Once hospitals define their own standard screening process, they will be held to that standard. For example, if a hospital's screening policy states that all patients will be triaged within 10 minutes, any triage carried out at 15 or 20 minutes after arrival constitutes a violation of the law because the hospital did not follow its own policy.

Registration Process, Collections or Insurance Information, and Authorization

CMS allows hospitals to conduct reasonable registration procedures in the ED, including collection of insurance data at the time of registration, as long as the process does not delay the MSE.[3,7] A reasonable registration process may obtain demographic data and the name of the patient's physician and determine whether the patient is insured and the type of insurance. During the registration process, the patient can sign the hospital's usual "informed consent to be examined" form and a routine form that holds the patient financially accountable for any charges not covered by the patient's insurance carrier.[7] Delaying a necessary examination because the registration clerks are collecting insurance information probably is a violation.

Hospitals are not permitted to use unreasonable registration processes to coerce patients into leaving before they receive their federally guaranteed MSE.[3,7] Collection of co-payments, down payments, advanced beneficiary notifications, or signatures on managed care financial forms are prohibited until after the MSE is completed and stabilizing treatment has been initiated. Hospitals should also ensure that staff behavior does not create a hostile environment or constructive denial of the MSE.

CMS explicitly bans prior authorization for managed care plans before completion of the MSE and commencement of stabilizing treatment.[7] Hospitals may obtain authorization for payment from insurance entities only concurrently with stabilization of the patient.[3,7]

Regardless of insurance or social status, all patients should be processed in the same manner. In addition, the triage team, emergency clinician and nursing staff, and all clinical personnel should be blinded to the patient's insurance status throughout the initial screening and stabilizing care. This removes insurance status as an issue should there later be a claim that the staff was motivated in some way by financial class. After the MSE and initiation of stabilizing treatment, insurance status and ability to pay can be considered in determining the patient's future care, such as hospital admission, transfer, or discharge and follow-up.

Central Log

Hospitals must maintain a central log of all patients presenting to the ED requesting examination or treatment. The log must contain the name and disposition of the patient, including whether the patient refused treatment, whether the hospital refused to provide an MSE or treatment, and whether the patient was treated and stabilized, admitted, transferred, or discharged.[8] The purpose of the log is to permit CMS and state surveyors to select and review individual records to investigate whether the hospital is in compliance with the law.[3,8]

The log must include all persons presenting to the ED, ambulatory care or fast-track areas contained within the ED, freestanding emergency centers, labor and delivery suites, and psychiatric intake centers. The logs are not required to be collated into a single document but must be retrievable at CMS's request.

Medical Record

All areas of the hospital used to conduct the MSE must create a medical record with appropriate documentation for the patient's presentation and evaluation.[3,8] If members of the hospital medical staff see their patients in the ED, on either a scheduled or an unscheduled basis, the hospital must create a medical record and require the physician to document the care provided in that record. The physician's private office records documenting care provided at the hospital are insufficient.

Stabilization Requirements

The screening section of EMTALA mandates the hospital to provide only those services within the capability of the ED, including ancillary services routinely available to that department.[1] The stabilization section, however, requires the level of services within the capabilities of staff and facilities available at the hospital.[1]

Two elements must be present to trigger EMTALA's stabilization requirement: (1) the patient must have an EMC, as defined by law, and (2) the hospital must determine that an EMC exists. That an EMC exists is not sufficient to invoke the duty to stabilize; the hospital also must have actual knowledge that the EMC exists. *Actual knowledge* is a legal term that means the examining emergency clinician subjectively determined that an EMC existed. Whether the physician's judgment

PHYSICIAN

Emergency Medical Condition (EMC) Identified: (*Mark appropriate box(s), then go to Section II*)

I. MEDICAL CONDITION: Diagnosis_____

☐ **No Emergency Medical Condition Identified:** This patient has been examined and an EMC has not been identified

☐ **Patient Stable -** The patient has been examined and any medical condition stabilized such that, within reasonable clinical confidence, no material deterioration of this patient's condition is likely to result from or occur during transfer.

☐ **Patient Unstable -** The patient has been examined, an EMC has been identified and patient is not stable, but the transfer is medically indicated and in the best interest of the patient.

I have examined this patient and based upon the reasonable risks and benefits described below and upon the information available to me, I certify that the medical benefits reasonably expected from the provision of appropriate medical treatment at another facility outweigh the increased risk to this patient's medical condition that may result from effecting this transfer.

II. REASON FOR TRANSFER: ☐ Medically Indicated ☐ Patient Requested _____

☐ On-call physician refused or failed to respond within a reasonable period of time.

Physician Name: _____ Address _____

III. RISK AND BENEFIT FOR TRANSFER:

Medical Benefits :	**Medical Risks :**
☐ Obtain level of care/ service NA at this facility. Service _____	☐ Deterioration of condition in route _____
☐ Benefits outweigh Risks of Transfer	☐ Worsening of condition or death if you stay here. There is always risk of traffic delay/accident resulting in condition deterioration.

IV. Mode/Support/Treatment During Transfer As Determined by Physician– (Complete Applicable Items):

Mode of transportation for transfer: ☐ BLS ☐ ALS ☐ Helicopter ☐ Neonatal Unit ☐ Private Car ☐ Other_____

Agency:_____ Name/Title accompany hospital employee:_____

Support/Treatment during transfer: ☐ Cardiac Monitor ☐ Oxygen – (Liters): _____ ☐ Pulse Oximeter ☐ IV Pump ☐ IV Fluid: _____ Rate: _____ ☐ Restraints – Type: _____ ☐ Other:_____ ☐ None

Radio on-line medical direction control *(If necessary):* ☐ Transfer Hospital ☐ Destination Hospital ☐ Other

V. Receiving Facility and Individual: __The receiving facility has the capability for the treatment of this patient (including adequate equipment and medical personnel) and has agreed to accept the transfer and provide appropriate medical treatment.

was negligent, or even grossly negligent, is irrelevant under EMTALA. The subjective perception of the examining emergency clinician controls whether EMTALA's stabilization requirement is triggered.

Once the hospital determines that an individual has an EMC, EMTALA requires the hospital either to stabilize the EMC or, if it lacks the capability to stabilize the patient, to transfer the patient to another medical facility that can provide the necessary stabilizing treatment.[1] A sample form for use in documenting such transfers and patient consent to transfer is shown in Figure e7.1.

The treating emergency clinician needs to decide whether a patient's EMC is stable or unstable. If two clinicians disagree about whether the patient is stable but only one of the clinicians is at the bedside caring

for the patient, the on-site clinician should make the decision.[3] If an outside physician wants to overrule the determination of the on-site clinician, he or she must come to the hospital and personally examine the patient.

EMTALA defines the term *stabilized* as follows: "no material deterioration in the [emergency] condition is likely, within reasonable medical probability, to result from or occur during the transfer of the individual from a facility."[1] For a pregnant woman having contractions who has an EMC, stabilized means that delivery (including the placenta) has occurred.[1]

The question of stabilization typically arises only when the patient deteriorates during or after the transfer and experiences an adverse medical result. It is likely to appear, particularly in hindsight, that the patient was not completely stabilized before transfer. A plaintiff need not show improper motive for a transfer to prevail on a failure-to-stabilize claim under EMTALA, merely that the patient was not properly stabilized before the transfer.

When and if the patient is stabilized has significant ramifications for hospitals and physicians, because once patients are stabilized, EMTALA no longer applies.[1,9] After stabilization, hospitals are free to refuse to provide further treatment or to transfer stabilized patients for purely financial reasons. On-call clinicians can refuse to treat or admit stable patients or insist that stable patients be transferred owing to their lack of or type of insurance. An MCO can refuse further payment to the hospital and request that the stabilized patient be transferred to one of its contracting facilities. Other federal, state, or local standards may govern further treatment or transfer of ED patients. For example, state laws often prohibit hospitals from transferring patients for any reason except that they are incapable of handling the patient's medical problem.

Disposition Issues Under Emergency Medical Treatment and Labor Act

Admission

Once a hospital admits the patient for further treatment, the hospital's obligation under EMTALA ends.[2,3] It does not matter if the situation changes later and the patient can be discharged or transferred to another hospital and does not actually use the bed overnight. The key element is that the patient be formally admitted with a documented admission order.

CMS does not consider patients admitted to observation status to meet the regulatory definition of admitted patients (not admitted for purposes of receiving inpatient services), so EMTALA still applies to the care of observation patients, such as patients managed in ED chest pain or observation units.[2,3] Patients directly admitted through or held in the ED from a physician's office, nursing home, or in transfer from another ED or another hospital inpatient setting are no longer covered by EMTALA, even though they have come to the hospital's emergency department.

"Discharge" or "Transfer" to Home

Because EMTALA defines any patient movement away from the hospital as a transfer, all patients discharged from an ED are legally considered to have been transferred.[1] Sending a patient home after treatment in the ED who is retrospectively determined to be unstable is considered to represent a transfer of an unstable patient and, as such, a violation of the law. This exposes the hospital to civil litigation under EMTALA for the failure of its emergency clinicians to stabilize patients with known emergency conditions before discharge (transfer) home.

To avoid such retrospective analyses, emergency clinicians should document that no emergency condition was found or that the patient was stable on discharge.

Discharge or Transfer from the Emergency Department to an On-Call Physician's Office

Because all discharges from the ED are defined as transfers under EMTALA, so too are discharges from the ED sent directly to an on-call physician's office for acute evaluation or treatment. In general, transfer to an office for care is only acceptable if the level of care required was not possible in the ED, such as with an ophthalmology referral.

Also, it is reasonable to send patients to an office for further treatment, such as definitive orthopedic treatment after splinting, so long as they meet the legal definition of stable at the time of discharge from the ED. The determination of whether the patient is stable for transfer to the orthopedist's office rests solely on the judgment of the examining emergency clinician. If the patient has accompanying injuries or is too uncomfortable to be moved, or if the emergency clinician believes the injury is such that the patient should not travel, then the orthopedic surgeon should be asked to care for the patient in the ED.

Follow-Up Care After Discharge from the ED

Whatever decision the hospital and physicians make about responsibility for ED follow-up, they should explicitly define those requirements in the medical staff bylaws or policies so that all personnel understand what it means to be on call for the ED at that hospital. ED discharge instruction sheets also should include a fail-safe clause advising patients to return to the ED if their condition deteriorates before seeing the referral specialist or if the follow-up arrangements disintegrate for any reason. Such a statement could help the hospital avoid liability when the on-call specialist fails to implement the prescribed follow-up plan.

Transfers to Other Acute Care Hospitals

EMTALA regulates the transfer of unstable patients only; it does not apply to the transfer of stable patients.[1,2] If no EMC is found, the patient is considered stable. The determination of whether a patient is stable must be made at the time of transfer to be valid under the law. Unstable patients can be transferred for only one of two reasons: if the transfer is medically indicated, or if the patient requests the transfer.[1] Patients usually are transferred out of the ED because the transferring facility lacks the capability or the resources necessary to treat the identified EMC.

EMTALA defines such transfers as medically indicated transfers because the purpose of each transfer is to obtain a higher level of medical care necessary to treat the patient's condition that is not available at the transferring facility. EMTALA governs almost every aspect of medically indicated transfers, including requiring hospitals to adopt and enforce policies to ensure compliance with federal transfer laws and mandating specific actions by the transferring and receiving hospitals (summarized in Boxes e7.2 to e7.4).[1-3,8] Some states have enacted their own transfer laws. Most state laws parallel EMTALA, but some are even more restrictive, so emergency clinicians responsible for patient transfers should be aware of the controlling laws and regulations in their own state as well as under federal law.

Duty to Accept Appropriate Transfers from Other Hospitals

Medicare-participating hospitals that have specialized capabilities or facilities are required by EMTALA to accept appropriate transfers of patients who require such capabilities or facilities if the hospital has the capacity to treat the patient, even if the receiving hospital does not have an ED.[1,2]

The duty to accept appropriate transfers is a hospital duty, not a physician duty, and EMTALA does not require that a physician accept the patient.[1] Hospitals should ensure that on-call physicians understand the duty to accept patients in transfer.[10] Because the duty to accept rests

BOX E7.2 Recommended Procedures for the Transferring Facility

- Stabilize the patient whenever possible.
- Complete a physician certificate of transfer, including the risks and benefits of transfer.
- Obtain the patient's informed consent to the transfer.
- Arrange for another hospital and physician to accept the patient in transfer.
- Send appropriate patient medical data to the accepting facility.
- Arrange the transfer through qualified personnel and appropriate transportation equipment.
- Maintain records of all transfers for 5 years.

BOX E7.3 Invalid Reasons for Refusal of an Appropriate Patient Transfer

- Lack of insurance or out-of-network managed care plan
- Lack of citizenship
- Veteran status
- Patient's physician not on medical staff
- Transferring hospital is out of network or outside hospital's defined referral area
- Unaffiliated hospital
- Transfer originating out of county or out of state (including transfer of out-of-state Medicaid patients)
- EMS bypassed closer hospital
- Another hospital refused the transfer in violation of the law
- Another hospital's on-call physician refused to respond to its ED in violation of the law

BOX E7.4 Recommendations for the Facility Asked to Accept the Patient in Transfer

- Accept all appropriate requests for transfer, regardless of whether the patient is an ED patient or an inpatient of the hospital
- Develop a formal system for accepting or rejecting transfer requests and document the reasons for any refusal to accept a patient in transfer
- Maintain records of all transfers for 5 years
- Report all EMTALA transfer violations of unstable patients to CMS

with the hospital, any inappropriate refusal by an uninformed on-call physician subjects the hospital to termination from Medicare, civil monetary penalties, or civil liability if the patient is harmed because of the refusal to accept the patient in transfer.

Current CMS-issued regulations state that no hospital has a legal duty under EMTALA to accept an inpatient in transfer from another hospital.[2] Therefore, even if a requested hospital could treat an inpatient's EMC that the transferring hospital is unable to treat, it may refuse the transfer for any reason, including an economic reason, and not be in violation of EMTALA. There are seven reasons for which a hospital can refuse a request for transfer under EMTALA, which are summarized in Box e7.5.

There are no other reasons for which a hospital may refuse a request to accept a patient in transfer from another acute care hospital under EMTALA. Furthermore, no contingencies are allowed to be placed on the acceptance of a transfer. The receiving hospital may not condition

BOX E7.5 Valid Reasons to Refuse a Transfer Request

1. No emergency condition present
2. Not medically indicated
3. Don't have capacity
4. Patient admitted to inpatient service
5. Patient not in a hospital
6. Patient outside the United States and its territories

acceptance of the patient on the transferring hospital's agreeing to take the patient back once the emergency condition is resolved, may not require that the transferring hospital have additional consultations completed before the emergency clinician transfers the patient, and may not require the transferring hospital to use the receiving hospital's transport ambulance or helicopter service as a condition for accepting the patient.[3] Refusals of appropriate transfers on the basis of the patient's insurance status or delay of appropriate transfers until the transferring hospital obtains authorization for payment from the patient's managed care plan are illegal under EMTALA.[1]

Duty to Report Transfer Violations

Any time a hospital has reason to believe it may have received a patient transferred in an unstable condition from another hospital, in violation of EMTALA, it must report the transferring hospital to CMS.[8] The duty to report rests with the hospital, so emergency clinicians who receive unstable patients in transfer should inform the hospital (risk management or the hospital's legal counsel), which then can determine the appropriate action.

CONSENT FOR MEDICAL CARE

Informed Consent

The doctrine of informed consent is a fundamental principle of the United States' legal system. Emergency clinicians may not examine or treat any person without consent, and that consent must be informed. This means that the patient must be given all pertinent information concerning the nature, risk, and alternatives of the treatment before that patient can be deemed to have effectively consented to the medical intervention. Clinicians should endeavor to obtain informed consent yet remain cognizant of the significant limitations of and multiple exceptions to the doctrine, especially in the ED setting. Delaying treatment in an emergency to obtain informed consent is a much more serious and common medicolegal problem than failure to obtain proper informed consent.

Emergency clinicians rarely have time to seek legal consultations, let alone wait for a court to render a decision concerning the legal nuances of consent issues. In these situations, it is helpful for emergency clinicians to use a when-in-doubt rule to guide their immediate actions. This rule simply states that when emergency clinicians are in doubt about the legality of a situation, "they should do what they believe to be in the patient's best interest and worry about the legal consequences later." Although emergency clinicians risk criminal and civil charges of false imprisonment, battery, and even negligence for failure to obtain appropriate informed consent, the courts almost universally rule in favor of physicians who act in good faith on behalf of their patients in emergency situations. Successful civil litigation regarding an issue of consent theory against an emergency clinician acting reasonably, and consistent with the appropriate standard of care, is extremely rare. An emergency clinician is much more likely to be sued for failure to treat while waiting for consent than for providing reasonable treatment without consent.

Federal Versus State Laws

Both federal laws (EMTALA) and state laws govern consent.[1] EMTALA comes into play primarily in the evaluation of minors and with patient refusal of stabilizing treatment or transfer. State consent laws vary widely. The concepts discussed next are generally applicable to emergency medical care, but all emergency clinicians should learn the consent laws specific to their own state.

The law presumes that an adult is mentally competent to make medical decisions and is entitled to sufficient information to make an informed decision concerning the physician's proposed course of examination and treatment. Under the doctrine of informed consent, clinicians have the duty to disclose the following information to patients:

- The patient's condition or diagnosis
- The nature and purpose of the proposed treatment, including the likelihood of success in the clinician's practice
- Reasonable alternative measures related to the diagnosis and treatment, including the probable outcome of those alternatives
- The particular known inherent risks that are material to make an informed decision about whether to accept or to reject the proposed treatment, including the consequences of refusing that treatment

Reasonable Person Versus Professional Disclosure Standard

The states are split on the standard used to determine what should be disclosed for patients to make informed decisions, but most require the reasonable person standard of disclosure. Under this standard, an emergency clinician is required to disclose all of the information that a reasonable person would require to make a decision. The less frequent standard, the professional disclosure standard, requires the physician to provide the same information that other physicians in the community would provide to patients in the same or similar circumstances. This is less stringent than the reasonable person standard.

Clinicians are not required to disclose every remote risk associated with a procedure or risks that are common knowledge or obvious to the patient. The law requires disclosure only of risks that are material, as judged by their seriousness or chance of occurrence. Courts define material information as information that "the physician knows or should know would be regarded as significant by a reasonable person in the patient's position when deciding to accept or reject the recommended medical procedure."

Emergency Clinician Role in the Consent Process

The emergency clinician who proposes to undertake the procedure must be the one to obtain the patient's informed consent. This cannot be delegated, so clinicians cannot ask nurses or other health care providers to obtain patients' consent on their behalf. The clinician who will care for the patient is best qualified to discuss the treatment and its risks and benefits with the patient. Nurses, as well as physicians who are not credentialed to perform the procedure, cannot obtain valid informed consent.

A summary of the discussion held with the patient and family concerning the elements of informed consent should be entered into the medical record. Particular attention should be made to documentation of those material risks discussed with the patient. Consent is a process, not a signature. A written, signed, separate consent form is not legally required under the doctrine of informed consent; however, hospitals may require emergency clinicians to complete standardized consent forms and to obtain the patient's signature. The signed form is not a substitute for the consent process. It cannot replace the exchange of information that occurs between the physician and the patient and family, the answering of questions, and the ultimate agreement of the patient to undergo the medical or surgical intervention.

Implied Consent in Emergency Situations

If an unconscious or incapacitated patient cannot express consent, the law will assume the patient consented to treatment for the emergency situation. Implied legal consent is premised on two principles: (1) duty to obtain informed consent is excused if death or irreparable harm may result if the clinician delays treatment, and (2) the law presumes that a reasonable, competent, lucid adult would consent to lifesaving treatment. The emergency treatment allowed is limited to the circumstances of the emergency, and only treatment required to resolve the emergency should be undertaken without consent. The emergency condition must require immediate medical attention, with insufficient time to inform the patient or to seek consent from another person. This is one situation in which use of the when-in-doubt rule and documentation of the clinician's concerns will weigh greatly in the court's determination of whether the clinician acted appropriately without obtaining informed consent.

Minors

Minors Accompanied by a Parent or Legal Guardian

Parents and legal guardians have the right to consent on behalf of their minor children. However, they need to act reasonably and in the best interests of their children. If they do not, their right to consent can be abrogated by the state or the courts. Parents are not allowed to refuse treatment for a child with a life-threatening emergency condition. The management of children with emergency conditions whose parents refuse to give their consent to treatment is discussed later.

Either natural parent of the minor child may provide legally binding consent. If one parent agrees with a proposed treatment and the other does not, consent may be accepted from the agreeing parent. Even if separated or divorced, either parent may give consent unless one parent has been judicially granted sole legal custody of the child, in which case only the custodial parent may consent. The child's biologic father, even if never married to the mother, also may consent for his child.

Unaccompanied Minors

EMTALA mandates that all persons presenting to an ED requesting care be examined to determine whether an emergency condition exists.[1] Because EMTALA is federal law, it takes precedence over all state consent laws regarding the initial evaluation of a minor child. The hospital should not delay this initial screening evaluation to wait for consent from a parent or legal guardian (and nurse triage does not qualify as the required medical screening, no matter how non-urgent the child's condition appears to the nurse).

If an emergency condition is discovered through the initial screening examination, the clinician may treat the emergency under either state or federal legal theories. Preserving life, preventing permanent disability, alleviating pain and suffering, and avoiding eventual harm have been used as guidelines for emergency treatment without consent. Any minor presenting to the ED should be triaged and provided with an MSE to determine whether an emergency condition exists. Under EMTALA, if an emergency condition is present, the hospital and emergency clinicians are required to provide stabilizing treatment.[1] The stabilization requirement includes transfer as necessary to an institution capable of handling the minor's emergency condition.

If the MSE does not reveal an emergency condition, clinicians need to obtain proper consent from the minor's parents or legal guardian. However, state laws and the courts have applied a number of exceptions to allow minors to seek treatment on their own without parental consent. These exceptions (such as the mature minor and the emancipated minor exceptions) vary widely from state to state. Most states have statutory reasons, such as sexually transmitted diseases, pregnancy, or

domestic violence injuries that allow minors to seek care without the consent of their parents.

Incompetent or Incapacitated Adults

If a person has been declared legally incompetent by a court, consent must be obtained from the person's court-appointed legal guardian. In addition, people may appoint legal surrogates to make legal decisions for them should they become incompetent. State-sanctioned living wills, advance directives, and durable medical power of attorney documents all transfer consent powers from a person who becomes incompetent to a legally appointed surrogate.

If an incompetent adult lacks a legal guardian or an appointed surrogate, emergency clinicians typically look to the patient's family for consent to treatment. However, consent to treatment by a family member, even the patient's spouse, generally is not acceptable under United States law unless the spouse or family member has been appointed legal guardian by a court of proper jurisdiction. Marriage does not confer one spouse the legal capacity to consent to medical treatment for the other spouse, even when the ill or injured spouse is incompetent.

Some states recognized this problem and enacted family consent statutes, which outline a hierarchy of family members who can legally provide consent when the family member becomes incapacitated. Even when families have no legal standing to consent, it is wise to involve family in the medical decision-making process. Communication and concern for the family will avoid misunderstandings, surprise, and anger, which are the primary sources of litigation. If an emergency exists, no authorization from the family is necessary to provide such reasonable care as is necessary to correct the life-threatening situation. Once the emergency is resolved, consent should be obtained from someone authorized to act on behalf of the incompetent patient. If there is no appointed legal guardian or surrogate and no state statute on family consent, the emergency clinician should seek consent authorization from the courts.

Other Special Populations of Patients

Prisoners

Competent prisoners generally do not surrender the right to consent by virtue of being incarcerated. However, a state or court may compel treatment on the basis of interests perceived as paramount to the prisoner's interests.

Alcohol-Intoxicated Patients

Alcohol intoxication itself may not render a patient incompetent to give informed consent. The emergency clinician should evaluate each situation individually to determine whether the patient is incapacitated by alcohol to the extent that he or she is no longer able to understand the proposed treatment, risks and benefits, and rational alternatives. However, the when-in-doubt rule is particularly applicable in these cases because alcohol intoxication often is associated with occult serious illness or injury.

Alcohol intoxication, especially if it is documented by a measured blood alcohol concentration (BAC), is strongly suggestive to courts and juries of impaired mental status, even though health care workers recognize that many alcoholics are entirely rational and competent at fairly high BACs. Conversely, low BACs do not guarantee competence because other processes (e.g., hypoglycemia, blood loss, impairment from other illicit substances) may cause the patient to be incompetent.

The state legal limit of intoxication is not a measure of a patient's competence. The legal level for driving has little to do with the capacity to make informed medical decisions. This distinction is sometimes difficult for judges and juries to understand, and the emergency clinician can actually use the blood level to support a judgment that the patient was not competent to make informed decisions in a particular instance. At other times, it is better not to have a number so that the only relevant criterion for determination of the patient's competence is the clinician's judgment.

Patients Given Pain Medications

As with alcohol intoxication, the fact that a patient has been given narcotic analgesia does not render that patient incapable of consenting to invasive diagnostic procedures or surgery. When consent is sought from a patient who has received pain medication, the patient's ability to understand the ramifications of the procedure should be assessed and taken into consideration, involving the family in the process if possible. The emergency clinician should document that the patient's premedicated state was considered in judging the patient's competence to make an informed decision.

REFUSAL OF MEDICAL CARE

Informed Refusal

The corollary to a patient's right to give informed consent is the patient's right to refuse medical care, even if such refusal results in death. The United States Supreme Court holds that a competent adult has a constitutionally protected right to refuse medical care. However, that right is not absolute. Under particular circumstances, courts will consider countervailing compelling state interests, such as preventing suicide, preserving life, and protecting innocent third parties.

Emergency clinicians who honor a competent patient's decision to refuse treatment are not liable for any resulting bad outcome. Emergency clinicians are more likely to be successfully sued for treating patients over their objections or without their consent, even when the treatment is lifesaving. When a competent adult refuses an indicated medical intervention, it often is because of a failure in communication in the clinician/patient relationship. Before allowing a patient to refuse care, the emergency clinician should try to determine and resolve the underlying reasons behind the patient's refusal. The attending physician must always be involved when a patient refuses medical care or expresses the intent to leave against medical advice.

As with consent, refusal of medical care is a process, not a signature. There are four essential components of the refusal process: (1) determining competence, (2) ensuring an informed decision, (3) involving others, and (4) documenting appropriately.

Determining Competence

The emergency clinician must determine that the patient is competent to make decisions. Normal findings on the mental status examination without evidence of diminished mental capacity from a closed head injury, severe pain, hypoxia, hypotension, alcohol intoxication, developmental delay, or mind-altering substances constitute good evidence of competency. Documentation of the patient's rationale for refusing care, even if it is not reasonable, provides additional evidence of competency.

Ensuring an Informed Decision

To be legally binding, a decision to refuse a test or treatment or to sign out against medical advice must be an informed decision. The emergency clinician should explain the severity of the patient's condition, the potential complications, and the alternative treatments available. The emergency clinician should use terms that the patient can understand and provide the patient an opportunity to ask questions. The patient should understand that the risks of refusing care include the possibility of permanent disability and death. Ideally, a witness should be present when the clinician informs the patient and any family members.

Involving Others

The patient's family, friends, and personal physician should be involved whenever possible. These persons should hear the same message as that conveyed to the patient, because they may be able to persuade the patient to accept the recommended therapy. If the patient expressly forbids the emergency clinician to speak with others, as is the patient's legal right, this should be explained to them and documented in the medical record.

Documenting Appropriately

Appropriate documentation of the refusal process is necessary to protect the physician and hospital from litigation. The patient should be asked to sign the refusal form. Figure e7.2 shows a sample leaving against medical advice form. If the patient refuses to sign the form, that fact should be documented, and the form signed by a hospital representative who witnessed the patient's refusal. The medical record should reflect the patient's mental status examination findings and competency to make informed decisions, the risks and benefits of recommended treatments, the available alternatives, and the participating family or friends. Documentation of the patient's rationale for refusing treatment, that the patient was treated to the extent allowed by the patient, and that the patient was invited to return for care at any time offers added protection.

Federal Rules

EMTALA requires hospitals to take and document specific actions when patients refuse medical screening, treatment and stabilization, or transfer. The government and the federal courts presume that the patient requested emergency care and place the burden of proof on the hospital to demonstrate that the patient voluntarily refused care.

There are essentially two scenarios in which patients leave the ED after refusing examination or treatment. First, some patients simply pick up and leave, without the knowledge of anyone affiliated with the hospital. Second, the patient's departure is witnessed, but the patient does not respond to requests to return for the examination or to discuss the issues with the hospital staff. These patients are generally referred to as those who leave without being seen (LWBS) or leave before examination. In the second scenario, the hospital personnel are aware that the patient is about to leave and have an opportunity to interact before the patient leaves. Hospitals generally refer to this as leaving against medical advice. The Office of the Inspector General and CMS refer to both of these scenarios as voluntary withdrawal of the patient's request for evaluation or treatment.

Leaving Without Being Seen

If a patient walks out before the MSE and later has an adverse medical result, the burden will be on the hospital to prove that the person left voluntarily and was not denied examination or treatment by the hospital. Hospitals need to have a policy and practice for LWBS patients that adequately documents pertinent findings and protects the hospital from liability. In most hospitals, the staff calls the patient and checks the waiting area at least three times before declaring that the patient has left the department. These serial checks, with the time of day they were performed, should be documented on the patient's record, and once it is evident that the patient is no longer present, the record should be reviewed on a timely basis by the emergency clinician on duty. If the reviewing clinician discovers something of concern regarding the patient's chief complaint or triage data, the person can be contacted and encouraged to return to the ED. The registration papers, triage records, nursing documentation at triage, and emergency clinician's review and documentation of that review should be kept in the patient's permanent medical record.

Leaving Against Medical Advice

If hospital personnel are aware that a patient intends to leave before completion of the MSE or stabilizing treatment for whatever reason (e.g., tired of waiting, changes mind, concerned about cost of care), the hospital should handle and document the interaction carefully to avoid EMTALA or medicolegal liability (Box e7.6). In each case, the following steps should be taken:

1. Inform the patient of the hospital's obligation under the law. The ED staff should inform patients of their rights under EMTALA to receive medical screening and any necessary stabilizing treatment from the hospital, regardless of their ability to pay for that service.
2. Determine the patient's competence. Only legally competent persons can refuse necessary medical care.
3. Explain the risks and the benefits to the patient. For patients to make an informed consent to voluntarily withdraw their request for services, they need to understand the benefits and the risks of withdrawal before refusing examination and treatment. These risks and benefits should be specific to the patient's chief complaint.
4. Secure the patient's written informed consent to refuse care. The hospital should take all reasonable steps to secure the patient's written and informed consent (i.e., obtain a signature) to refuse medical care and whether the patient's family was available to be involved in the discussions. If the patient refuses to sign the form and simply walks out after the interaction with the hospital, the person who discussed the issues with the patient and witnessed the patient's refusal should sign the form and document the interaction.
5. Offer alternative care within the scope allowed by the patient. An appropriate strategy is to negotiate with them to allow the best possible care under the circumstances that they define. Negotiation aims for the best alternative that the patient is willing to accept, even if that means providing less than optimal treatment. Patients should always be invited to return to the ED (or encouraged to see their private physician) if they change their mind and become willing to accept the recommended treatment. A patient's refusal of the more appropriate treatments as well as communication of offers to provide treatment within the circumstances proscribed by the patient should be delineated.
6. Document the interaction in the patient's hospital record. The record reflects the hospital's conformity to the law and the patient's leaving of his or her own accord—specifically, the risks of refusing the examination and the reasons for the patient's refusal. Documentation of the reasons for refusal provides evidence that the hospital did not economically coerce or in any way financially deter the patient from remaining for the MSE.

Parent or Guardian Who Refuses Care or Blood Transfusions for a Minor

In general, state laws support parental control of health issues affecting their children. However, the state will not allow parents to deny children needed emergency medical care under the doctrine of *parens patriae*, the state's paternalistic interest in children. When a child's injuries are potentially life-threatening, the emergency clinician can take custody of the child and provide indicated treatment, including blood transfusions. In deciding whether to act, the when-in-doubt rule applies, and all jurisdictions statutorily protect clinicians from criminal and civil liability for acting in good faith to protect children.

The courts have specifically addressed the issue of Jehovah's Witness parents attempting to refuse emergency blood transfusions for their minor children. All jurisdictions hold that a parent's right to freedom of religion does not include the right to deny life-sustaining medical intervention for that person's children. Conversely, courts refuse to rule against the parents' wishes when the child's medical condition is not

INFORMED CONSENT TO REFUSE EXAMINATION, TREATMENT, OR TRANSFER

I understand that the hospital has offered: (Check all that apply).

A. ☐ To examine me (the patient) to determine whether I have an emergency medical condition, or

B. ☐ To provide medical treatment or to provide stabilizing treatment for my emergency condition, or

C. ☐ To provide a medically appropriate transfer to another medical facility.

The hospital and physician have informed me that the ***benefits*** that might reasonably be expected from the offered services are:

_____

_____

and the ***risks*** of the offered services are: _____

_____

Physician Documentation

☐ The patient appears competent and capable of understanding risks and benefits.

☐ Alternative treatments discussed with the patient.

☐ Patient's family involved. ☐ Family not available. ☐ Patient does not want family involved.

Signature of Physician _____

Patient or Legally Responsible Person Documentation.

☐ I have declined to have the physician fully explain to me the risks, benefits, and alternatives to leaving the hospital against medical advice. I knowingly and willingly take and assume the responsibility for all risks incurred.
or
☐ The physician has fully explained to me the risks and benefits but I choose to refuse the offered services. I understand that my refusal is against medical advice, and that my refusal may result in a worsening of my condition and could pose a threat to my life, health, and medical safety. I understand that I am welcome to return at any time.

Signature/Patient or Legally Responsible Person _____

Print Name _____ Address _____

City _____ State/Zip _____ Date _____ Time _____

Witness/Signature _____ Print Name_____

The patient or person legally responsible for the patient was offered but refused to sign form after explanation of their rights and the risks and benefits of the services offered.

Date _____ Time _____

Informed Consent to Refuse Examination Form [Hospital Addressograph or Sticker Goes Here]
White/Patient Record Yellow/Transfer with Patient Pink/Q/A

Fig. e7.2 Leaving against medical advice form: Informed consent to refuse examination, treatment, or transfer.

BOX E7.6 Protocol for Management of Leaving Against Medical Advice Cases in the Emergency Department

- Involve the emergency clinician in the situation in which a patient wishes to leave AMA.
- Involve the family or the patient's personal physician whenever possible.
- Explain the risks and benefits specific to the patient's condition; "You could die" alone is too generic.
- Explain any alternative treatment options to the patient.
- Ascertain the patient's capacity to make informed medical decisions.
- Ask the patient and at least one witness to sign the leaving against medical advice form.
- Ask a member of the hospital staff to sign the leaving against medical advice form if the patient refuses to sign, and state that the patient refused to sign.
- Provide the best possible treatment within the scope allowed by the patient, including antibiotics and analgesics when warranted.
- Provide appropriate discharge instructions and welcome the patient to return to the ED at any time if he or she reconsiders and decides to accept the recommended care.
- Document discussions with the patient, the risks explained, and the patient's medical decision-making capacity and understanding of the ramifications of leaving against medical advice in the medical record (and in real time; not hours after the patient has left).

serious or life-threatening. If there is no life threat or potential for serious impairment, the parents' refusal should be respected. Parental refusal of indicated nonemergency medical treatment is usually statutorily defined as child neglect, which is not legally sufficient to take custody of the child. Child neglect should still be reported to the appropriate authorities; treatment for the child can then be obtained under a court order.

Jehovah's Witnesses

Adult Blood Transfusions

Jehovah's Witnesses and the issue of blood transfusion present difficult medicolegal issues in the ED. State courts may have widely divergent views on the issue. The current trend is granting patients greater autonomy to refuse blood, even when the state asserts compelling interests to override a person's refusal. General principles of consent and the when-in-doubt rule apply, but hospitals and medical staff also should develop policies and procedures in advance to resolve potential conflicts with the Jehovah's Witness patients in the community.

Competent Adult

The courts have found that "the competent adult has the right to refuse a transfusion regardless of whether his refusal to do so arises from fear of adverse reaction, religious belief, recalcitrance, or cost." This applies even though others may consider a patient's beliefs unwise or foolish. However, even this right is not absolute. If the patient's refusal conflicts with compelling state interests such as the preservation of life, the prevention of suicide, or the protection of innocent third parties, the courts may order transfusions despite the person's objections. Some courts, however, have significantly restricted the hospital's or state's ability to assert compelling interests challenging a competent person's right of self-determination.

Unconscious or Medically Incompetent Adult

In an emergency, if the Jehovah's Witness' beliefs are unknown, physicians may transfuse the patient because consent will be implied under the emergency doctrine. It is irrelevant if the spouse, mother, or other family members adamantly refuse to allow the transfusion for religious reasons. The state's compelling interest in preserving life outweighs the family's expression of the patient's religious preferences.

When a Jehovah's Witness' beliefs and transfusion preferences are known in advance but the patient is incompetent at the time of the emergency, the courts tend to accept objective evidence of the patient's wishes. For example, a signed card carried by the patient that identifies him or her as a member of the Jehovah's Witnesses and sets out the religious objection to blood transfusion may be accepted as adequate evidence of the patient's intent. Advance directives are merely a means to express an individual's rights and are not the exclusive means to express those rights legally. Jehovah's Witnesses increasingly use state statutorily defined advance directive methods to legally express their intentions. Emergency clinicians should, of course, be certain the card or advance directive actually belongs to the patient.

REPORTING REQUIREMENTS

All states require hospital EDs to report certain events, such as deaths, violent acts, animal bites, child abuse, or certain illnesses, particularly those of epidemiologic concern, to local public health authorities. The state's primary intent is to prevent the spread of communicable diseases, protect its citizens from disease and violence, and prosecute criminal acts. In each instance, the state statute overrides patients' rights to confidentiality. The statutes typically also provide clinicians with immunity from civil liability or criminal prosecution if the reporting is done in good faith. All EDs should maintain up-to-date lists of diseases and incidents that must be reported to the state. The process and responsibility for appropriate reporting should be clearly articulated in departmental policy.

CHAPTER E7: QUESTIONS AND ANSWERS

1. Which of the following is a common source of liability for failure to comply with the Emergency Medical Treatment and Labor Act (EMTALA)?
   - **a.** Failure to comply with written hospital policies and procedures
   - **b.** Failure to diagnose an emergency medical condition (EMC)
   - **c.** Failure to properly treat an admitted patient who is boarded in the emergency department (ED) while waiting for an intensive care unit (ICU) bed to become available
   - **d.** Failure to stabilize a patient after admission to an inpatient unit

Answer: A. Hospital policies become the hospital's standard under EMTALA. Thus, failure to comply with written policies, a failure to follow your own rules, becomes an EMTALA violation when the policies are related to the medical screening and stabilization of patients in the ED.

2. Which of the following violates the Emergency Medical Treatment and Labor Act (EMTALA)?
   - **a.** A 7-hour wait after triage to be medically screened by the emergency clinician
   - **b.** Boarding an admitted patient in the emergency department (ED) for 72 hours after the patient's physician has accepted the patient for admission
   - **c.** Delaying the patient's access to an ED bed by declining to promptly accept the patient from an arriving emergency medical service (EMS) unit or by failing to immediately triage or evaluate the patient to determine if the patient can wait on a stretcher with the EMS folks until a bed becomes available
   - **d.** Delaying the patient's medical screening examination (MSE) in the ED to triage the patient, and then for the emergency clinician to see the patients in the order based on the triage nurse's perception of the patients' acuity

Answer: C. Centers for Medicare and Medicaid Services (CMS) guidelines require the hospital to immediately triage ambulance patients arriving at the hospital's ED.

3. A 73-year-old woman is brought by private ambulance to the emergency department (ED) for shortness of breath. Due to ED overcrowding, there are several ambulance stretchers in line ahead of her at triage. At what point does the hospital accept responsibility for this patient?
   - **a.** When she was placed in the ambulance
   - **b.** When the ambulance arrived on hospital property
   - **c.** When the patient is seen by the emergency clinician
   - **d.** When the patient is seen by triage personnel

Answer: B. The Emergency Medical Treatment and Labor Act (EMTALA) defines the time of acceptance of responsibility as when the patient comes to the ED. In its EMTALA regulations, the Centers for Medicare and Medicaid (CMS) defines the term *comes to the ED* to include anywhere on hospital property, so the hospital's duty and responsibility for the patient are triggered when the ambulance arrives on hospital property.

4. A physician on-call for the hospital's emergency department (ED) has a duty under the Emergency Medical Treatment and Labor Act (EMTALA) to come to the ED under which of the following circumstances?
   - **a.** If asked to help stabilize a patient in the ED who has an emergency medical condition (EMC)
   - **b.** To help transfer a stable patient to another acute care hospital that has a specialist available that is not available at the transferring hospital
   - **c.** When asked to consult on a patient who has been stabilized in the ED and is being admitted by the patient's primary care physician
   - **d.** Whenever requested to come to the ED by the emergency clinician on-duty

Answer: A. Under EMTALA, the on-call physician only has a duty to come to the ED if needed to help determine whether the patient has an EMC or to stabilize an EMC. Any other requirements concerning when the on-call physician must come to the ED are governed by state law and/or by the hospital's medical staff bylaws, not by EMTALA.

5. According to the Centers for Medicare and Medicaid Services (CMS), which of the following patients may a hospital with specialized capabilities and available capacity refuse to accept in transfer solely because the patient is uninsured?
   - **a.** A patient with an unstable emergency condition admitted to observation at another hospital that is unable to stabilize the patient's condition
   - **b.** Any patient the hospital chooses to reject
   - **c.** An emergency department (ED) patient with an unstable emergency condition who is at another hospital that is unable to stabilize the patient
   - **d.** An inpatient with an unstable emergency condition at another hospital that is unable to stabilize the patient

Answer: D. CMS guidelines state that hospitals do not have to accept an inpatient, as defined by CMS, in transfer from another hospital under any circumstances, even if its decision to decline to accept the patient in transfer will result in the patient's death.

Quality Improvement and Patient Safety

Quality Improvement and Patient Safety

Bryan A. Stenson and Shamai A. Grossman

KEY CONCEPTS

- The work of health care occurs within a complex socio-technical system so that a change in even one component has an impact on other parts of the system and ultimately on safety.
- Patient safety and mitigation of risk emerges from multifactorial interactions within the clinical work system. Incidents of patient or staff harm are most often the result of system failures, not individual human error.
- Process improvements to clinical care often have unintended consequences elsewhere within the work system. Partnerships with information technology; cognitive, behavioral, and social scientists; and engineers can help reduce the likelihood of these events and improve adoption by workers.
- Don't set up reporting systems without the resources to fully analyze the reports.

PRINCIPLES

Background

Patient care in the emergency department (ED) begins with an initial decision by the patient (or caregiver or family) to seek emergency assistance and ends with the patient's disposition and follow-up. The care process is highly complex, with many separate components, people, and interfaces with other processes in the health care organization. This complexity provides many opportunities for process failures and adverse outcomes.

Although adverse events and failures in health care have been studied for decades, most health care professionals were largely unaware of this for some time. This began to change in the early 1990s when the Harvard Medical Practice Study reported that almost 4% of hospitalized patients suffered significant adverse events during their care and attributed a large proportion of those to "human error." Although that study noted that failures in ED care accounted for only 3% of all adverse events in hospitals, the authors (who did not have ED experience) judged more than 90% of ED events to be preventable. This study and others ultimately led the Institute of Medicine (IOM) to issue a report in 2000 titled *To Err Is Human: Building a Safer Health System*. This report provoked the interest of the media and the general public, and it thrust the issue of safety in health care onto the national agenda. The major accomplishment of the IOM report was the introduction of some of the fundamental concepts regarding safety in complex systems into the world of health care. The most radical concept was that most failures in care are not the result of poor decisions or incompetent practitioners but instead are related to the varied processes involved in patient care throughout the health care system. Thus, efforts to reduce these failures should be focused primarily on changing the processes of care rather than on identifying, retraining, or punishing the workers. Although retraining and reeducating providers may be included in improving the health care system, it is important to differentiate between error, which should not be penalized, and negligence, which may require disciplinary action.

Following the Institute of Medicine report, error was reported as the third leading cause of death in the United States (US) accounting for 250,000 deaths per year or 9.5% of all deaths.[1] Medical mistakes, medication, or test error rates have been reported in as many as 34% of all patients in the United States—the highest rate of any nation. A follow-up study performed 11 years after *To Err Is Human* found little improvement. Additionally, the quality of outpatient medical care underwent minimal improvement over the subsequent decade. Despite increases in pay-for-performance systems, patient-centered medical homes, public reporting programs, and other national efforts, many quality measures ranging from avoidance of inappropriate medical treatment to ordering recommended screening tests remained stagnant or worsened.[2] Although those early studies classified adverse event rates as 100% preventable, subsequent reviewers estimate only 3% to 5% of deaths to be preventable.[3]

Although systems rhetoric is abundant in discussions of patient safety, the majority of safety efforts to date still focus on the individual practitioner (e.g., "wash your hands, use the checklist, perform a timeout"). This view of how safety is created tends to perpetuate the longstanding practice of assigning responsibility primarily to those working closest to the patient, at the "sharp end" of care, while diminishing the responsibility of those farther away—managers at the "blunt end" of care.

Current solutions remain largely focused on rooting out "human error," resulting from the actions of a few practitioners who are not sufficiently accountable or attentive to safety. Educational efforts focused on adverse events testify to a persistence of this mentality. Punitive measures, such as suspension, termination, or in extreme situations, criminal indictment of health professionals caught up in a medical mishap, remain common.[4]

Root cause analysis (RCA), when used appropriately, can be valuable in allaying this mentality. RCA targets the identification and analysis of factors that result in adverse outcomes. RCA establishes which behaviors, actions, inactions, or most importantly, conditions lead to an error. This information can then be circulated, debated, and ultimately used to implement system improvements designed to reduce errors and improve outcomes.

RCA starts by describing the error and delineating the facts of the event. This is best done by utilizing a timeline outlining sequential events leading to each behavior, condition, action, and inaction, with demarcation within the timeline of the correct behavior and

deviations. To be effective, the analysis should investigate the relationship between contributing factors and the problem or event—the "multiple why method." By asking "why" sequentially through each phase and system involved in the case, one can identify the roots of the error within each step of the sequence that led to the problem or event. At the same time, RCA enables identification of all other potentially unsafe factors that could have brought about the root cause or error. The final step is to identify and address other related instances of potential harmful factors or outcomes. RCA should then determine corrective actions focused on preventing recurrence of each potentially untoward outcome.

Solutions must be within the institution's control, meet departmental goals and objectives, and must be measured after implementation to ensure that both the intended consequences occur and that unintended negative consequences are recognized and analyzed. In this chapter, we attempt to elucidate the abundant and varied sources of error and adverse events in emergency care including workspace design, communication, triage, transitions in care, crowding, cognitive processes, shift work, and medication administration. These represent many of the factors involved in health care delivery and components subject to breakdown and error often leading to adverse events. By uncovering these components during root cause analysis, targeted adjustments and changes to the health care system may be implemented.

Work Systems

Health care today has evolved far from its origins when independent practitioners acted as isolated agents. Today's work system requires the integration of humans, tools, and technologies to deliver a wide variety of clinical care in numerous settings from hospitals to freestanding EDs. The interactions among workers, technologies, and the organization determine the outcomes in the system, and in most cases the interactions among components are more important than the components themselves in causing errors and adverse events.

For example, unexpected downtime of two dialysis machines for several days in a dialysis unit markedly delays patients' treatments, increasing the risk of cardiac and respiratory complications from hyperkalemia and fluid overload. This results in an increased number of blood draws to check potassium levels, with increasing risk of needle sticks for workers, as well as the risk of internal shortages of medications for managing hyperkalemia. There may also be organizational consequences, such as overtime pay for dialysis staff to accommodate patients whose treatments were delayed. Finally, there is also potential for intensive care unit (ICU) admissions for patients who become unstable awaiting dialysis. Hence, any change in a work system, no matter how small, has implications for the system as a whole. This is encapsulated in the systems thinking adage that in a complex system, you cannot change only one thing.

Safety is commonly thought of in terms of a lack of danger and risk or the absence of something going wrong. This is predicated on the hidden assumption that safety is somehow the natural and normal state of the system and that adverse events are aberrancies that must have some special cause. This assumption is common in health care and has led to an emphasis on adverse events rather than error so that, unless an adverse event occurs, one may inaccurately assume that no error occurred. This obscures the concept that often there are numerous near misses—errors that fortuitously did not lead to an adverse event. For example, if a medication order entry system does not have an updated allergy list, a patient may be given a medication to which he or she has had a prior allergy. Thankfully in some instances patients do not have adverse reactions to erroneously administered medications. However, unless allergy warning systems are changed, another patient may receive the wrong medication and develop anaphylaxis.

Resilience

Not all deviations from guidelines or expected behavior are erroneous or unsafe in medicine. Real-life work adaptations rely on resilient behaviors that respond to current or potential problems that increase risk or delay completing the clinical work. For example, on a busy day a clinician asks for an intravenous (IV) line on a patient she has just seen before she goes to a resuscitation. The ED technician, seeing no labs have been ordered, "draws a rainbow" where he obtains blood from the patient and places a sample in every color of laboratory blood tube available. Organizational policy, however, requires blood not to be drawn until an order has been placed and a label generated for each tube. The technician draws a rainbow without orders because he: (1) knows that the patient has poor peripheral veins and does not want to have her suffer through another painful blood draw; (2) anticipates that he may not be able to get back and perform another draw once orders are in because he might be pulled to another area; and (3) believes the patient looks ill, so the physician is likely to order a number of tests when she returns.

This fairly simple workaround is an example of resilient behavior. The ED technician's decision to draw the blood despite the organizational policy requiring orders for drawing blood addresses a number of existing and potential obstacles to the patient's care. The technician's modification of work processes contributes to the patient's care and the ED's overall effectiveness. The majority of resilient behaviors in the ED are hidden (in part because they may involve bending the rules) and are done without any special thinking that "it's time to be resilient." Interestingly, seasoned nurses, technicians, and physicians can frequently be overheard orienting new staff to similar workarounds, because they have proven to help with workload management and to benefit patient care. Resilient behavior in health care can often be preventive, ameliorating adverse events, as illustrated in the following case.

A 24-year-old non-English-speaking long-limbed sailor presents to the ED with 3 days of intermittent pain and numbness in his left leg with recurrent brief episodes of dizziness and low blood pressure. On review of imaging, the emergency clinician notes a dramatically abnormal chest radiograph and intermittent hypotension, making the diagnosis of aortic dissection almost a certainty. A page to cardiovascular surgery goes unanswered, an atypical occurrence in this ED. Based on a hunch that perhaps the cardiovascular team is in the operating room, the provider turns to the unorthodox solution of calling the operating room and asks the nurse to pull up the patient's chest x-ray on the computer in the operating room, thinking this will most easily and effectively alert the surgeon to the need. This novel method for escalating an urgent case gets this patient with Marfan syndrome and aortic dissection into the operating room shortly after his arrival in the ED.

This is an important example of how a workaround strategy and extra steps contribute to resilience and potential improvement in healthcare delivery, avoiding potential errors in delay of care and subsequent adverse events.[5,6]

SOURCES OF FAILURE IN EMERGENCY CARE

Many characteristics of emergency medical practice make it vulnerable to error (Table e8.1). Studies have identified a number of unexpected yet highly consequential failures of information technology (IT) that are difficult to detect, some occurring during emergency resuscitations. Ergonomic shortcomings in the workplace have been identified with potential to contribute to failures in care. Studies have also shown significant delays related to ED layout, with time to assessment of chest pain patients being longer for patients placed behind a door or who were 25 feet or farther away from the physicians assigned to their care. This section focuses on some of the principal factors that contribute to

TABLE E8.1 Performance-Shaping Characteristics of the Emergency Department

Intrinsic[a]	Extrinsic[b]
Limitations of human cognition	High communication load
High levels of uncertainty	Poor teamwork
High decision density	Overcrowding
High cognitive load	Production pressures
Narrow windows of opportunity	High ambient noise levels
Multiple interruptions or distractions	Information gaps
Low signal-to-noise ratio[c]	Report delays
Surge phenomena[d]	Inadequate staffing
Novel or infrequently occurring conditions	Poor feedback
Patient factors (e.g., acuity, language, delirium)	Inexperience Inadequate supervision Sleep deprivation or sleep debt Fatigue Multiple transitions of care Poorly designed procedures ED layout

[a]Intrinsic factors are intimately part of the nature of emergency care and as such are not amenable to change but instead must be compensated for.
[b]Extrinsic factors are in principle manageable and typically relate to resource constraints.
[c]Low signal-to-noise ratio refers to the low likelihood of a critical diagnosis compared with a benign diagnosis for similarly presenting symptoms and findings (e.g., subarachnoid hemorrhage vs. tension headache).
[d]Surge phenomena are the rapid changes in volume and acuity routinely experienced in many EDs.
ED, Emergency department.

adverse outcomes and how they might be better managed to improve safety.

Communication and Interruptions

Emergency clinicians are interrupted, on average, approximately once every 6 minutes and two-thirds of the interruptions cause a change in task. Both interruptions and task switching have been shown to lead to errors. Self-detected errors occur in almost 20% of all ED cases but only 2% are associated with adverse events. Errors are ubiquitous but only rarely, when combined with other factors, produce adverse events. Therefore, in order to achieve improvement, it is important not to focus on eliminating errors alone, but to also understand the downstream negative consequences of interruptions and create mechanisms to prevent an error from becoming an adverse event.

Workspace Design

Two frequently overlooked contributors to lowered safety in any work environment are the design of the workspace and the availability of tools, technology, and procedures used to perform the work. This is especially true for EDs because many were not designed for the work currently being done in them. ED caregivers are required to adapt to the space by creating "workarounds" to cope with the limitations and impediments of the workspace.

There is often inconsistency in equipment across or between areas. For instance, the monitors in the ED are often not the same as those used in the radiology department or ICU. Similarly, tools and technology are seldom developed to be user friendly when integrated into an existing workspace. This is most apparent with regard to health IT.[7,8] Issues arising from health care IT range from poor user interface, to inaccurately copying information between patient charts, to missing important abnormal findings due to excessive alerts. Many of these functions were not designed with the providers in mind and often make the work more cumbersome and may inadvertently lead to errors. These potential pitfalls should not overshadow the possible benefits that technology can contribute. These include allowing patients to address medication reconciliation discrepancies at home, ensuring correct dosages and notifications of potentially dangerous medication interactions, and alerting providers to abnormal laboratory or imaging results.[9,10]

The contribution of a poor IT design and the difficulty in maintaining safety in a health care environment are generally overlooked by staff members who cope with these difficulties as "part of the job." Vigilance is the common solution, but despite caregivers' best efforts it cannot be sustained, given competing demands for their attention. This increases the risk that a failure will be linked to the workplace, the procedures, or the equipment, despite not being connected to any or all of these.

Crowding

ED crowding has long been recognized as a major source of time-delay failures and error and may be a threat to patient safety. Such delays are not simply an inconvenience to the patient but may give rise to significant adverse events. For example, patients with atypical presentations of severe illness who have been mistriaged to low levels of acuity may experience inordinate and, occasionally, fatal delays. In other cases, such as community-acquired pneumonia, cellulitis, and lacerations, more expedient care may significantly improve the outcome of the illness. A significant proportion of patients who leave the ED without being seen may have serious illness and incur delays in diagnosis and treatment. Similarly, when a patient is ready for admission to the hospital from the ED, further time-delay errors related to lack of inpatient space may occur. Not only do such delays create throughput problems and contribute to crowding, but they also create discontinuities in care and may lead to adverse events that are difficult to identify, because they manifest themselves after the patient has left the ED. The need to adapt to challenges created by crowding contributes to greater use of mental shortcuts and less accurate, efficient, and thorough decisions.

Information Gaps

Missing information is common in emergency care and can significantly affect quality of care. Hospital records, especially discharge summaries, details of past medical history, and other important information, are often difficult to access. Even with electronic medical records, pertinent information may be difficult to locate. Referral notes sent by family physicians with the patient may not reach the emergency clinician or may not contain relevant or significant details. In these situations, clinicians often make decisions and take action on the basis of incomplete, limited, or erroneous information. Emergency clinicians may not seek additional or clarifying information because of time pressures, patient volume, or limited methods to obtain more information (e.g., the referring physician's office is closed), essentially accommodating to this potential gap in continuity of care and its associated increase in patient risk for adverse events.

Performance-Shaping Factors

A wide variety of systemic conditions contribute to the majority of adverse events and near misses that occur in the ED (see Table e8.1). Some performance-shaping factors are part of the milieu of emergency medicine and thus not easily amenable to control (e.g., cognitive

workload, multiple distractions and interruptions, and high acuity). These factors must be managed by strategies that buffer or mitigate their effects. In contrast, other extrinsic performance-shaping factors reflect limitations of resources (e.g., staffing ratios, production pressure, and ED layout) and may be more amenable to improvement.

Violation-Producing Factors

Although at first one might think that violations of organizational policies, rules, and procedures would always cause failures and adverse events, as noted above, some violations may be necessary for the safe functioning of the system, and others fall somewhere in between. Aside from recklessness, drug use on the job or other egregious acts, more subtle factors can be associated with rule and safety violations and error. For example, the "normalization of deviance" is an accumulated acceptance of small variances from safe operating conditions that develops over time, ultimately compromising safety. This is evidenced in overtaxed EDs coping with crowding (e.g., examining and managing of patients in hallways). Violation-related error can also occur in response to perceptions of authority. This may occur through a directive supporting a policy violation from an authority figure (e.g., nursing supervisors order admitted patients moved to inpatient beds without patient sign-out if there are delays in reaching inpatient nurses), the absence of a disapproving authority (e.g., physicians leaving shifts early but the medical director does not address the behavior), or an individual's self-perception that he or she is authorized to disregard or to deviate from prescribed procedures (e.g., ED electrocardiograms done on patients in chairs because there are no available stretchers). Violations differ from workarounds in that violations tend to undermine safety and increase error and adverse events, whereas workarounds and extra steps support safety and mitigation of error, although at times it may be difficult to distinguish between a beneficial workaround and a potentially dangerous violation.

Teamwork

Good teamwork is essential to the safe practice of emergency medicine, but emergency caregivers are not trained or evaluated as teams. Teamwork training in other fields, such as aviation, has been successful in reducing error related to poor communication, cross-monitoring (observing others' behaviors to reduce risk of failure and share workload), and authority gradients (both within and between professions). Work on transferring teamwork training principles to emergency medicine suggests that teamwork failures are involved in approximately 40% of malpractice cases. Lack of cross-monitoring across team members and failure of advocacy on behalf of the patient by caregivers to avoid patient harm are two of the factors most frequently identified. Multidisciplinary teamwork training courses have often showed significant decreases in observed clinical errors. A multidisciplinary teamwork training course implemented in eight EDs showed a sixfold decrease in observed clinical errors. Teamwork is not a specific fix for any one type of error, but it should be viewed as one type of adaptable human factor intervention.

Efficiency/Thoroughness Trade-Off

EDs are under constant pressure to reduce waiting time and increase the throughput of patients. This forces a trade-off between improving efficiency and thoroughness. This tradeoff is seldom directly acknowledged in official policies, but it can be observed in the ED, especially when the volume is high. For example, the question "What is the one thing you are most worried about?" posed by a caregiver to a patient, may indicate that efficiency is the priority and send a message that there will not be an opportunity to address all of the patient's concerns or medical complaints. Although efficiency/thoroughness trade-off decisions are often not articulated explicitly, organizations and regulators implicitly and explicitly demonstrate the importance of efficiency in their monitoring of throughput goals, length of stay, patients leaving prematurely, and staffing and supply levels. Thoroughness in most settings often only arises secondarily from hindsight following an adverse event. Although simultaneous improvements in efficiency and thoroughness are sometimes possible, eventually every work system reaches a limit where improving one element degrades the other, leading to errors and adverse events.

Authority Gradients

Humans in groups often sort themselves by degrees of authority. This hierarchy can be based on profession (physicians have greater authority than nurses) or organizational rank (attending physicians have greater authority than residents). These authority gradients can impede the free flow of information among team members if low-authority members are intimidated by differences in seniority, stature, expertise, profession, or social status. There are many examples of cases in which authority gradients have been responsible for adverse events. For example, a nurse defers to a physician in prescribing the wrong medication dose, making the faulty assumption that "the doctor always knows best." A work environment in which all team members feel comfortable expressing their viewpoint, especially if it is a dissenting one, requires a cultural change that can begin with the physicians who occupy the highest authority position in the clinical setting. Authority figures can support a flattened hierarchy by openly recognizing the value of perspectives other than their own and eliciting them from other clinicians and staff (e.g., asking a nurse what they think might be going on with a patient). Senior clinicians are in a powerful position to bridge gradients by fostering open communication through multidisciplinary rounds, demonstrating that they are approachable (e.g., acknowledging staff by name), and using clinical narratives from their own experience that illustrate near misses and judgment failures.

Cognitive Processes

Patient care in the ED is a process of making clinical sense out of often ambiguous and interrupted stimuli and data. The goal of this process is an accurate diagnosis, if possible, or more commonly, to create a plan with which to guide testing, management, and disposition. Although many presentations, such as lacerations, dislocations, fractures, and foreign bodies, are self-evident, other chief complaints (e.g., chest pain, fever, headache, abdominal pain, and syncope) are often associated with high levels of ambiguity and uncertainty and are more likely to lead to error or adverse events. Cognitive biases are frequently identified retrospectively on root cause analysis, but prospective identification of these biases in order to avoid errors upfront is challenging.

Fatigue and Shift Work

Both fatigue and shift work contribute to error, yet relatively little research has been directed to their respective impacts on clinical performance in the ED. Although fatigue and shift work are often considered together, they are different entities and exert different effects on performance.

Shift work has extensive, well-documented, detrimental effects on health that in turn have an impact on well-being and job performance. Importantly, it leads to disruption of circadian rhythms that can result in sleep deprivation. This disruption largely occurs through missing sleep in the anchor period, approximately midway through the sleep phase when core temperature and arousal level are at their lowest. Decreased performance of someone who has been up all night has been described as roughly equal to that of a person with a blood alcohol level of 0.1% (Box e8.1).

BOX E8.1 Effects of Sleep Deprivation

Longer reaction time
Lapses in attention or concentration
Lost information
Errors of omission
Poor short-term memory
Poor mood (increased confusion, stress, and irritability)
Reduced motivation
Distractibility
Sleepiness
Poor psychomotor performance
- At circadian low points
- When sedentary
- On long, difficult, or externally paced tasks with no feedback
- In unchanging surroundings, particularly with reduced light or sound, or with low motivation, interest, or novelty

Modified from: Bonnet MH. Sleep deprivation. In: Kryger M, Roth T, Dement WC, eds. *Principles and Practice of Sleep Medicine*. Philadelphia: WB Saunders; 2000: 53-71.

The acute effects of sleep deprivation are well known, but the chronic effects are less appreciated. Working a night shift results in less sleep the following day, and subsequent sleep is often disrupted and fragmented in the struggle to restore the circadian rhythm before the night-shift cycle repeats itself. This results in the accumulation of a sleep debt that has a significant impact on performance. A study of anesthesia residents on a normal work schedule, with no on-call duty in the preceding 48 hours, showed daytime sleepiness scores comparable to those of patients with narcolepsy or sleep apnea. The on-call schedule of these subjects (five periods per month) entailed considerably less sleep deprivation and fragmentation than an average emergency clinician's schedule. Additionally, increasing age is associated with decreased tolerance for sleep deprivation.

Performance declines as work hours increase, but the optimal shift length in the ED is unknown and difficult to delineate for several reasons. The relationship between workload and acuity is not well defined, and some workers exhibit contradictory incentives, such as preferring to work longer shifts to get more days off. More recovery time between shifts might be expected to enhance job performance, but these issues remain relatively unexplored. A survey of emergency clinicians found a preference for 8-hour over 12-hour shifts, but it is not known whether job satisfaction in the ED translates into improved clinical performance and fewer adverse events. Additionally, many other factors contribute to the selection of optimal shift length when staffing an ED. Shorter shifts allow for potential flexibility to increase staffing during times of high volume. However, low-volume departments with limited staffing may have no other option apart from 12-hour shifts to fill the schedule. Longer shifts and increased fatigue may be necessary due to those external factors. Other conditions within the ED, competing commitments outside the ED, age, ill health, and other factors contribute to fatigue, with evidence pointing toward additional health implications for clinicians.

The appropriate management of shift work and fatigue to improve patient safety is not well understood, and further research is needed in this area. In most high-hazard industries, the assumption is that fatigue and long, aberrant work hours lead to poor performance; however, in the health care industry, issues about discontinuity of care have minimized these concerns. Given that medical personnel, like all human beings, function suboptimally when they are fatigued, efforts to reduce fatigue and sleepiness should be undertaken, and the burden of proof should be in the hands of the advocates of the current system to demonstrate that it is safe. In the meantime, shift scheduling should be optimized to reduce the impact of circadian disruption, and ED personnel should practice good sleep hygiene. Some basic approaches are listed in Box e8.2.

BOX E8.2 Rational Approaches to Shift Work

Optimize circadian-friendly schedules
Forward rotating (clockwise with circadian rhythms)
Rapid changes
Minimize consecutive nights (1 or 2)
24 to 48 hours off after nights
Allow social time, including some weekends
8-hour shifts (absolute maximum 12 hours)
Institute regular, predictable template
Practice proper sleep hygiene
Use a sleep-friendly room: room-darkening blinds, "white noise" (e.g., electric fan) or earplugs, no phones, family aware
Maintain a regular sleep routine
Try anchor sleep
Avoid caffeine, alcohol, and drugs
Prophylactic naps
Modulate circadian rhythms
Exercise
Consider bright light
Eat healthy
Eat a balanced diet
Avoid junk food
Keep regular mealtimes
Promote a healthy lifestyle and work style
Promote a personal healthy lifestyle
Educate friends and family about shift work issues
Educate colleagues about shift work issues
Advocate for department improvements in working conditions
Advocate for shift worker–friendly community services
Avoid pharmaceuticals
Use caffeine in moderation, prn
Do not use sedatives or stimulants
Avoid alcohol before sleep

PROBLEM AREAS IN EMERGENCY CARE

The mechanisms of error in emergency care are remarkably varied. Areas of consistent concern include triage, technical procedures, laboratory and radiographic tests, transitions in patient care, orphaned patients (patients who inadvertently are unassigned to a provider in the ED), and medications.

Triage

Triage, or sorting by acuity, is by definition an abbreviated decision-making process that can never be completely safe because of the limited information available, the lack of time invested, and the variety of presentations of illness and injury. Inevitably, the triage process

TABLE E8.2 Emergency Severity Index (ESI) Triage Criteria

ESI Level	Criteria
1	Requires Immediate Life Saving Intervention
2	High Risk Situation; Lethargic; Severe Distress; Dangerous Vital Signs
3	Multiple Required Resources, but Stable Vitals
4	One Required Resource
5	No Required Resources

Adapted from: Emergency Severity Index (ESI): A Triage Tool for Emergency Departments. Content last reviewed May 2018. Agency for Healthcare Research and Quality, Rockville, MD. https://www.ahrq.gov/patient-safety/settings/emergency-dept/esi/index.html.

involves tradeoffs between sensitivity and specificity. Undertriage for a particular patient would have a greater potential for an adverse event than overtriage, whereas overtriage affects resource utilization and may have an impact on the care of other patients.

Triage assessments are important contributors to process failures and adverse events. Beyond treatment delays, which can occur with undertriage or be produced by overtriage, an incorrect assessment may be the triggering event that initiates a chain of failures. An inappropriate triage to a specific treatment area may create a bias in the minds of the treating clinicians and staff. The emergency severity index (ESI) is one of the most popular and commonly used systems, with five levels based on risk and required resources (Table e8.2). While it offers a significant opportunity to reduce triage-related errors, it has shown poor reliability when compared across multiple countries.[11] Still, we believe it is the best current option available and is broadly employed across EDs in the United States.

Technical Procedures

The practice of emergency medicine requires proficiency in a wide range of procedures with varying degrees of difficulty. Patients who require procedures are at greater risk for adverse events. Contributors to this higher risk include problems developing expertise in low frequency but higher risk procedures. Critical procedures, such as cricothyrotomy, pericardiocentesis, and thoracotomy, are rarely or less commonly performed; when they are needed, they are highly consequential events involving significant time pressure. An important challenge in emergency medicine is the acquisition and maintenance of a requisite level of skill. Simulation techniques have considerable potential to ameliorate skill degradation but require both capital and human investment to be effective.

Laboratory Tests

The interface between the ED and its ancillary services is critically important. Errors can occur at three phases of laboratory processes. Pre-analytic errors mostly occur through inappropriate collection of specimens because of lapses in technique, timing, and identification of both patient and specimen. Analytic errors are those that arise directly from the testing process. Post-analytic errors occur after the test result has been obtained and can take many forms (e.g., keyboard entry errors, overlooked or lost data, or failure of results to reach the physician). The majority of failures occur in the pre-analytic and post-analytic stages, with less than 5% in the analytic stage. Overall, the laboratory defect rate is less than 1%, but the number of exposures is large. Of the failures that do occur, up to 50% may have a moderate impact and up to 8% a severe impact on patient care.

Radiology Studies

Radiographic imaging is a critical aspect of diagnosis and management in the ED. Although patient identification and wrong-side problems are important sources of failure, the majority of errors lie in interpretation. Assuming the radiologist's interpretation to be the criterion standard, the rate of error in interpretation by emergency clinicians may be as high as 16% for plain radiographs and more than double that rate for computed tomography scans. Clearly, not all misinterpretations are consequential, and emergency clinicians typically seek the advice of the radiologist when they recognize difficult interpretations. The introduction of digital imaging and picture archiving communications systems has resulted in new patient safety issues related to usability, the effect of monitor resolution on interpretation, and reconciliation of ED clinician and radiology readings. Significant interpretation errors can be detected with prompt review of all films by the emergency clinician and radiologist, but in the dynamic setting of an ED this is not always practical. Timely and appropriate feedback and review may help ameliorate future interpretation error. This approach has been demonstrated to substantially reduce the rate of clinically important misinterpretations.

Transitions in Patient Care

The need for 24-hour access to care and the fragmented nature of health care delivery require transitions of care between providers, either within the ED (at shift changes) or between the ED and other care areas (when patients are admitted, transferred, or discharged). The shift "sign-over," "sign-out," or "handoff" is generally thought of as a communication activity performed for the transfer of clinical information, but it also embodies the transfer of responsibility and authority from one provider to another. The sign-over also conveys general situational awareness (e.g., the state of the department, hospital, and city) and provides a forum for review of decision making and treatment plans.

Although transitions of care have been studied in recent years, few of these efforts have engaged with the cognitive, behavioral, and social sciences essential to a deep and systematic understanding of the problem.[12] Survey studies have shown that most EM residents learn to do handoffs informally without structured training, and programs don't properly evaluate handoff tools.[13] When viewed superficially, sign-overs seem highly variable in their content, the number of individuals involved, the physical configuration (e.g., walking, stationary, and at bedside), the tools used to facilitate the transition (e.g., white boards, medical records, and written notes), and the length of the transition process; however, they have a fundamentally similar deep structure. Although widely regarded as a major contributor to adverse events, sign-overs also provide an opportunity for review of decision making by clinicians and may provide opportunities for improved care by bringing "fresh eyes" to a patient's case. Potential threats to effective transitions include:

- Interruptions during the turnover (e.g., phone calls and sidebar conversations) can cause a loss of focus and lead to the omission of important information.
- Lack of consistent structure to the turnover. Although the traditional case presentation narrative is often followed (chief complaint, history, physical examination, initial laboratory results, impression, and plan), the case presentation format may not provide opportunities for noting pending or as yet uncompleted tasks.
- Patients are commonly labeled in ways that can sometimes be helpful but sometimes harmful, especially for at-risk groups such as the homeless, psychiatric patients, alcoholics, and drug abusers.

Given how high-risk these transitions of care are, it is important to take steps as a group to mitigate errors. Many institutions now require formal, structured sign-outs. The I-PASS study group is a notable

TABLE E8.3 Elements of the I-PASS Handoff System

I	Illness Severity	Stable, "watcher," unstable
P	Patient Summary	Summary statement Preceding events Emergency department course Ongoing assessment Plan
A	Action List	To do list Time line and ownership
S	Situation Awareness and Contingency Planning	Know what's going on Plan for possible events after handoff
S	Synthesis by Receiver	Summarization by receiver Asks clarification questions Restates key action items

example that implemented a pediatric handoff bundle and reduced preventable adverse events by 30% (Table e8.3). Other groups have taken a different approach, staggering the shift schedule in order to reduce the total number of patients undergoing a handoff from 7.9% to 5.9%.[14] Some groups have also studied methods of improving the handoff to the inpatient teams, with one study describing an electronic handoff as a useful method of improving efficiency of medical admissions while reducing interruptions to the ED provider.[15] All of these methods illustrate how critical this time is during patient care, and therefore is likely where meaningful change can occur.

Orphaned Patients

Orphaned patients are those who have suffered temporary loss or diminished supervision or accountability for their ED care. This may occur at several stages in the ED stay. Patients who are seen and assessed at triage and then go to the waiting room are temporarily orphaned. Those who are brought in by paramedics sometimes remain on stretchers for hours before being admitted to the ED. Patients who leave without being seen or before treatment is completed have "orphaned" themselves. Patients can also be temporarily orphaned out of the ED for radiographic studies or other special tests. On occasion, patients get "lost in the shuffle" and are overlooked at shift change, or they may get "lost" after one or more consultations with other services. With prolonged wait times, occult conditions can progress to serious and potentially catastrophic levels. A significant cause of orphaning in some EDs is the boarding of admitted patients because no inpatient beds are available. In such cases, patients may be put in holding areas in or adjacent to the ED and receive sporadic care from a succession of caregivers who know increasingly less about their conditions.

Medications

Medication errors constitute the largest proportion of care failures in most studies, with errors occurring in all six steps of the process (prescription, transcription, dispensing, administration, monitoring, and discharge). The attempt to bypass pharmacists while dispensing some ED medications also obviated their ability to identify and potentially correct errors. In addition, team communication errors can contribute to many failures—missed medications, wrong medications, and duplicate dosing. Pediatric patients are at higher risk. Although drug errors are no more common in pediatrics than in adults, they are typically more serious in children.

The presence of a pharmacist on the clinical team has been shown to reduce medication errors in several settings. There is great interest in the potential of computer technologies, such as bar coding and computerized physician order entry, to enhance medication safety. However, despite this potential, there is evidence that such systems introduce new problems to replace old ones. The Institute for Safe Medication Practices has recommended specific problem practices to be avoided in writing orders or prescriptions, such as avoiding error-prone abbreviations. Success in this area will require more than just individual attentiveness; nurses, unit secretaries, and pharmacists need to feel comfortable challenging improper use by physicians. Whether ED medication orders are reviewed by pharmacist pre- or retrospectively, an order should never placed with the assumption the nurse or pharmacist will contact the provider if it happens to be suboptimal.

SUMMARY

Having reviewed the wide range of variables in the ED, we can better understand which components play a role when errors and adverse events are identified and need review. Situations can be influenced by a multitude of factors that will need to be investigated during root cause analysis. For example, a diabetic patient undergoing ED workup fails to receive his correct dose of insulin, progressing to diabetic ketoacidosis requiring intensive care admission. Further review shows the patient had a prolonged ED course while awaiting imaging and inpatient bed placement and had multiple transitions of care during his stay. The adverse event occurring in this case may have been caused by multiple factors—the initial provider working too quickly and failing to order his home medications, the wrong dose/type of insulin ordered if his medications were not up-to-date, or poor communication during sign-out between providers. Additionally, ED crowding may have caused the backlog for imaging and bed availability, prolonging length of stay and leading to the patient being orphaned with less supervision from nurses and providers.

A similar case of multifactorial error can be seen in a patient who presents with a severe headache and has a head CT initially read as normal by the radiology resident. The ED resident discharges the patient based on this interpretation and fails to notice that the report has been updated by the radiology attending who noted an intracranial hemorrhage. This situation may have been impacted by poor verbal communication between departments, suboptimal alerts in the medical record indicating abnormal studies, or an authority gradient with the emergency and radiology residents not seeking counsel from their attendings sooner when they were uncertain of the imaging or safety for discharge. In both examples, figuring out where a lapse occurred allows for effective quality improvement by designing systems to prevent repeat episodes.

The safe management of patients in the ED depends on a multitude of processes. All appear vulnerable to error yet all have the potential for improvement through judicious process management. Efforts by front-line workers are not sufficient; considerable effort is required at the administrative or "blunt end" of the system as well. Root cause analysis must review, utilizing a step-by-step approach, each system involved in the health care process. The establishment and maintenance of a successful safety culture within health care requires acceptance by health care organizations, a willingness to adopt new ideas and tools from outside of health care, and a commitment to continued effort and investment.

CHAPTER E8: QUESTIONS AND ANSWERS

1. Which of the following triage assessments are important contributors to error in emergency medicine?
- **a.** Triage by age
- **b.** Triage by nursing personnel
- **c.** Inappropriate triage to a treatment area
- **d.** Triage based on comorbidities
- **e.** In-room patient triage and registration

Answer: C. An inappropriate triage to a specific treatment area may create a bias in the minds of the treating physician and staff, leading to delays in care or misdiagnoses. This may be more pronounced with undertriage versus overtriage.

2. A senior attending asks a resident to discharge a young patient with abdominal pain. The resident has noted lab abnormalities she believes merits further work-up, but assumes the attending has seen these results and defers to the attending's judgment. These abnormalities had in fact been overlooked by the attending and the patient gets sent home without appropriate work-up. This is an example of which potentially negative process?
- **a.** Authority gradient
- **b.** Anchoring
- **c.** Countertransference
- **d.** Fatigue and shift work
- **e.** Visceral bias

Answer: A. The hierarchical nature of medicine can lead to authority gradients which may contribute to errors. If a more junior member of the team does not feel empowered to voice a concern regarding patient safety, it can potentially have adverse consequences.

3. Which of the following may ameliorate the effect of shift work?
- **a.** Five consecutive night shifts
- **b.** Assigning more senior staff to nights only
- **c.** Sedatives
- **d.** Circadian schedule

Answer: D. A circadian schedule with forward rotating shifts has the potential to improve sleep habits for those with a rotating shift schedule. Excessive amounts of consecutive nights, sedatives, and increased night shifts for senior attendings are all poor strategies to deal with the burden of shift work.

4. Which of the following are more likely to cause error in emergency medicine?
- **a.** Low patient volumes, poor teamwork, electronic health record
- **b.** Inadequate supervision, high communication load, multiple transitions of care
- **c.** Overstaffing, multiple distractions, low numbers of transitions in care
- **d.** Physician salaries, language barriers, quiet work environment

Answer: B. Many factors affect an ED's performance, making it more at risk for a medical error (see Table e8.1). Although each choice contains at least one of these performance-affecting factors, only choice B contains three of the factors.

Patient Experience in the Emergency Department

Emily L. Aaronson and Benjamin White

KEY CONCEPTS

- Factors that can improve the patient experience in the emergency department include:
  - Communication that expresses empathy
  - Working as a high-functioning team
  - Setting realistic expectations regarding wait time
- Clear discharge instructions
- Improvement in the patient experience has been shown to impact composite outcomes such as health-related quality of life to patients, reduced malpractice risk, and improved staff satisfaction.

FOUNDATIONS

Patient experience is a growing area of focus in emergency medicine (EM). Increasingly, it is recognized that the traditional paradigm defining adequate care in the emergency department (ED) as providing the right diagnosis and medical management no longer suffices. Instead, there is a growing appreciation for the importance of providing a high-quality experience for patients that encompasses many aspects of their care in addition to their medical management. In addition, there is a new understanding that patient experience is a key driver of best care and is integral to many of the shared goals of both patients and health care providers. To that end, regulatory bodies have begun to embrace the importance of patient experience, and a new Center for Medicare and Medicaid Services (CMS) measure of patient experience in the ED, the Emergency Department Patient Experiences with Care (EDPEC) Survey, is currently under development.[1]

One impetus for increased focus on ED patient experience stems from the growing body of literature linking superior patient experience to important health outcomes. Optimal emergency clinician empathy and communication skill has been shown to impact composite outcomes such as health-related quality of life, various pain scores, anxiety, depression, as well as specific disease conditions such as asthma, blood pressure, diabetes, osteoarthritis, and weight loss. In addition to these important health outcomes, ED patient experience is also linked to staff experience and satisfaction, including staff burnout, prompting some to refer to these themes as "flip sides of the same coin."[2,3] For example, poor patient experience has been shown to increase patient complaint frequency and malpractice risk; at the same time, physician burnout has been associated with suboptimal patient care, and poor patient experience.[3] On the other end of the spectrum, optimal patient experiences and positive patient feedback can reduce depersonalization and emotional exhaustion, and increase joy at work.[4]

SPECIFIC ISSUES

Challenges and Opportunities

Despite the well-documented links between patient experience and health outcomes, providing high-quality experiences in the ED remains a challenge, and it has been shown that patients who enter the hospital through the ED often have lower overall satisfaction with their care.[5] To understand this, one must understand the key drivers of patient experience in the ED, among which are communication, wait times and timeliness of care, empathy and compassion, technical competence, information dispensation, pain management, and the environment of care.[6]

EDs are often challenged by limited physical space capacity and crowding, and subsequently by uncomfortable and chaotic care environments that lack physical privacy and in which effective communication is difficult.[7] The impact of crowding is likely attributable to some of the associated challenges related to timely, compassionate care and the provision of adequate analgesia, both of which are key drivers of patient experience.[8] As such, understanding the drivers of patient experience can help extrapolate the modifiable aspects of practice that will drive best practice in patient experience. These include excellent communication that demonstrates empathy, working as a high-functioning team, reducing or setting expectation regarding wait times, and clear discharge communication.

Focusing on Communication

Communication and empathy are widely recognized key drivers of the patient experience. These learned skills are ones that enable physicians to ask questions in a way that is maximally effective, listen in a way that enables patients to feel heard, and speak in a way that provides clarity and demonstrates empathy. Several programs appear in the literature to help teach skills for effective communication, including one in EM[9] and several in general internal medicine. Additionally, national academies have formed around the teaching and dissemination of health care communication, some with courses specific to ED providers.[10,11]

In addition to general patient-provider communication, specifically keeping patients updated on their care has been shown to be another driver of patient experience.[12] To that end, providers should focus on creating systems either within their own clinical practice, or by leveraging other team members within the ED, to ensure that patients are kept informed about their care throughout their stay in the ED.

The perception of a high-functioning team has also been strongly associated with better overall patient experience.[6] In the ED, however, it has been shown that patients often are not encouraged to ask questions and engage actively in decision making. To that end, engaging in experiences that cultivate the skills associated with high-functioning teams is recommended. Several different frameworks have been shown to be effective.[13,14] Examples of training curricula include Crisis Resource Management (CRM) and Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS). Both employ simulation-based training to cultivate nontechnical skills related to effective communication between team members.[15,16] The key principles include having strong leadership, situational awareness, a culture that allows for mutual support, and strong systems to support clear

communication. In addition to improving teamwork and improving safety in the ED, these interventions have also been shown to increase ED staff satisfaction and team morale.[19]

Wait Times and Expectation Setting

Wait times are a concern for virtually all patients, and a driver of patient experience. To that end, focusing efforts on throughput and efficiency are essential. In addition to systems solutions aimed at increasing care efficiency and decreasing actual wait time, there are also modifiable interventions that can be undertaken at the physician level. For example, setting expectations has been shown to be a powerful intervention related to wait times, with studies demonstrating that if patients are informed about the wait time, they are significantly more likely to report higher satisfaction with the time spent waiting.

In addition to expectation setting, another tactic that emergency clinicians in the ED can employ to cultivate a sense of presence with patients is sitting. This relatively straightforward technique has been shown to increase patients' perception of the clinician's skill in communication and listening, makes instructions easier to understand, and leaves patients with a more positive evaluation of the experience.[18] Additionally, it is well known that providers who sit are perceived to have spent more time at the bedside, without having actually spent more time, than those who stand. To that end, we recommend that when possible, providers integrate sitting during the patient interview into their practice. This may require advocacy within their departments to ensure that stools are available in the room or leveraging make-shift seats using available equipment.

Discharge Instructions

In addition to a strong association with important health care outcomes such as compliance with prescription and referral recommendations and decreased adverse events, the clarity of discharge information and instructions about at-home care have been shown to be associated with improved patient experience. This is not entirely surprising, because it is well accepted that patients' understanding of their diagnosis, treatment, and follow-up plan are often not optimal. In an era of lengthy after-visit summaries that are automatically generated from the electronic health record, this is a challenge. Indeed, the majority of ED encounters offer an opportunity for improvement, with only the minority of patients being given the opportunity to ask questions or confirm their understanding. Instead, providers spend significantly more time gathering information than they do giving information.

Organizations such as the Agency for Healthcare Research and Quality (AHRQ) have proposed a set of best practices to help guide the development of optimal discharge processes within EM. Among them is a clear communication checklist at discharge (including reminding the patient about what happened during the visit, including treatments, tests, and procedures; educating the patient about the diagnosis and treatment plan; discussing any new medications and setting clear expectation about the course of the illness and reasons to return). Other EDs have leveraged dedicated nurse discharge coordinators or implemented systems to schedule follow-up appointments during the ED encounter to improve the quality of discharge.

SUMMARY

The many facets of ED patient experience are a growing area of focus in EM and are of increasing importance for patients and providers alike. There is a strong link between high-quality patient care and excellent patient experience. Additionally, there is now evidence demonstrating that improving the patient's experience can improve staff satisfaction and morale as well. Although no single intervention or tactic has been shown to be sufficient for improving patient experience, it is possible to intervene on the most important causative factors, and myriad opportunities exist in most emergency care settings.

CHAPTER E9: QUESTIONS AND ANSWERS

1. Which of the following outcomes are impacted by patient experience?
   - **a.** Health-related quality of life
   - **b.** ED length of stay
   - **c.** ED return visits ("bounce backs")
   - **d.** Staff salaries

Answer: A. Patient-related outcomes (health-related quality of life, various pain scores, anxiety, depression, and specific disease conditions such as asthma, blood pressure, diabetes, osteoarthritis, and weight loss) and staff-related outcomes (improve experience, satisfaction, and joy at work and decrease burnout, depersonalization, and emotional exhaustion).

2. What is a key driver of patient experience?
   - **a.** Communication
   - **b.** Years of staff experience
   - **c.** ED boarding
   - **d.** Nursing ratios

Answer: A. Key drivers of patient experience are communication, empathy, expectation setting, and wait times.

3. What is an evidence-based practice you can use to improve your patient's experience?
   - **a.** Using a computer on wheels
   - **b.** Sitting in the room
   - **c.** Bedside rounding
   - **d.** Direct bedding

Answer: B. Sitting is a straightforward technique that has been shown to increase patients' perception of the provider's skill at communication and listening, makes instructions easier to understand, and leaves patients with a more positive evaluation of the experience. It has also been shown to result in patients' perception that emergency clinicians have spent more time at the bedside, without having actually spent more time, than those that stand. None of the other mentioned strategies have been studied in relationship to patient experience in the ED.

Wellness, Stress, and the Impaired Physician

Wellness, Stress, and the Impaired Physician

Lori Weichenthal and Julius (Jay) A. Kaplan

KEY CONCEPTS

- Physician Wellness: A quality of life that includes the presence of positive physical, mental, social, and spiritual well-being experienced in connection with activities and environments that allow physicians to develop their full potentials across personal and work-life domains.[1]
- Physician Burnout: A work-related syndrome characterized by emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment. It is frequently associated with chronic stress and emotionally intense work demands for which resources are inadequate. Physicians exhibit a higher rate of burnout than the general population, with emergency physicians experiencing some of the highest rates in the medical profession.[2-6]
- Stress: A nonspecific response of the body to any demand that can have both positive and negative effects. Without any demand, performance suffers. With too much stress, anxiety and exhaustion lead to poor performance.[1] Chronic stress is associated with burnout.
- Compassion Fatigue: Resulting from exposure to a traumatized individual, compassion fatigue has been described as the convergence of secondary traumatic stress and burnout. It can lead to a reduced capacity and interest in being empathetic toward future suffering.[7]
- Resilience: The ability of a person, community, or system to withstand, adapt, recover, rebound, or even grow from adversity, stress, or trauma. When considering individual resilience, personality traits such as optimism and altruism are found in resilient people, but behaviors such as mindfulness and reflective practices also aid resilience. External factors such as social support and good self-care are also important.[8-10]
- Impaired Physician: A physician who is unable to practice medicine with reasonable skill and safety due to mental or physical illness; due to a condition that adversely affects cognitive, motor, or perceptive skills; or due to substance abuse. Substance abuse has been described as a direct consequence of work stress and burnout for physicians.[1,11]
- A Systems Model of Physician Burnout: The process of physician burnout is complex and occurs within a multilevel system that includes the individual, the front-line care delivery team, the health care organization, and the external environment (governmental agencies, regulatory bodies, societal norms, etc.). To effectively address burnout, interventions must be directed at all levels of this complex system.[10]

FOUNDATIONS

Stress is a nonspecific response of the body to any demand that can have both positive and negative effects. Performance may suffer when there is little demand or stress; however, with too much stress, anxiety and exhaustion lead to poor performance (Fig. e10.1). Occupation stress, defined as when the resources of the individual are not sufficient to cope with the demands of the situation, is a leading modern health and safety challenge and is common in the emergency department (ED) setting.[12]

The ED is a highly demanding environment because of around-the-clock patient care in settings where life-threatening illness and injury occur with great frequency, and arrival volumes, patient acuity, and nature of emergencies rapidly and unpredictably shift. Patients frequently arrive in severe pain and anxiety, and care is often affected by language barriers, mental health issues, or many other circumstances presenting challenges in care and communication.

Emergency clinicians deal with death and dying on a daily basis and generally have little time to process emotions because of the continuous demand for patient care. This became more pronounced during the COVID-19 pandemic, when the stress and demand on emergency clinicians became tragically visible.

Personal safety is also a major issue while working in the ED environment where exposure to acts of violence, verbal abuse, and risk of exposure to potentially life-threatening diseases are higher than in other practice settings. In addition to the aforementioned stresses is the expectation of error-free practice and diagnostic certainty, with the constant possibility of human error, a missed diagnosis, and the attendant risk of medical negligence, an ever-present stress for emergency clinicians. The continued focus on the patient experience, with the threat of patient complaint and punitive action related to this, adds to this burden.[12]

The 24/7 nature of emergency medicine also creates unique physiologic stress on the emergency clinician due to changing shifts and its impact on circadian rhythms. Shift work has been shown to lead to poor quality of sleep, fatigue, and mood disturbance; challenges to maintaining relationships; and difficulty coping with the demands of daily life.[13]

Faced with decreased hospital and community resources and growing public demand for emergency services, EDs frequently are stretched beyond capacity by patient load and the boarding of admitted patients. This is further complicated by commonplace workforce shortages, nursing understaffing, and the lack of availability of on-call specialists. These issues have been shown to correlate with poorer patient outcomes and have led to a new culture in which productivity is often viewed as more important than providing safe, compassionate care.[14]

The introduction of electronic medical records (EMRs) has added a new stressor to emergency clinicians. Recent studies suggest that EMRs lead to increased administrative burden (more time charting, performing order entry, etc.) and less face-time with patients, resulting in decreased job satisfaction.[15,16] The EMR also interferes with physician-nurse collaboration and the fulfilling sense of being part of a team and working together, as communication moves from face-to-face personal interaction to an electronic interface. Communication overload, interruptions, multitasking, and performance-based targets add additional stress to providers in the ED.[12]

Given the high degree and multifactorial nature of occupational stress in the ED, it is not surprising that emergency physicians suffer from high degrees of burnout. Burnout is a work-related syndrome characterized by emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment.[2-6] The study by Shanafelt and company in 2012 found that emergency physicians had one of the highest rates of burnout when compared to other specialties, with over 60% of emergency physicians reporting one or more characteristic of burnout.[3] Subsequent surveys have demonstrated some improvement

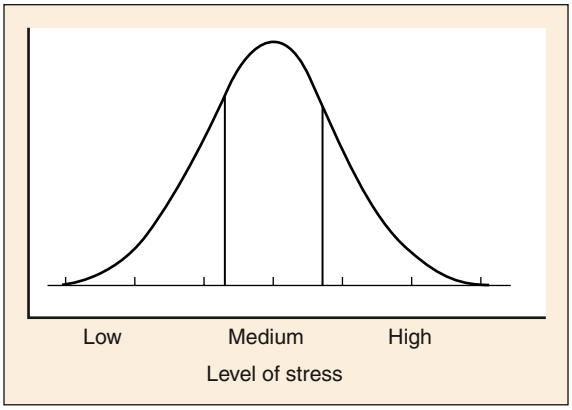

Fig. e10.1 The Yerkes-Dodson human performance and stress curve. (Yerkes RM, Dodson JD. The relation of strength of stimulus to rapidity of habit-formation. J Compar Neuro Psych. 1908;18:459-482.)

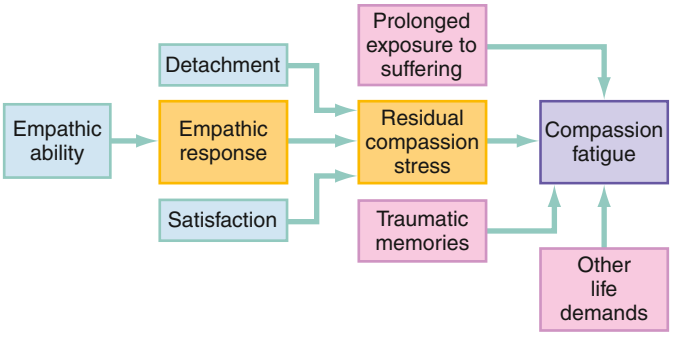

Fig. e10.2 Model of compassion fatigue. (Modified from: Figley CR. Compassion fatigue as secondary traumatic stress: an overview. In Figley CR, ed. Compassion Fatigue: Coping With Secondary Traumatic Stress Disorder. New York: Bruner/Mazel, 2005.)

in the rate of emergency physician burnout, but over 50% of emergency physicians surveyed in 2017 had symptoms of burnout, which remains above the level of many other specialties.[4,5]

Compassion fatigue also impacts emergency physicians at a higher rate than their colleagues and can be difficult to differentiate from burnout. Compassion fatigue has been described as burnout plus secondary traumatization. Secondary traumatic stress, which some describe as synonymous with compassion fatigue, is defined as the emotional and physical burden created by the additive trauma of helping others in distress that results in a reduced capacity and interest in being empathetic toward future suffering (Fig. e10.2).[17,18] Risk factors for emergency clinicians developing compassion fatigue include being in situations where they are a "first responder" or when they share some identity with the people for whom they provide care.[18] Along with leading to decreased empathy, compassion fatigue can also lead to sadness, grief, somatic complaints, detachment, anger, and changes in belief systems, which is similar to posttraumatic stress disorder (PTSD). Studies have shown that compassion fatigue impacts both residents and attending physicians in emergency medicine and may influence the desire of emergency physicians to seek early retirement.[17]

Resilience is defined as the process of adapting well and even thriving in the face of adversity, trauma, or significant stress.[9] Natural personality traits such as optimism and altruism help to support resilience; however, practices such as mindfulness and reflection are also important.[8-10] Personal resilience may have some protective benefit against burnout, but multiple studies suggest that personal resilience alone is not enough to protect emergency clinicians from the multifactorial issues that create burnout.[8,9,19]

Lack of wellness and resilience of emergency clinicians not only negatively impacts the personal and professional lives of the affected clinicians, but also has a significant impact on quality of care and the health care system as a whole. On the personal level, physicians experiencing burnout have higher rates of problematic alcohol use, distressed relationships, and depression.[2,10] At the far end of the spectrum of physician lack of wellness is physician impairment. The Federation of State Medical Boards defines an impaired physician as "one who is unable to practice medicine with reasonable skill and safety due to mental or physical illness; due to a condition that adversely affects cognitive, motor, or perceptive skills; or due to substance abuse."[1,11] Also of great concern, studies of physicians find burnout to be associated with a nearly 200% greater chance of suicide.[10] It is estimated that over 400 physicians die by suicide each year. As many as 6000 emergency physicians contemplate suicide and 400 attempt suicide each year.[6]

As concerning as the personal consequences of lack of wellness for emergency physicians are, burnout also has been shown to negatively impact quality of care and the patient experience. The presence of burnout leads to a decline in patient safety, and departments with higher burnout levels manifest a deterioration in teamwork and communication which has been shown to correlate with increased patient dissatisfaction and complaints by patients and families.[20,21] Physicians who are suffering from burnout have also been found to be less likely to follow practice guidelines and to self-report medical errors.[22,23] Physician burnout is also linked to increased absenteeism, reduced individual productivity, and increased likelihood of changing jobs or leaving the medical profession entirely.[10]

WELLNESS STRATEGIES

Individual

With the growing evidence of the burden of burnout, there has been increased focus on ways to mitigate its impact. For many years, the focus has been on educating physicians regarding self-care and tools to increase resilience. The current consensus, however, is that while it is important for physicians to focus on their own well-being, this alone is not enough to prevent burnout.[10]

Physical exercise has been shown to improve the mood of physicians and to help them cope with difficult situations.[24] Several small studies have shown that formal mindfulness meditation training can provide physicians and trainees with tools to help them deal with the burnout and manage stress.[25-27] Even small doses of mindfulness provided with the assistance of a mobile mindfulness app appear to be helpful.[28,29]

Peer groups that allow for reflection and sharing on the meaning inherent to the practice of medicine increase physician engagement and decrease depersonalization, a key component of burnout.[2,30] The benefits of such gatherings continue to show a positive impact, even a year after the termination of the intervention.

Health Care Organizations

To make meaningful progress in addressing the burden of burnout among health care professionals, change needs to occur within health care organizations. This begins with commitment from the highest level of the organization, including top executives and board leadership, that physician wellness is a top priority.[10] A strong business case exists for organizations to invest in and promote engagement in combatting and reducing physician burnout, including strategies of supporting executive leadership dedicated to improving and sustaining professional well-being across organizations.[31] Validated tools should be used to monitor the extent of burnout across organizations and in units/departments where significant burnout is discovered to develop interventions to reduce burnout and promote professional well-being.[10,31,32]

Many of these interventions will necessarily be focused on improving the work environment, including:

- Establishment of a culture of psychological safety and peer support;
- Alignment of incentives and rewards with the values of the professionals and the unit/department;
- Elimination of documentation and other administrative burdens that are not mandated and do not contribute meaningfully to patient care.[10]

After any intervention, the impact of the changes should be assessed by evaluating their impact on the well-being of the health care professionals in the unit/department where the changes were made. The results of this evaluation can be used to further refine the intervention or to suggest a need for re-direction and the need to attempt a different intervention.[31]

External Environment

The administrative burden of patient care that results from laws, regulations, policies through federal state or local government, accreditation bodies, and other standard-setting entities and agencies has also been identified as a major contributor to clinician burnout. There are proposed efforts to help address this issue by assessing laws and health care regulations and policies to determine their effects on clinician job demands, as well as their impact on patient care quality, safety, and cost.[10]

Requirements, such as those imposed by the majority of state licensing boards, that mandate physicians to report mental health histories including past professional support for mental health issues play a substantial role in physician burnout by exacerbating the already pervasive stigma regarding mental health conditions. This creates further disincentives for physicians seeking help to prevent or recover from burnout.[33-35] Efforts are underway across many states to recommend that state licensing boards either not ask about clinicians' personal health information or inquire only about current impairments due to any health condition that might negatively impact patient care. Other potential strategies include the development of legal protections through state legislative action to permit physicians to seek and receive assistance in support of the unique emotional demands of their professions as well as to manage any mental health conditions.[10]

Creating systemic changes to promote the wellness of health care providers will require a shift in culture, both within health care systems and in the external agencies that monitor and regulate them. This will require systematic efforts by policy-making bodies and other government and nongovernment entities, as well as singular commitments from health system leaders to ensure that clinicians and staff are included in the center of focus of putting patients, families, and caregivers first.

CHAPTER E10: QUESTIONS AND ANSWERS

1. Which of the following statements regarding factors that contribute to occupational stress of the emergency clinician are true?
- **a.** Emergency clinicians with experience are not significantly impacted by end of life issues in the emergency department.
- **b.** Personal safety is usually not a concern for the emergency physician as there is often sufficient security to guard against the impact of violence or verbal abuse in the ED.
- **c.** The expectation of error-free clinical practice is a major stressor for emergency clinicians.
- **d.** Most emergency departments are not significantly stressful environments because of the predictability of patient acuity and patient arrival volumes.

Answer: C. Personal safety is also a major issue while working in the ED environment, where exposure to acts of violence, verbal abuse, and risk of exposure to potentially life-threatening diseases is higher than in other practice settings. In addition to the aforementioned stresses is the expectation of error-free practice and diagnostic certainty, with the constant possibility of human error, a missed diagnosis, and the attendant risk of medical negligence as an ever-present stress for emergency clinicians. The ED is a highly demanding environment because of 24/7 patient care in settings where life-threatening illness and injury occur with great frequency, and where arrival volumes, patient acuity, and nature of emergencies rapidly and unpredictably shift.

2. What specific strategies exist to impact individual wellness for emergency clinicians?
- **a.** A focus on individual well-being alone is usually sufficient to prevent burnout.
- **b.** Vigorous daily exercise has been shown to improve the ability to cope with difficult situations but only improves mood less than 10% of the time.
- **c.** Peer groups that allow for reflection and sharing on the meaning inherent to the practice of medicine increase physician engagement and decrease depersonalization.
- **d.** Health care organizational engagement has little impact in individual physician wellness but can improve efficiency of care in the work environment.
- **e.** All of the above.

Answer: C. The current consensus suggests the importance of physicians focusing on their own well-being, but this alone is not enough to prevent burnout. Physical exercise has been shown to improve the mood of physicians and to help them cope with difficult situations. A strong business case exists for organizations to invest in and promote engagement in combatting and reducing physician burnout, including strategies of supporting executive leadership dedicated to improving and sustaining professional well-being across organizations.

3. Which of the following statements best describes physician burnout?
- **a.** A non-work-related syndrome characterized by emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment.
- **b.** Physician burnout is frequently associated with chronic stress and emotionally intense work demands for which resources are inadequate.
- **c.** Emergency physicians exhibit a lower rate of burnout compared to physicians in other specialties and to the general population.
- **d.** Physician burnout can often result in impairment that results in an inability to practice medicine and can lead to substance abuse.
- **e.** Both B and D are true.

Answer: E. Physician burnout is a work-related syndrome characterized by emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment. It is frequently associated with chronic stress and emotionally intense work demands for which resources are inadequate. Physicians exhibit a higher rate of burnout than the general population, with emergency physicians experiencing some of the highest rates in the medical profession.

4. A systems model of physician burnout includes all of the following features, except:
- **a.** The external environment
- **b.** Organizational support and buy-in
- **c.** Governmental agencies and regulatory bodies including licensing boards
- **d.** Religious factors

Answer: D. The process of physician burnout is complex and occurs within a multilevel system that includes the individual, the front-line care delivery team, the health care organization, and the external environment (governmental agencies, regulatory bodies, societal norms, etc.) (see Fig. e10.3). To effectively address burnout, interventions must be directed at all levels of this complex system

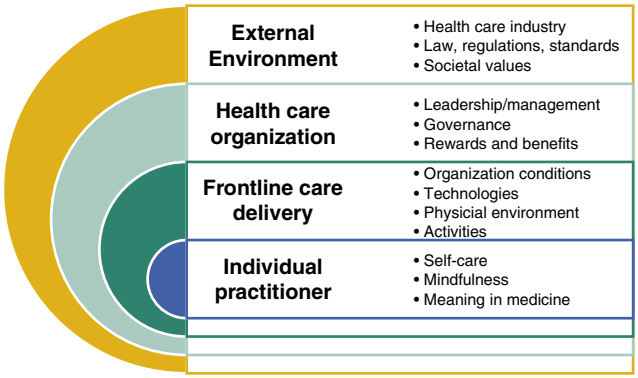

Fig. e10.3 The four levels of the systems model of physician burnout. (Modified from: National Academies of Sciences, Engineering, and Medicine. *Taking Action Against Clinician Burnout: A Systems Approach to Professional Well-Being*. Washington DC: The National Academies Press; 2019.)

Forensic Emergency Medicine

Adedamola A. Ogunniyi and Andrea W. Wu

Forensic Emergency Medicine

Adedamola A. Ogunniyi and Andrea W. Wu

KEY CONCEPTS

- Knowledge of wound mechanics, production, and appearance can provide practicing emergency clinicians with important clues regarding the forensic interpretations of injuries.
- Wounds and injuries should be diagrammed and photographed.
- The medical record should accurately document objective findings associated with a patient's wounds. Emergency clinicians should not speculate about their mechanism or cause.
- For the chain of custody to be preserved, any evidence collected during the course of treatment must be documented in the medical record, including to whom the evidence was given.

PERSPECTIVE

Clinical forensic emergency medicine is the application of forensic medical knowledge, techniques, and procedures to the management of patients in the emergency department (ED).[1] It is a key link through which patients or victims of violence can receive recourse for the actions against them. Emergency clinicians are in the unique position of being the first contact for most of these patients and play a crucial role in this process. They are also the clinicians who have the most contact with law enforcement and are therefore well suited to aid in evidence conservation. Many emergency clinicians have limited training in clinical forensic emergency medicine and, as such, critical information or data can be missed during these interactions.[1]

All patients who are victims of physical or sexual assault, abuse, or trauma have forensic needs. When treating injuries without consideration of their forensic significance, emergency clinicians may misinterpret wounds, fail to recognize signs of abuse or intimate partner violence, and inadequately describe the physical appearance of the wounds. During the provision of patient care, evidence that can be of critical significance to criminal or civil proceedings may be lost, discarded, or inadvertently washed away, despite requirements by the Joint Commission to "preserve evidentiary materials and support future legal actions." Prior studies have shown that evidence may be accidentally discarded during the initial evaluation and that injuries are also improperly documented.

Emergency medicine programs have identified and described the need for forensic training in their residency curricula. The American College of Emergency Physicians established the Forensic Medicine Section in 2006 to provide emergency clinicians with additional forensic resources and training. Unfortunately, no formal training programs currently exist in the United States. In contrast, the British Royal College of Physicians established the Faculty of Forensic and Legal Medicine (FFLM) in 2006 as the authoritative body on clinical forensic medicine in the United Kingdom. The FFLM has created training and certification programs and board-type certification examinations after 2 years of forensic practice for British physicians.[2]

There are several important ways to address this gap through training and exposure to clinical forensic emergency medicine. Forensic examinations should be conducted with the consent of the patient, legal guardian or court, or by implied consent. The evaluation should include a history and physical examination in which all wounds are documented and described in as much detail as possible, as well as photographs and anatomic diagrams.[1] Even simple findings, such as contusions or ecchymoses associated with injuries, may serve as important clues as to how the injury was sustained and may be invaluable in future legal proceedings. Evaluations of gunshot and stab wounds, physical or sexual abuse, intimate partner violence, and motor vehicle–related trauma should also be adequately documented for possible use as evidence. Documentation should include digital photographs (whenever possible based on the patient's clinical condition) as well as a narrative and diagrams.

Evidentiary material, such as clothing, bullets, and shrapnel, should be collected.[1] Clothing should be stored in a paper bag because plastic bags retain moisture and can promote bacteria growth, which leads to degradation of DNA; bullets and other metallic foreign bodies should be handled minimally and with gloved hands. Contact with metal instruments should also be avoided because these can alter the markings present.[1]

When physical injuries are misinterpreted and these misinterpretations are entered into the medical record, or when valuable evidence is lost or destroyed in the process of providing patient care, there are consequences for the legal proceedings that may follow.[2] These acts of omission or commission may deny patients their deserved redress in the justice system. A proper understanding of the forensic relevance of certain observations is the key to protecting the rights of victims of assault.

FORENSIC ASPECTS OF GUNSHOT WOUNDS

Background

Ballistics

Ballistics is the science of the motion of projectiles in flight.[3] Ballistic physics is broken down into three parts, based on the material with which the bullet interacts:

1. Internal ballistics, which pertains to the projectile while in the firearm
2. External ballistics, or the path of the projectile from when it leaves the firearm until it reaches the target
3. Terminal (or wound) ballistics

Internal ballistics factors in the design of the firearm and how the combustion of gunpowder within the firearm generates the pressure that subsequently projects the missile. External ballistics takes into consideration the effects of gravity and drag on the missile and how they affect the distance travelled and the accuracy with which it hits the intended target.

Wound ballistics is the most clinically relevant because it is the study of the effects of penetrating projectiles on the body. Tissue disruption (wound severity) is directly related to the amount of kinetic energy (KE = ½mv^2 [m = mass; v = velocity]) transferred to it, not to the total amount of kinetic energy possessed by the bullet. There are two broad categories of weapons based on the amount of potential kinetic energy that can be transferred from the missile to the tissue:

1. High-velocity weapons, which generate projectile velocities ranging from 1500 to 4000 ft/s (or >600 m/s). Examples of these are rifles or military weapons. Consequently, bullets fired from such weapons possess a higher kinetic energy and therefore theoretically have greater wounding capacity.
2. Low-velocity weapons, which generate projectile velocities ranging from 700 to 1600 ft/s (or <600 m/s). These weapons include handguns, shotguns, and air rifles (such as ball-bearing [BB] guns).

Rifle bullets have more kinetic energy and a theoretically higher wounding potential, but energy transfer (and, by extension, wound severity) is the result of multiple variables. The most important are bullet type (e.g., weight, deforming type, fragmenting type), bullet velocity, and the characteristics, location, and nature of the impacted tissue itself (tissue over bone or tissue over organs).[4] The formula KE = ½m(V_1 − V_2)^2 better reflects the actual energy transfer occurring during tissue penetration and wounding.[4]

The principal mechanism for tissue damage by bullets is crushing. A bullet traveling through tissue generates two cavities, one permanent and the other temporary. The size of the permanent cavity varies with the size, shape, and configuration of the bullet. A hollow point bullet that mushrooms can increase its diameter 2.5 times on impact and will increase the area of tissue crush 6.25 times compared with a non-deformed bullet. The temporary cavity results from a shock wave generated as the bullet enters the tissue, which results in a brief distortion or stretching of the tissue. This tissue distortion lasts for a brief amount of time, 5 to 10 milliseconds from its generation until its collapse, and leaves behind crushed tissue and the permanent cavity. The size of the temporary cavity is also dependent on bullet/missile mass and velocity, and the resulting effect depends on the elasticity of the tissue traversed. Solid organs such as the liver, bone, or kidneys do not tolerate this temporary deformation as well as more elastic tissue (such as lungs, skeletal muscle, skin), and therefore sustain more damage. Secondary wounding can occur in situations in which the bullet hits a target (usually bone) and fragments disperse, causing further tissue damage.

Forensic Evaluation of Handgun Injuries

The Weapon. Handguns are the most common firearm available. There are four categories of handguns: (1) the single-shot weapon (usually a target pistol); (2) the derringer (a small, concealable weapon, usually with two barrels); (3) the revolver (a weapon with a rotating cylinder that advances with the pull of the trigger); and (4) the semiautomatic pistol (which fires with each pull of the trigger). The semiautomatic handgun is the most popular because its magazine (or clip) can hold up to 17 cartridges, whereas revolvers hold five or six cartridges.

Handgun Ammunition. The cartridge, or round, is composed of the primer, cartridge case, powder, and bullet (Fig. e11.1). The bullet is the projectile that is propelled out of the muzzle. The primer is a small explosive charge in the base of the cartridge that ignites the gunpowder. The primer may contain lead, barium, or antimony. These materials may be deposited on the hands of the shooter, on the victim of a close-range assault, or on objects within a room in which the weapon was discharged.

The cartridge case is typically made of brass, although other materials may be used. The function of the cartridge case is to expand slightly, sealing the chamber against the escaping gases and propelling the bullet down the barrel. On detonation, a cartridge case is imprinted with unique microscopic marks that are valuable evidence and should be preserved for law enforcement.

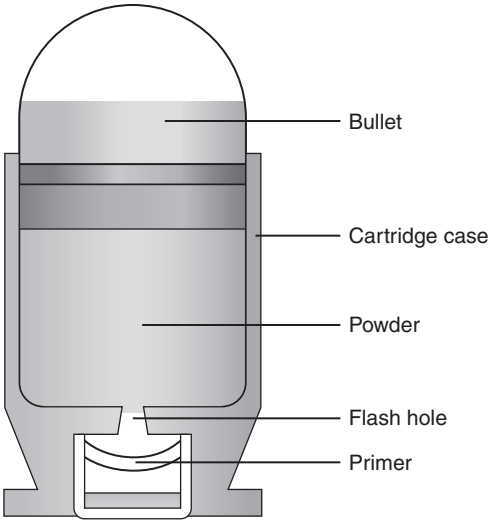

Fig. e11.1 A cartridge consists of several distinct components—bullet, cartridge case, gunpowder, flash hole, and primer.

The gunpowder found in all commercial cartridges except blanks a smokeless powder made with a single base (nitrocellulose) or a double base (nitrocellulose and nitroglycerin). When a weapon is discharged, not all the gunpowder is consumed. A percentage of the unburned or partially burned gunpowder will travel out of the end of the muzzle for a short distance (<48 inches or 60 cm). The distance depends on the physical characteristics and shape of the powder and the weapon's barrel length.

Blank cartridges, muzzleloaders, and other antiques or replicas may use black powder. Black powder (a combination of potassium nitrate, charcoal, and sulfur) does not burn as efficiently as the smokeless powder and results in a large flame and white smoke. As such, black powder can produce powder burns by igniting clothing.

The bullet is the projectile that is propelled down the gun barrel at velocities ranging from 700 to 1600 ft/s (213 to 488 m/s). The higher velocities are achieved by the inclusion of supplemental gunpowder in the cartridge case (a magnum load; hence, a .357 magnum). The diameter of the bullet's base is termed its *caliber.* Bullet caliber is described in hundredths of an inch or millimeters. Handgun bullets range from .22 caliber, or 5.56 mm, to .45 caliber, or 11.3 mm. A bullet's weight is measured in grains, with 7000 grains/lb.

The most common bullet types are the round nose, full metal jacket, hollow point, wad cutter, and semi–wad cutter. Bullets generally are a solid core of lead or steel. If a jacket covers the bullet core, the jacket's metal is usually copper or aluminum. If the jacket covers only a portion of the core, the bullet is said to be semijacketed. If the core is completely covered, it is said to have a full metal jacket. Some bullets have a hole in the tip and are called hollow points. The hole causes the bullet to expand on contact, which significantly increases the damage to tissue.

Forensic Aspects of Rifles

Rifles are shoulder-fired weapons designed to generate significant pressures in the muzzle and, as such, result in firing of ammunition at high speeds. Centerfire rifle bullets, .223 to .308 caliber, are similar in diameter to handgun ammunition but, based on the formula for kinetic energy (KE = ½mv^2), their wounding potential is greatly enhanced by the higher velocity of the round. Injuries result from the transference of energy from the projectile to tissue, organs, and bony structures.

With medium-velocity rounds (2000 to 3000 ft/s, approximately 600 to 900 m/s) and high-velocity rounds (>3000 ft/s), a temporary cavity is formed along the wound tract, which may be 11 or 12 times the diameter of the bullet. High-velocity rounds can also cause tissue damage away from the physical track taken by the projectile. Because of the amount of energy possessed and transferred to underlying tissue, exit wounds associated with centerfire rifles, in contrast to those associated with handguns, are generally larger than their corresponding entrance wounds (Fig. e11.2).

Forensic Aspects of Shotguns

Shotguns are similar to rifles, but the missiles are multiple small projectiles, all of which have the potential to cause injury. Shotguns have the barrel length of rifles but can discharge pellets or single slugs down a smooth bore barrel. The caliber of a shotgun is defined by the term *gauge*. Historically, the gauge of a gun referred to the number of lead balls of the given bore diameter that make up a pound—for example, 12 lead balls to make 1 lb. A shotgun cartridge may contain only a single slug or may contain hundreds of pellets (Fig. e11.3A). Pellets range in diameter from 0.05 inch (#12 birdshot) to 0.36 inch (000 buckshot). A shotgun cartridge is made of several components that will be of forensic value and should be collected in the ED (see Fig. e11.3B).

Shotgun slugs are projectiles that may weigh 200 times more than handgun ammunition; for example, a 12-gauge slug weighs 547 g, and a .22 long rifle bullet weighs 2.6 g (see Fig. e11.3B). The velocities of shotgun slugs are in the range of 1500 to 1800 ft/s (457 to 549 m/s). The sabot is the structure that helps seat the shotgun slug and allows it to be fired at higher muzzle velocities. These are usually made of lightweight materials such as plastic, carbon fiber, or light metals (such as aluminum). Sabots themselves can cause injury if they make contact with tissue.

Fig. e11.2 This patient sustained a high-velocity gunshot wound to the forehead. High-velocity rifle rounds, due to their kinetic energy, can cause massive damage when the energy is transferred to underlying tissue.

Forensic Aspects of Air Guns/Rifles

Air guns/rifles (such as BB guns and pellet air guns) work very similarly to traditional firearms and generate muzzle velocities comparable to low-velocity weapons. As such, they possess enough kinetic energy to cause injuries because they can penetrate tissue, and particularly because they are often fired at close range. In fact, recent studies have shown that these weapons pose a significant health concern, particularly in the pediatric population.[5]

Epidemiology

According to the National Vital Statistics report from the Centers of Disease Control and Prevention (CDC), 39,773 people died from firearm-related injuries in the United States in 2017 with about 14,542 being firearm homicides.[6] On average, 645 people die from firearm violence a week and 1565 more are treated in an emergency department for a firearm-related injury.[7,8] A recent study by Fowler et al. provided similar information; on average between 2010 and 2012, over 32,000

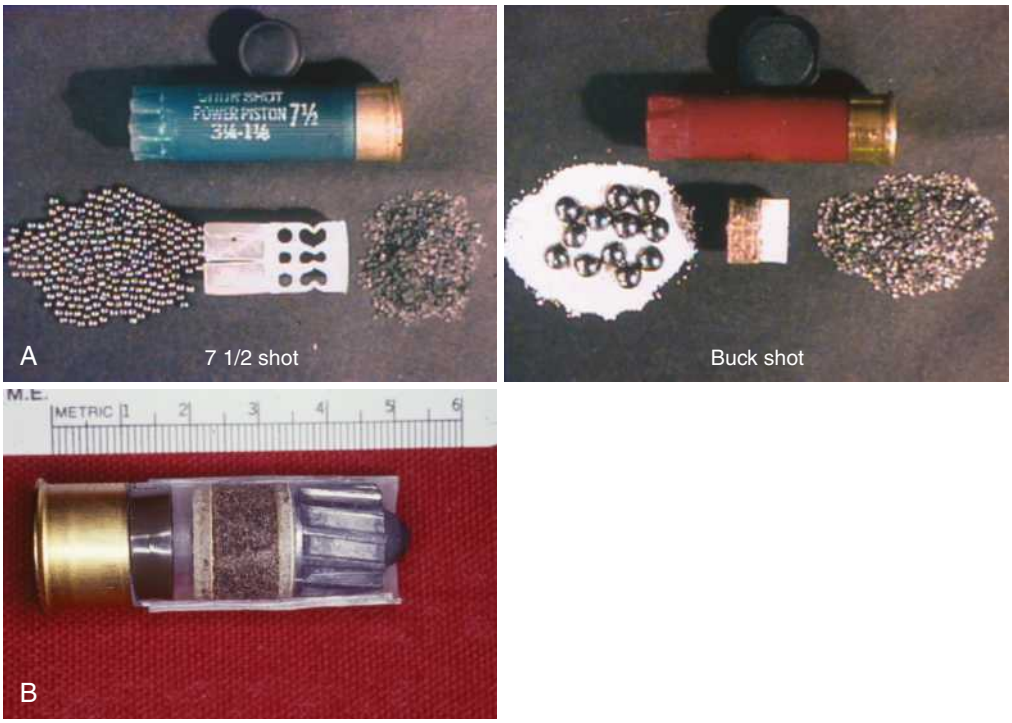

Fig. e11.3 (A) Shotgun cartridges may contain eight to hundreds of pellets. (B) A single shotgun slug and components of the cartridge.

people died and over 67,000 people were injured by firearms per year, with case fatality rates being the highest for self-harm–related injuries (85%), followed by assault-related injuries (19%).[8] Studies have suggested that the rates of firearm violence (nonfatal and fatal) declined and then stabilized over the last few decades; however, when disaggregated, unintentional firearm deaths appear to have declined while rates of firearm suicide and nonfatal firearm assaults have increased.[8] While the number of firearm injuries have stabilized, the mortality rate has largely remained unchanged.[9-11]

Firearm injuries occur predominantly in certain groups, particularly in young people, males, and racial/ethnic minorities.[8] The rates of fatal firearm injuries are highest in males aged 25 to 34 (followed by those aged 15 to 24), with homicides being more common in this age range.[8] Firearm injury rates on the whole are highest in males between the ages of 15 and 45 years old, particularly in those of African American ethnicity.[8,11] Suicides are more common than homicides, and the incidence of the latter appears to be decreasing. Suicides accounted for 60.5% of all firearm fatalities from 2002 to 2012[11] and tend to be more common in those over the age of 65 and in non-Hispanic white males.[8] In a recent study, firearm homicide was the leading cause of death in African American males aged 15 to 34 years in 2012 and was the second leading cause of death for whites or Hispanic males of the same age range.[11] Firearm violence was the second leading cause of death in females aged 15 to 24 years.[11] In contrast, suicide rates were higher in white males, and the divergence increased with age, starting in adolescence.

Hospitalizations for nonfatal firearm injuries have followed the same trend: males account for 90% of nonfatal firearm visits to the emergency department and young people under the age of 35 are responsible for 72% of nonfatal firearm ED visits.[8] Stray bullet injuries are also important because they frequently affect females, children, or older adults, who may not have any relation to the associated violence.

Firearm injuries are not limited to adults. Firearm homicide is the leading cause of death in African American youth aged 14 to 24 years and the second leading cause of death in other youth, regardless of age or race.[12] Firearm-related deaths are the third leading cause of mortality among US children aged 1 to 17 years and are the second leading cause of injury-related death in this age group, surpassed only by motor vehicle injury deaths.[13] The American College of Surgeons issued a report in 2013 stating that firearm injuries were the second leading cause of death in pediatric trauma centers.[14,15] A recent study showed that approximately 1300 children (aged 0 to 17) died and 5790 were treated for gunshot wounds annually from 2012 to 2014, with a higher case fatality rate for self-harm injuries.[13] Males, children aged 13 to 17, and African Americans had disproportionately higher rates of mortality from firearm injuries.[13,16] While unintentional injuries and homicides have declined, there has been an increasing trend of firearm suicides, as noted by Fowler.[13] The medical impact is significant. A recent study noted that there were 21,416 pediatric ED visits in those younger than 19 from 2009 to 2014 based on data from the National Trauma Data Bank[16]; these patients were more likely to be male, African American, aged 12 to 18 years, and victims of assault.[16]

Air rifles and other nonpowder firearms also contribute to the prevalence of firearm injuries. A recent review noted that there were approximately 10,288 pediatric air gun injuries in 2011 in patients under 19 years of age[5] and another study by Jones *et al.* showed that on average, 13,486 pediatric non-powder firearm injuries are treated in US EDs annually (in patients < 18 years).[17]

To manage patients with firearm-related injuries properly, it is also important to have a thorough understanding of the pathophysiology involved. Several misconceptions exist in the management of these injuries, such as a poor understanding of wound sterility following gunshot injuries, the need for wound debridement, and the need for prophylactic antibiotics.[4] A study published in 2015 showed that such misconceptions were prevalent and were not influenced by prior Advanced Trauma Life Support (ATLS) training.[4] As such, focused training in forensic medicine is necessary to improve knowledge and the ability to treat these patients adequately.

Clinical Features

Errors of Interpretation and Terminology

Emergency clinicians are in the ideal position to evaluate and document the state of a gunshot wound because they see and explore it before it is disturbed, distorted, or destroyed by surgical intervention.[1] Documentation of gunshot wounds should include the anatomic location of the wound as well as its size, shape, and distinguishing characteristics. Digital photographs of the wound should be taken whenever possible with a ruler for size reference. Wounds should be described according to the standard anatomic position, with the arms to the sides and palms facing forward.

Emergency clinicians should not describe wounds as "entrance" or "exit" but, using appropriate forensic terminology, should document a detailed description of the wound, including its appearance, characteristics, and location, without attempting to interpret the wound type or bullet caliber.[1] Exit wounds are not always larger than entrance wounds, and wound size does not consistently correspond to bullet caliber.[1]

The size of any wound (entrance or exit) is determined by five factors—the size, shape, configuration, or angle, and velocity of the projectile at the instant of impact with tissue and the physical characteristics of the impacted tissue itself. If the projectile is slowed and its shape unchanged on exiting the skin, the exit wound may be the same size as or smaller than the corresponding entrance wound. If the projectile increases its surface area by fragmenting or changing its configuration while maintaining a substantial velocity, the exit wound may be significantly larger than the entrance wound. If the bullet strikes bone, fragments may extrude from the exit wound and contribute to the size and shape of the wound. Tissue elasticity also affects wound size so that entrance or exit wounds may be smaller, equal to, or larger than the projectile that caused them. Wounds on the palm or sole may appear as slits and can be easily mistaken for stab wounds.

A treating emergency clinician may be requested to render factual testimony, expert testimony, or both in a criminal case. Expert forensic testimony rendered without an appropriate forensic examination or adequate forensic training may mislead participants in the criminal justice system (e.g., "the exit wound is always larger than the entrance wound"). Opinions related to entrance versus exit wounds or the range of fire can affect the determination of innocence or guilt and should not be used except by trained practitioners.

The subsequent sections highlight the clinical features of entrance and exit wounds that result from the use of different types of firearms. This information is provided to make emergency clinicians aware of the varying presentations, depending on the distance from the target. Clinicians should refrain from speculating on the type of wound and simply document the findings noted on examination.

Handgun Entrance Wounds

Range of fire is the distance from the muzzle to the victim and can be divided into four general categories: contact, near-contact or close range, intermediate or medium range, and indeterminate or distant range (Table e11.1). The size of the entrance wound does not correlate with the caliber of the bullet because entrance wounds over elastic tissue will contract around the tissue defect and have a diameter much less than the caliber of the bullet.

TABLE E11.1 Range of Fire

Range	Inches/Centimeters (Barrel to Skin)	Physical Properties
Contact	0	Soot, seared skin, triangular tears
Close	0–6 (0–15cm)	Soot, abrasion collar (abrasion collar may be obscured by soot)
Intermediate	<48 (<121cm)	Tattooing, abrasion collar
Distant or indeterminate	Any distance	Abrasion collar (intermediate objects will prevent soot and gunpowder from contacting the skin)

Contact Wounds. There are three subcategories of contact wounds: (1) tight contact, in which the muzzle is pushed hard against the skin; (2) loose contact, in which the muzzle is incompletely or loosely held against the skin; and (3) contact through clothing.

In a tight contact wound, all materials—the bullet, gases, soot, the incompletely burned pieces of gunpowder, and metal fragments—are driven into the wound. These wounds can vary from a small hole with seared blackened edges from the discharge of hot gases and an actual flame to a gaping stellate wound (Fig. e11.4). Large wounds occur when the wound is inflicted over thin, inelastic, or bony tissue, and the injected hot gases cause the skin to expand until it stretches and tears. These tears will have a triangular shape, with the base of the triangle overlying the entrance wound. Tears are generally associated with .32 caliber or greater, or with magnum loads. Large stellate contact wounds are easily misinterpreted as exit wounds if the determination is based solely on their size (see Fig. e11.4B).

Stellate tears are not pathognomonic for contact wounds, however. Tangential wounds, ricochet or tumbling bullets, and some exit wounds may also be stellate. These wounds' appearance differs from that of tight contact wounds by the absence of soot and powder within the wound and a lack of seared wound margins.

In some tight contact wounds, expanding skin is forced back against the muzzle of the gun, leaving a characteristic muzzle abrasion or muzzle contusion (Fig. e11.5). Patterns such as these should be documented before wound débridement or surgery because they are helpful in determining the type of weapon used (revolver vs. semiautomatic).

When a gun's muzzle or barrel is in loose contact with or is angled to the skin, the soot and gunpowder residue are present within and surrounding the wound. The angle between the muzzle and skin determines the soot pattern. A tangential, loose, or near-contact wound produces an elongated searing and soot deposit surrounding the wound. Discharge of a weapon in contact with clothing results in the gases and soot being deposited between the garment and skin. This results in a diffuse pattern of soot surrounding a wound, with seared margins (see Fig. e11.4C).

Close-Range Wounds. Close range is the maximum range at which soot is deposited on the wound or clothing. The muzzle to target distance is usually less than 6 inches (15 cm) but may be as much as 12 inches (30 cm). Beyond 6 inches, most of the soot usually falls away and does not reach the skin or clothing. The concentration of soot varies inversely with the muzzle-to-target distance and is influenced by the type of gunpowder and ammunition used, length of the weapon's barrel, and caliber and type of weapon itself (Fig. e11.6). A precise range of fire (e.g., 2 vs. 5 inches) cannot be determined from examination of the wound alone. Because soot can be removed with débridement or wound cleansing, its presence and configuration around the wound should be noted and photographed before débridement unless the patient's clinical condition precludes this.

Intermediate-Range Wounds. Tattooing, or stippling, is pathognomonic for an intermediate-range gunshot wound. Tattooing appears as punctate abrasions and is caused by contact with partially burned and wholly unburned pieces of gunpowder (Fig. e11.7). Tattooing or stippling cannot be wiped away. The appearance differs from powder burns due to black powder because black powder burns rapidly and at high heat, resulting in a burn appearance more reminiscent of those from thermal injuries. Tattooing rarely occurs on the palms of the hands or soles of the feet because of the thickness of the epithelium.

Tattooing may occur as close as 1 cm to and as far away as 1.3 m from the weapon but is generally found at distances of 60 cm or less. The density of the tattooing and associated pattern depends on the length of the barrel, muzzle-to-skin distance, type of gunpowder, presence of intermediate objects, and caliber and type of ammunition. Clothing, hair, or other barriers may prevent tattooing from occurring. The presence of partially or entirely unburned pieces of gunpowder and gunpowder residue on clothing or skin aids in determining the range of fire. On rare occasions, pieces of gunpowder can penetrate thin clothing and leave punctate abrasions (Fig. e11.8).

Long-Range Wounds. The distant or long-range wound is inflicted from far enough away that only the bullet makes contact with the skin. There is no tattooing or soot. As the bullet penetrates the skin, the skin is indented, resulting in the creation of an abrasion collar, also termed an *abrasion margin*, *abrasion rim*, or *abrasion ring* (Fig. e11.9). This collar is an abraded area of tissue that surrounds an entry wound as the result of friction between the bullet and epithelium. The width of the abrasion collar varies with the angle of impact. Most entrance wounds will have an abrasion collar. Entrance wounds on the palms and soles are exceptions because these wounds usually appear slit-like.

The abrasion collar is secondary to friction and is not the result of thermal changes associated with a hot projectile. The abrasion collar of a contact or close-range wound may be undetectable because hot gases and a flame have seared the tissue. When an abrasion collar is the only visible superficial clinical finding present, the term *indeterminate range* describes the range of fire. A wound inflicted from 10 feet will appear the same as a wound inflicted from 100 feet. An exact range cannot be determined with a distant wound.

Determining the range of fire may be complicated when clothing prevents the deposition of soot and powder on the skin. Without the overlying clothing or without information regarding the crime scene, the wound may appear to be from a distant range of fire. In reality, the range may have been close or intermediate. Conversely, a projectile discharged from a distant range of fire may mimic an intermediate range if it strikes an object, such as glass, that fragments. As with unburned gunpowder, when the glass fragments strike the skin, they may also cause punctate abrasions, resulting in pseudotattooing (Fig. e11.10).

Atypical Entrance Wounds. Atypical entrance wounds occur when a bullet encounters an intermediate object, such as a window, wall, or door, before striking the victim. The intermediate object can cause the bullet to tumble and may change the its size, shape, or path. Such changes can result in entrance wounds with large stellate configurations that mimic close-range or contact wounds (Fig. e11.11). Ricochet bullets may also cause atypical entrance wounds. Graze wounds are atypical wounds from tangential contact with a passing bullet.

Handgun Exit Wounds

Exit wounds are the result of a bullet pushing and stretching the skin from the inside out. The skin edges generally are everted with sharp but irregular margins. The size of the exit wound is determined by

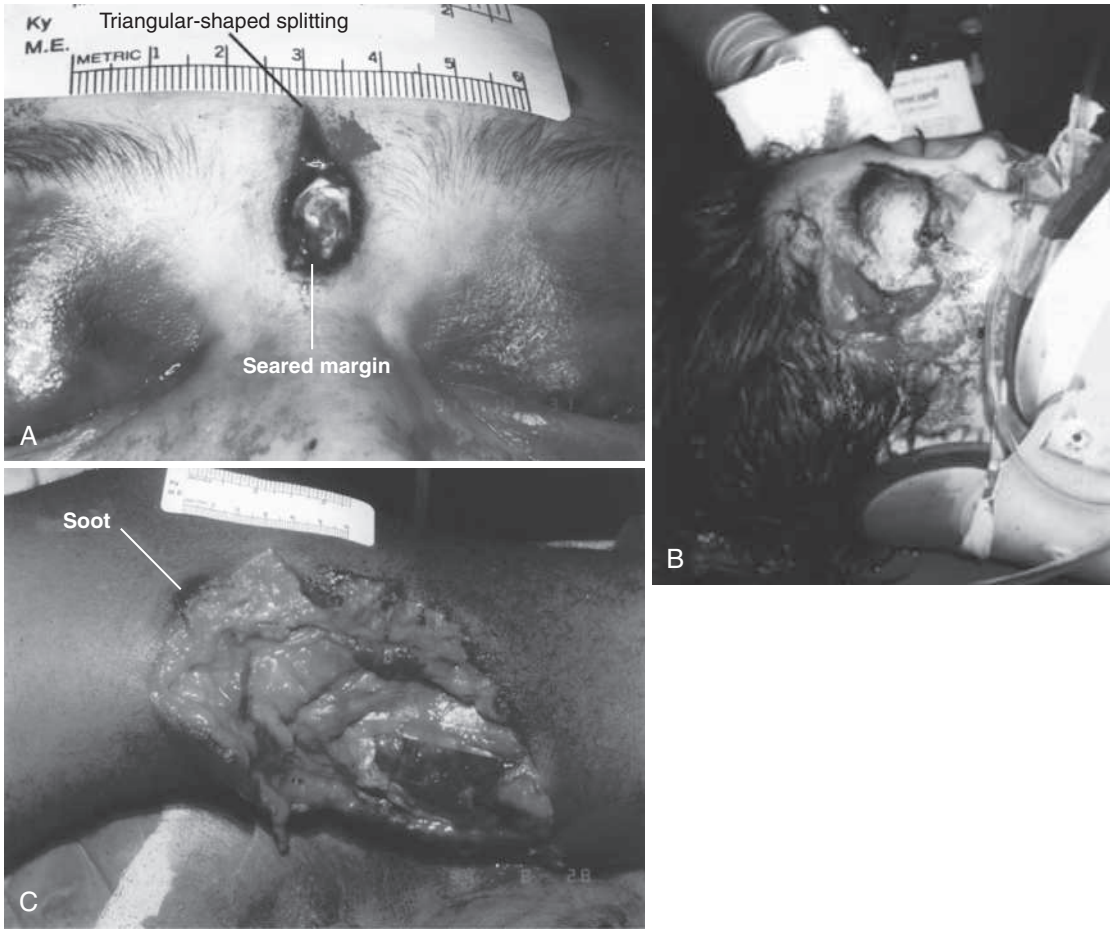

Fig. e11.4 (A) Tight-contact entrance wound from a .38 caliber revolver. The wound margins are seared from the discharge of hot gases and flame from the end of the barrel. The triangular tear is the result of tissue expansion from the discharge of gases into the tissue. (B) Tight-contact entrance wound with large stellate tears from a .38 semiautomatic pistol. The large triangular tears are the result of rapid expansion of gases under the skin. (C) Tangential-contact wound from a 9 mm pistol on the medial aspect of the left calf. The presence of soot at the superior aspect indicates a close range of fire. The patient initially reported that he was shot from a distance of 3 or 4 feet (0.9–1.2m) and later admitted that he had accidentally shot himself while withdrawing his pistol from his boot. Large wounds, as seen in B and C, may be misinterpreted as exit wounds because of their size.

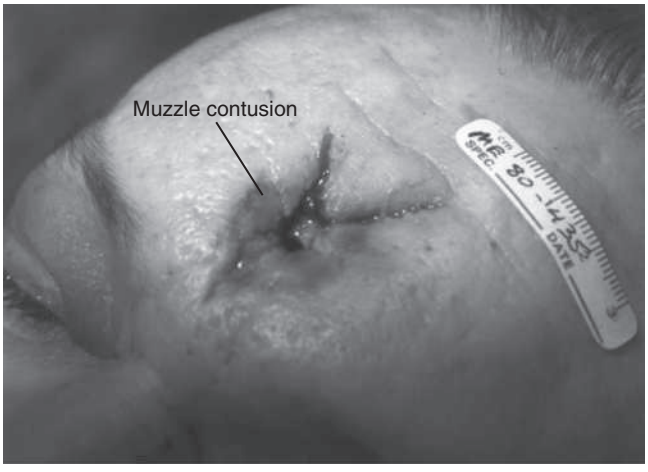

Fig. e11.5 A muzzle contusion is a contusion caused by skin expansion against the barrel of the weapon. Muzzle contusions are associated with contact wounds.

the energy transferred from the bullet to underlying tissue and by the bullet's size and configuration as it exits the skin (Fig. e11.12). Once a bullet enters the skin, its configuration may change from its usual nose-first attitude owing to tumbling and yaw. A bullet that exits the skin sideways, or one that has increased its surface area by mushrooming or transferring its energy to underlying bone, will have an exit wound larger than its entrance wound.

Atypical Exit Wounds. A shored exit wound is a wound that has an associated false abrasion collar. If the skin is pressed against or supported by a firm object or surface at the moment the bullet exits, the skin can be compressed between the exiting bullet and supporting surface (Fig. e11.13). Examples of supporting structures include belts, floors, walls, doors, chairs, and mattresses.

Centerfire Rifle Wounds

Projectiles discharged from centerfire rifles have the potential to inflict massive tissue damage (see Fig. e11.2). Entrance wounds associated with high-velocity, centerfire projectiles do not significantly differ from those of handguns. Entrance wounds will generally exhibit abrasion collars or microtears on the skin surface (Fig. e11.14). Wounds will also have associated soot deposition and tattooing but, because of a number of variables such as muzzle length, amount of powder in a given cartridge, muzzle configuration, and type of gunpowder, the range of fire in rifle wounds is not as clearly defined as in handgun wounds. The determination of an exact range of fire for rifles and shotguns is best

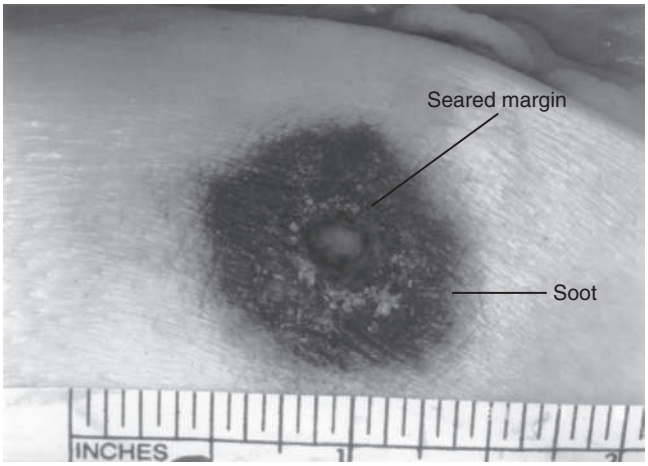

Fig. e11.6 Close-range wound with soot deposition. Soot is associated with a range of fire of 6 inches (15 cm) or less.

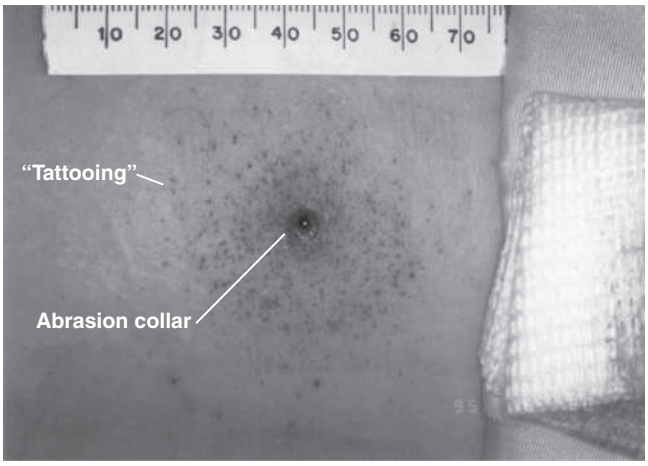

Fig. e11.7 Tattooing results from contact with pieces of unburned gunpowder. These punctate abrasions are associated with an intermediate range of fire, generally less than 36 inches (90 cm). The density of these abrasions depends on the length of the gun's barrel, distance from the muzzle to the skin, type of gunpowder used, and presence of any intervening objects.

established through controlled testing performed by a firearms examiner at a crime laboratory.

High-velocity bullets with jackets and lead cores generally break up into hundreds of fragments, termed a *lead snowstorm*, on entering tissue, resulting in significant tissue damage (Fig. e11.15). If the tissue penetrated is deep, the bullet fragments may fail to exit and remain embedded. It is therefore possible to sustain an injury from a high-velocity round and not exhibit an exit wound. High-velocity rounds with steel cores will almost uniformly exit intact. Steel core ammunition is not available for civilian use so such injuries will rarely be encountered by most ED providers.

Shotgun Wounds

The massive damage caused by slugs may obliterate the abrasion collar usually associated with entrance wounds. Shotgun slugs will almost uniformly exit the body with large exit wounds. Tissue penetration is more limited with shotgun pellets as the projectile velocities are much lower, particularly if fired at long range. If fired at close range, however, the damage is much more significant, again depending on the elasticity of the tissue encountered.

Fig. e11.8 Gunpowder can penetrate thin clothing and deposit tattooing on the skin. A 3-year-old was shot with a .45 caliber round at close range, and pieces of gunpowder passed through his T-shirt.

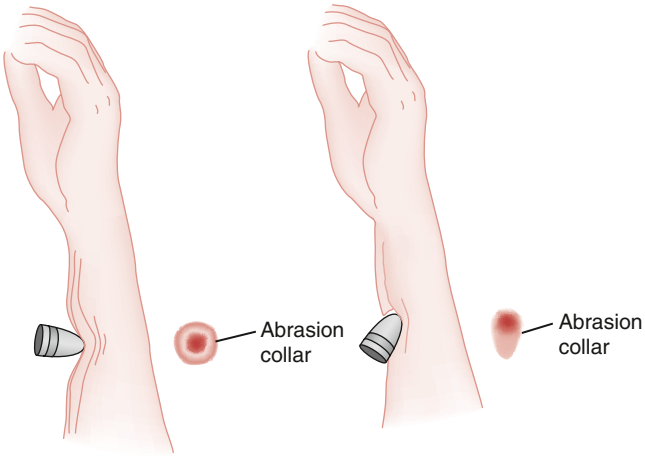

Fig. e11.9 An abrasion collar is the abraded area surrounding the entrance wound created by the bullet when it indents and passes through the epithelium. The collar or rim is the result of friction between the bullet and the epithelium. The width of the abrasion collar will vary with the angle of impact.

Clinical Features of Firearm Injuries

Patients with firearm injuries have varying presentations, depending on the anatomic location of the injury and type of weapon used. It is important to identify all wounds to guide the determination of the potential missile trajectory and anticipate the other possible injuries. It is also important to consider how the temporary and permanent cavities may manifest anatomically to guide imaging and management.

Patients with injuries to the head and neck often present in critical condition due to the abundance of vital neurovascular structures in this area. Head-injured patients can present in extremis with altered mental status and signs of impending herniation, in which case emergent airway management and resuscitation are necessary. Emergent airway management may also be required in cases with intraoral involvement or a need for operative intervention for other reasons (e.g., an exploratory laparotomy). Neck injuries can present with a multitude

of symptoms, depending on the structures affected. Symptoms can run the gamut from asymptomatic to active bleeding (from trauma to the vasculature), dysphonia or hoarseness (due to pharyngeal or tracheal injuries), or hemiplegia or hemiparesis (if the internal carotids are disrupted). Urgent airway and bleeding control are required in these cases unless the patient is clinically stable.

Fig. e11.10 Pseudotattooing, or punctate abrasions from glass fragments, not unburned gunpowder, on the medial aspect of the thigh associated with a gunshot wound. The leg was showered with glass fragments after the round penetrated a windowpane.

Gunshot injuries to the thorax can result in damage to the cardiac musculature, cardiac tamponade, pneumothoraces or hemothoraces, or other mediastinal pathology. Clinical symptoms include shortness of breath, chest pain, tachypnea, hypotension, and altered mental status.

In general, extremities are the most commonly injured anatomic region with nonfatal firearm injuries.[8] Injuries to the extremities can result in fractures, vascular or nerve injury, and compartment syndrome, because bullet tracts do not necessarily decompress fascial compartments. Fractures are associated with vascular and nerve injuries, and with isolated fractures increasing the risk for compartment syndrome. Vascular injuries alone are also associated with an increased risk of compartment syndrome and deep vein thrombosis. A combination of fractures and vascular injuries has been shown to increase the risk of wound infection.

Gunshot wounds to the perineum should raise concern for bowel or bladder injury. Patients may not necessarily complain of any symptoms, but findings of gross hematuria or gross blood on rectal examination indicate that such injuries have occurred.

Air gun/rifle injuries deserve a special mention. Although they may seem innocuous, injuries to areas containing vital structures should prompt further investigation because pellets can cause significant tissue damage. Recent studies have shown that the head/face and neck were the most frequently injured areas,[5,17] with an increasing incidence of eye injuries.[17] Occasionally, injuries can be significant enough to warrant operative intervention.[5] Previous case reports have also shown that air rifle pellets may embolize from the initial location of injury and can also result in damage to vital structures such as the brain and heart.

Diagnostic Testing

The imaging modalities used will differ depending on the location of the injury. Details of the appropriate diagnostic strategies are outlined in the chapters on trauma (Part II of this text). In brief, most injuries will require computed tomography (CT) imaging to delineate the extent of tissue damage. However, this may not be possible in unstable patients, in which case plain radiographs of the chest and pelvis may be the only feasible imaging modality to help guide management.

A non-contrast CT scan of the head can show associated skull fractures, intracranial hemorrhages, or retained missiles. A CT angiogram of the neck is useful to evaluate for injuries to essential neurovascular or aerodigestive structures. Patients with persistent pain to the posterior neck with negative CT imaging may require magnetic resonance

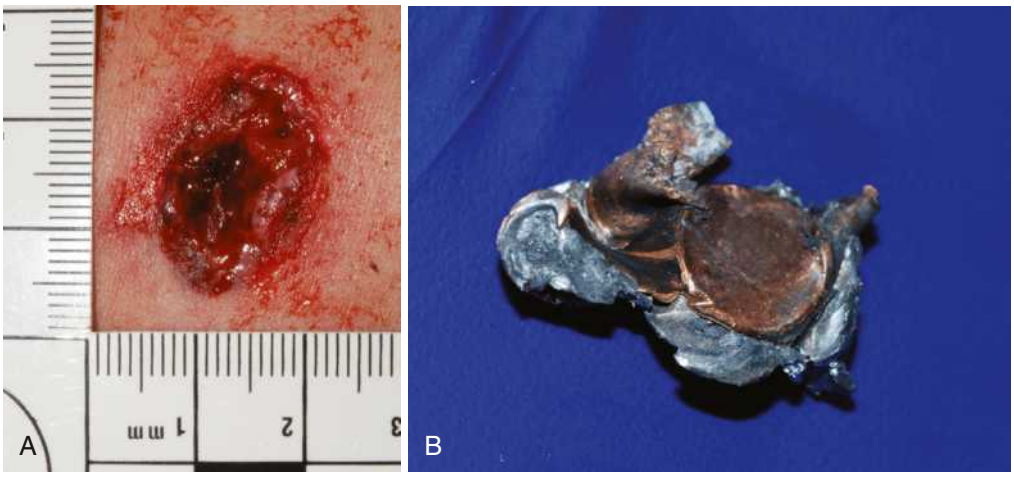

Fig. e11.11 (A) An atypical entrance wound from impact with a .40 caliber bullet. (B) The projectile was deformed as it penetrated a windshield.

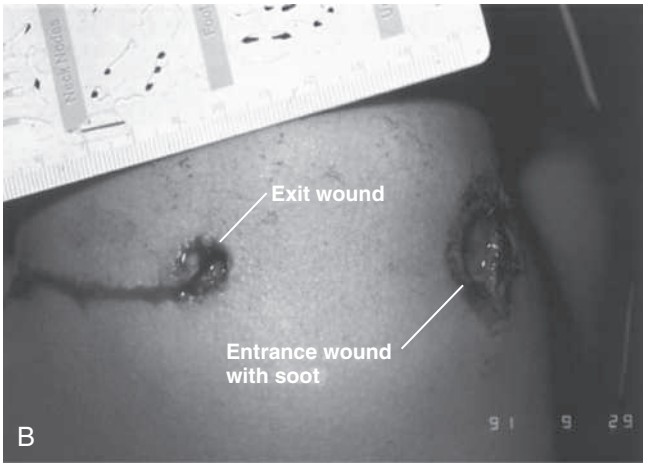

Fig. e11.12 (A) Slit-like exit wound from a .22 caliber bullet. (B) Perforating gunshot wound to the left deltoid area, with soot deposition around the larger entrance wound. No soot is present around the smaller exit wound. Exit wounds are not consistently larger than their corresponding entrance wounds.

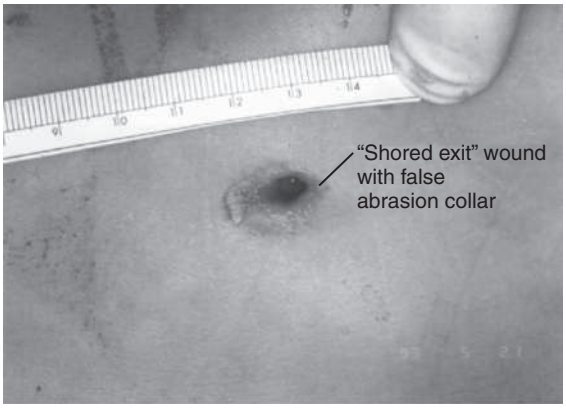

Fig. e11.13 Shored exit wound with a false abrasion collar. This type of wound occurs when the skin in the region of the exiting bullet is in contact with a supporting structure (e.g., wall, floor, mattress). The skin is pressed against the supporting structure, which results in a false abrasion collar.

imaging (MRI) to evaluate further for ligamentous pathology. However, MRI is contraindicated if there are retained missiles in close proximity to vital structures (such as nerves and blood vessels). Thoracic injuries often mandate a chest CT to assess for injuries to the lungs, heart, and mediastinum, as well as to define the bullet trajectory. Chest x-rays are sensitive for pneumothoraces but are not sensitive or specific for mediastinal injury, which requires more advanced imaging. X-rays can also be used to diagnose diaphragmatic injuries when specific findings are present, such as a visualized herniated viscus (the collar sign) or a nasogastric tube in the stomach above the diaphragm. However, a negative x-ray cannot rule out diaphragmatic injury, and CT imaging is more sensitive and specific. Abdominal or genitourinary injuries will also require CT of the abdomen and pelvis to identify the tissues injured. Given that thoracic and abdominal injuries tend to occur concurrently, it is recommended to obtain CTs of both the chest and abdomen/pelvis if there is an injury in either area. A CT urogram or cystogram may be indicated if there is a concern for upper tract or bladder injury respectively. Spinal cord or vertebral injuries are well visualized by MRI or CT, respectively—but note that the metallic nature of most bullets may preclude imaging with MRI.

Differential Diagnosis

There is a limited differential diagnosis for firearm injuries because the mechanism is usually known, often prior to the patient's arrival to the ED. However, patients may sustain multiple injuries, so it is important to be vigilant to avoid missing subtle or smaller concomitant injuries. It is also critical to realize that bullets and bullet fragments may travel, embolize, or cause damage by way of the temporary cavity, so a change in the patient's clinical condition should trigger a prompt reevaluation.

Management and Disposition

Management of patients with gunshot injuries varies by injury location. Resuscitation is key, with use of crystalloid and/or blood as needed, as well as stabilization of the airway and actively bleeding wounds. If possible, procedural incisions should be made away from the site of injury

Fig. e11.14 (A) An exit wound from a high-velocity rifle round. Exit wounds from high-velocity rounds are generally larger than their corresponding entrance wounds. The large size is a result of energy transfer from the projectile to underlying tissue, with the expelling of tissue, principally bone. (B) An entrance wound from a high-velocity rifle round. Entrance wounds of high-velocity projectiles will also display an abrasion collar.

Fig. e11.15 A lead snowstorm from a high-velocity rifle round. High-velocity projectiles have a tendency to fragment into hundreds of tiny particles on contact with bone. This fragmentation contributes to the massive tissue damage associated with these projectiles.

to preserve the evidence; however, this may not be feasible in all cases and patient care always takes precedence.

Head and Neck Injuries

In addition to resuscitative measures, it is important to minimize/prevent hypoxia and hypotension in head-injured patients with a traumatic brain injury (TBI). Emergent operative procedures may be required to evacuate intracranial hematomas in patients with significant mass effect, shift, or other evidence of increased intracranial pressure. Neck injuries are managed with emergent intubation as needed, and control of active hemorrhage. Vessel ligation might also be required if unable to control the hemorrhage with direct pressure. Damage to vital structures may necessitate emergent operative intervention. Patients with penetrating injuries to the neck may also require endoscopy, esophagoscopy, and/or bronchoscopy, depending on the path of the missile.

Thoracic Injuries

Decompression of pneumothoraces, hemothoraces, and hemorrhagic pericardial effusions is usually emergently required. An ED thoracotomy is performed for patients who present in cardiac arrest within 15 minutes of their injury or for a witnessed arrest on ED arrival. Tension pneumothoraces or pericardial tamponade should be decompressed emergently, prior to advanced imaging. Mediastinal and aerodigestive injuries should be elucidated by esophagoscopy, bronchoscopy, and possible angiography. Suspected diaphragmatic injuries should also be evaluated with laparoscopy because patients may initially be asymptomatic but may subsequently develop bowel herniation and eventual strangulation of the herniated tissue (which can happen years after the injury).

Abdominal Injuries

Gunshot wounds to the abdomen can be managed expectantly if the patient is stable with no injuries to the peritoneal cavity or with moderate solid organ injuries (grades 1–3 liver or splenic lacerations). Unstable patients or those with concomitant bowel injuries (including evisceration) or severe splenic or liver lacerations (grade 4 or 5) require emergent exploratory laparotomy. Genitourinary injuries are often managed after other life-threatening injuries have been addressed, aside from severe renal lacerations (grade 4 or 5), which may require nephrectomy. Urethral injuries are managed with Foley catheter placement before or after the appropriate diagnostic modalities have been performed (retrograde urethrography or retrograde cystourethrography). Intraperitoneal bladder injuries are managed operatively, whereas extraperitoneal injuries are managed with Foley catheter placement and decompression.

Extremity Injuries

Management of these injuries involves irrigation, débridement of devitalized tissue, and traction or splinting of fractures. Bullet removal is only required in certain cases. It is required for missiles in contact with synovial fluid (i.e., intra-articular missiles) or within intervertebral disks, given the potential for dissolution and resulting systemic symptoms.[4,18] Other indications for bullet removal include bullets limiting joint motion, impinging on nerves, bullets in a vessel lumen, those resulting in lead poisoning, or bullets in subcutaneous locations (especially in the hands and feet).[18] Patients should also be monitored for compartment syndrome, and vascular or neurologic injuries, especially following high-energy injuries. Operative intervention is required for patients with unstable fractures, fractures with exposed bone, compartment syndrome, or vascular injuries requiring repair. Transabdominal injuries with pelvic fractures also mandate prophylactic antibiotics.

High-energy gunshot wounds with associated fractures are managed as open fractures and are generally treated with prophylactic antibiotics because contaminants can be sucked into the wound due to cavitation.[19] Low-energy injuries can be managed as closed fractures with superficial débridement and prophylactic antibiotics (those covering for gram-positive organisms/skin flora), although the literature suggests that there are low infection rates with or without antibiotics.[18] A recent study by Nguyen et al. recommended that operatively managed fractures from low-energy gunshot wounds should receive prophylactic antibiotics;[20]

however, the study had a small number of patients and may not be applicable to all patient populations. At this time, there is no clear consensus about the type, duration, and dosages of prophylactic antibiotics in patients with low-energy injuries.[18] However, it is reasonable to initiate a course of prophylactic antibiotics in the ED for these patients, particularly in patients who have multiple comorbidities and are at higher risk for wound infections. Intra-articular fractures also appear to warrant débridement.

Soft Tissue Injuries

Soft tissue wounds are managed with irrigation, but wounds are left open. Prophylactic antibiotics are not routinely recommended. The previously cited study by Nguyen et al. found that a single dose of intravenous antibiotics given in the ED for a soft tissue injury (without a fracture) seemed to be associated with a lower rate of infection.[20] The rates of deep infections in this study were not statistically significant when comparing patients who received antibiotic prophylaxis to those who did not,[20] so the findings should again be interpreted with caution. Currently, the use of prophylactic antibiotics in these patients is not uniformly recommended. Because high-energy injuries and shotgun wounds produce a significant amount of devitalized tissue, they often require operative débridement. Aggressive débridement along the wound tract or path of the projectile is not routinely recommended.[4]

Tetanus vaccinations should be updated, and tetanus immunoglobulin given to those without prior immunity. Bullet removal is only indicated for certain extremity injuries (see earlier), for missiles with the potential to embolize, or for those in the myocardium.[4] Prophylactic antibiotics are also not routinely recommended, despite the fact that bullet wounds are not sterile.[4] Indications for prophylactic antibiotics are grossly contaminated wounds, abdominal wounds with hollow viscus injury, intra-articular injuries, intracranial injuries, open fractures/exposed fractures, and high-energy gunshot injuries.

Evidence

A victim's clothing may yield information about a bullet's range of fire and help distinguish entrance from exit wounds. Clothing fibers will deform in the direction of the passing projectile. Gunpowder residue and soot will deposit on clothing as they do on skin. Residue may be invisible to the naked eye, but nitrites and vaporized lead can be visualized with standard forensic staining techniques. Some bullets, as they make initial contact with clothing, leave a lead or lubricant residue that is termed *bullet wipe*. Articles of clothing removed from a wounded patient need to be placed in separate paper bags to avoid cross-contamination of evidence.

The bullet, bullet jacket, and cartridge case are invaluable for identifying or excluding a suspect weapon. When a weapon is discharged, the discharge imprints multiple microscopic marks on the sides of the bullet and on the bottom or side of the cartridge case. The markings result from the bullet's contact with the tool marks, or rifling, in the gun's barrel. These marks are unique to each barrel and are reproducible. These marks are the gun's fingerprint, so to speak. Cartridge case marks are from contact with the firing pin, breech lock, magazine of semiautomatic weapons, and extractor and ejector mechanisms. These microscopic fingerprints can be obliterated by removing a bullet with hemostats or pickups. Therefore, bullets should be handled with gloves, and the tips of surgical instruments should be covered with gauze (Figs. e11.16 and e11.17) or plastic tips (so-called suture booties) to ensure the preservation of these microscopic marks. It is not necessary to place initials or other markings on the bullet if adequate notes are made in the patient's medical record regarding the chain of custody.

Radiographs also help locate retained projectiles and may be of evidentiary value in determining the number of projectiles and the direction of fire. It is important to maintain a chain of custody to preserve as much evidence as possible. This should also be documented, ideally on a chain of custody form.[1] There is a new trend of forensic care programs in EDs to facilitate this process.[1] It in essence expands on the concept of sexual assault nurse examiner programs, in which a dedicated forensic staff member is responsible for evidence collection,[1] which should theoretically improve documentation and collection due to specialized training.

Fig. e11.16 To determine whether a projectile was discharged from a specific weapon, firearms examiners use microscopic marks on the surface of the bullet.

Fig. e11.17 Hemostats should be covered with gauze or plastic tips when bullets are being removed. Metal-to-metal contact destroys the microscopic marks used to identify the weapon from which the bullet was discharged.

Conclusions

The impact of firearm injuries cannot be understated, and it is a tremendous public health issue.[8] Not only do firearms result in injuries and fatalities, they also have other important downstream effects, including disability,[8] the number of productive years lost for adults, missed school for children and adolescents, long-term mortality in children and adolescents,[21] and long-term psychological effects.[22] They also contribute to health disparities and there are high rates of recidivism for violent injuries.[23] Economically, firearm-related injuries result in over $48 billion in medical and work loss costs annually, particularly fatal firearm injuries.[8]

This does not take into consideration the emotional impact that fatalities have on families and communities as a whole. Therefore, the focus should be on prevention as much as possible to avoid incurring such costs.

A number of organizations, including the American College of Emergency Physicians, American College of Physicians, American Pediatric Surgical Association, and American Academy of Pediatrics have all noted that firearm violence is a significant public health problem and have advocated for a public health approach to reduce the burden of firearm-related injuries and deaths. Measures suggested include stricter background checks, stronger legislation regarding illegal firearm sales, and limitation of access to children/adolescents and those with a history of mental health issues and substance use disorders, as well as patient education about firearm injury prevention, especially in patients at risk.[10,14,24,25] Interventions such as safe storage of firearms (or having none at all in the home), screening for access to firearms during routine primary care visits and participation in firearm risk injury education is recommended by multiple groups (including the Society for Adolescent Health and Medicine) to minimize the burden in pediatric patients.[16,26]

There is also support for using the ED or outpatient visits following nonfatal injuries as teachable moments to educate patients about future firearm violence.[12] Hospital-based violence intervention programs have been instituted at some facilities and have been shown to reduce recidivism and reinjury through intensive case management.[23] These programs have also been shown to be cost-effective in recent studies.[27] Other preventative public health approaches for youth and adolescents may also be useful, including street outreach (such as Cure Violence) and school-based violence prevention programs that provide education aimed at curbing violence as a whole.[13,26] Such a public health approach has been successful in reducing the fatalities from motor vehicle trauma and may be a good model to apply to firearm injuries to reduce the burden on society.

FORENSIC ASPECTS OF PHYSICAL ASSAULT

Perspective

Interpersonal violence is a leading cause of death in the United States, particularly among children, adolescents, and young adults. Rates of violence vary by age, gender, ethnicity, and geographic location. Homicide is one of the leading causes of death for children and young adults from non-Hispanic Black backgrounds. The high rate among African Americans is primarily driven by the remarkably high rates among young adult males. Differences in child maltreatment rates, as well as other forms of violence, are attributable to underlying risk factors, such as poverty.[7] Urban areas have higher homicide rates than suburban or rural areas. Overall, the proportion of assaults resulting in death has declined markedly since the 1960s, thought to be due to the availability of organized trauma care.[28] It is the emergency clinician's responsibility not only to care for these patients clinically, but also to assist law enforcement with thoughtful documentation of injuries, evidence preservation, and collection.

Accurate documentation of the anatomic location of the injuries makes it easier to determine the implement, tool, or weapon responsible for producing each wound. Descriptions of wounds should include their shape, precise body location, and measured size. Specific characteristics should be noted, such as the presence of other materials, coloration, and patterned injuries. Such pattern injuries of abrasions or contusions may retain some features of the impacting object, possibly allowing it to be identified. Every weapon leaves a mark, design, or pattern stamped or imprinted on or just below the epithelium. The epithelial imprints of these weapons, termed *pattern injuries*, are consistently reproducible. These injuries are classified into major categories according to their source—blunt force, sharp force, thermal, and chemical.

Correct terminology is also important when describing wounds. When referring to blunt force wounds, these injuries are termed *lacerations* caused by blunt force trauma, as opposed to an incised wound or cut, which is the violation of epidermis caused by a sharp instrument that is longer than it is deep. This terminology use of *laceration* differs from the typical usage within emergency medicine, which tends to be used more broadly. When documenting these injuries, it is better to use the more specific terminology of incised wound if caused by a sharp weapon or laceration if caused by a blunt mechanism. Stab wounds are deeper than they are wide. Also, wounds and bruises should be described as they are seen, and no comment on age or time of occurrence should be documented.

When cutting clothes, avoid cutting through defects caused by sharp force injuries. Clothing items should be placed into paper bags, labeled, sealed, and then turned over to law enforcement. Plastic bags retain moisture and promote the growth of bacteria, which could degrade DNA evidence. Sharp force weapons that are recovered should be wrapped in craft paper or cardboard to protect them from causing injury and sealed for evidence collection.

Conclusions regarding the alleged perpetrator and the mechanism of injury should generally be avoided. It may be helpful to the investigation or legal proceedings to document what the patient states in quotations.

Blunt Force Pattern Injuries

The most common blunt force injury is the contusion, along with abrasions and lacerations. A weapon with a unique shape or configuration may stamp a mirror image of itself on the skin (Box e11.1).

Pattern Contusions

A blow from a linear object leaves a contusion that is characterized by a set of parallel lines separated by an area of central clearing (Fig. e11.18). The blood underlying the striking object is forcibly displaced to the sides, which accounts for the pattern's appearance (Fig. e11.19). Circular or linear contusions suggest abuse or battery. Circular contusions 1.0 to 1.5 cm in diameter are consistent with fingertip pressure and grab marks (Fig. e11.20). One commonly overlooked anatomic location for fingertip pressure contusions is the medial aspect of the upper arm. The sole of a shoe from a kick or stomp may also leave a pattern contusion that can assist in identifying the assailant (Fig. e11.21).

Some injuries allegedly occur during police custody. Specific pattern contusions can include parallel contusions from a flashlight or nightstick. Handcuff or shackle marks are narrow parallel contusions or abrasions on the wrists or ankles. Handcuff and shackle marks are generally more prominent on the lateral aspects of the extremity.

A bite mark may appear as a pattern contusion, abrasion, or combination of both (Fig. e11.22). Bite marks vary greatly in the quality of their identifiable features, depending on the location of the bite and motion of the teeth relative to the skin. Some bite marks may not be readily identifiable as such and may appear as nonspecific contusions, abrasions, or contused abrasions. Generally, adult marks have an interdental distance of more than 3 cm.

BOX E11.1 Commonly Inflicted Pattern Injuries

Slap marks with digits delineated
Looped or flat contusions from belts or cords
Circular contusions from fingertip pressure
Parallel contusions with central clearing from linear objects
Contusions from shoe heels and soles
Semicircular contusions and abrasions from bite marks

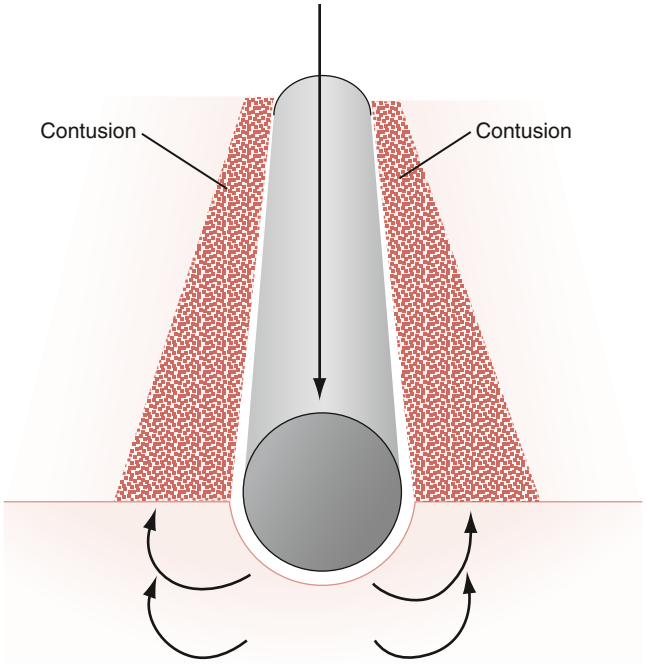

Fig. e11.18 A direct blow from a linear object results in a pattern contusion with central clearing surrounded by parallel linear contusions. The blood directly beneath the impacting object is displaced laterally and accounts for the distinctive contusion.

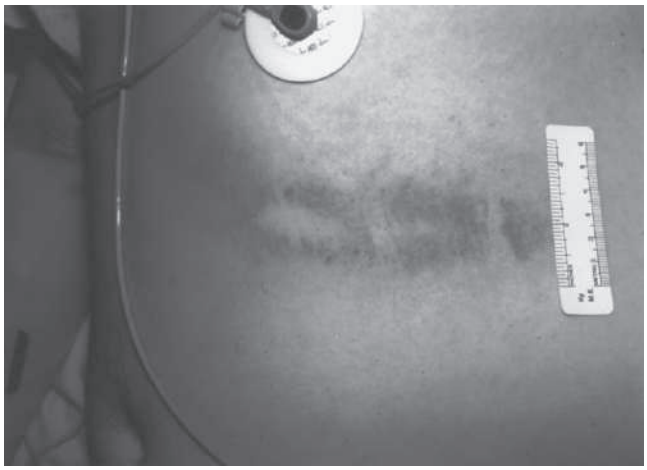

Fig. e11.19 Pattern contusion with parallel lines and central clearing from contact with a baseball bat.

When an acute bite mark is identified, care should be taken not to wash away potential evidence. The skin surface should be swabbed with a sterile cotton-tipped applicator moistened with sterile saline. DNA from buccal cells may also be deposited over an acute bite mark.

The emergency clinician should not render an opinion on the age of a contusion. The development of a contusion is based on a number of variables, such as the amount of blunt force applied to the skin, vascularity of the tissue, oxygenation of the extravasated hemoglobin, depth of the hematoma, skin tone, and amount of blood that escapes into the surrounding tissue. As a result, no reproducible standard for the dating of a contusion is possible based on its color.

Pattern Abrasions and Lacerations

A pattern abrasion is a rubbing or scraping away of the superficial layers of the epidermis, which is not important for treatment but may be

Fig. e11.20 Circular contusions documented on the medial aspect of the upper arm. These injuries resulted from fingertip pressure applied during an assault.

Fig. e11.21 Pattern contusion on the patient's upper chest from the sole of a tennis shoe after a kick. This type of pattern injury can assist in the identification of a suspect and provides a physical connection between the victim and the attacker.

invaluable from a forensic and injury reconstruction perspective. A laceration is defined as a tear in the skin produced by blunt trauma and should not be confused with an incised wound produced when a sharp-edged implement (e.g., knife, scalpel, piece of glass) is drawn across the skin. A laceration has characteristically abraded or crushed skin edges and unique so-called tissue bridges (Fig. e11.23).

Sharp Force Pattern Injuries

An incised wound is longer than it is deep, and a stab wound is defined as a puncture wound that is deeper than it is wide. The wound margins of sharp force injuries are clean and lack the abraded edges and tissue bridges of injuries resulting from blunt forces.

Fig. e11.22 Bite marks may display characteristic arches or appear as a pattern abrasion. A bite mark can be used to identify the assailant if the injury is correctly documented by a forensic photographer or forensic odontologist.

Fig. e11.23 A laceration is the result of blunt trauma and characteristically displays tissue bridges and crushed wound margins.

Forensic information can be gathered during the examination of a stab wound. Some of the characteristics of a knife blade, single-edged or double-edged, can be determined from visual inspection (Fig. e11.24A, B). Additional blade characteristics, such as serrated versus sharp, can be seen if the blade was drawn across the skin during its insertion or withdrawal (see Fig. e11.24C).

Patients with self-inflicted wounds may visit the ED claiming an accident, self-defense, or assault. When the patient history, injuries, and forensic evidence are not consistent, the forensically informed emergency clinician is in a unique position to extrapolate the truth. With an understanding of how to identify the patterns of self-inflicted knife wounds, the emergency clinician can provide appropriate referrals, conserve resources, and assist law enforcement in the investigation of an alleged crime.

When a patient claims to have been assaulted as the victim of a crime, his or her injuries become physical evidence. It is important for the treating emergency clinician, who may be called as an expert witness, to recognize patterns of self-inflicted injury and to distinguish self-inflicted wounds from those sustained during an assault (Fig. e11.25; Box e11.2). Certain patterns may be used to distinguish these injury patterns. Assaults show other associated stab and cut wounds or defensive wounds often on the patient's dominant upper extremity, whereas self-inflicted cases predominantly show isolated cut wounds or associated superficial hesitation marks on the side of the patient's nondominant hand.[29] Defensive injuries most frequently present as cuts on the hands, followed by the forearms, typically on the extensor sides of the forearms and hands, as well as the flexor sides of fingers. Wounds located on the head, limbs, hand, neck, or back are predictive of an assault, whereas wounds located solely on the anterior parts of the trunk, neck, or forearms are more likely to be self-inflicted. The presence of bone or cartilage wounds is suggestive of assault, and their absence is suggestive of self-infliction.

Thermal Pattern Injuries

A thermal pattern injury is a common form of abuse or battery, particularly in pediatric patients. The history should include the position of the patient relative to the thermal source. This information will help determine whether the injury was intentional or accidental. The location of the burn may also be helpful in delineating the intent of the burn; burns to the gluteal area or perineum are very rarely accidental, whereas burns to the hands and upper trunk are common with unintentional injuries.

Intentional burns tend to be deeper and well demarcated and are often due to hot objects, such as curling irons, cigarettes, or hot liquids. A sharp or clear line of demarcation between burned and unburned tissue characterizes immersion or dipping burns. In contrast, splash burns are characterized by an irregular or undulating line or by isolated areas of thermal injury, usually round or oval in shape, caused by droplets of hot liquid.

The severity of thermal or scald injury depends on the length of contact time and the temperature. Skin damage can result from a number of different mechanisms whereby temperatures in excess of 49°C (120°F) cause cellular damage but, again, the exact temperatures required depend on contact time. Law enforcement routinely measures the household's or institution's water temperature in any investigation involving a scald injury.

It is important to be attentive to concomitant injuries in burn patients, particularly those who are victims of significant violence. These patients may sustain associated injuries, such as fractures, that need to be addressed emergently. If there is concern for non-accidental trauma, then a report should be made to law enforcement.

Chemical Injuries

Chemical injuries are a rare means of assault in the United States and Europe but have been noted in countries such as Bangladesh and Jamaica. The victims tend to be female, often following domestic disputes. The most commonly used agents are those found around the home, such as car battery acid, which is usually thrown at the victim. The head, face, and neck are predominantly affected but the fluid may spread to the chest and trunk as well. Patients present with findings consistent with burns from acids or alkalis with cellular damage resulting from coagulative or liquefactive necrosis, respectively.

Primary management is similar to that for other chemical injuries and consists of prompt removal of contaminated clothing or other materials as soon as possible and irrigation of the affected area with copious amounts of water. Tap water has been shown to be adequate for this purpose. Patients may also require rapid resuscitation with intravenous fluids and pain control, with or without airway management depending on the injury location. These patients may also develop significant electrolyte abnormalities, such as metabolic acidosis or hypocalcemia, which require close monitoring and treatment.

FORENSIC ASPECTS OF MOTOR VEHICLE TRAUMA

Perspective

Globally, road traffic injuries are among the leading causes of death and have become the leading cause of death for children and young adults.

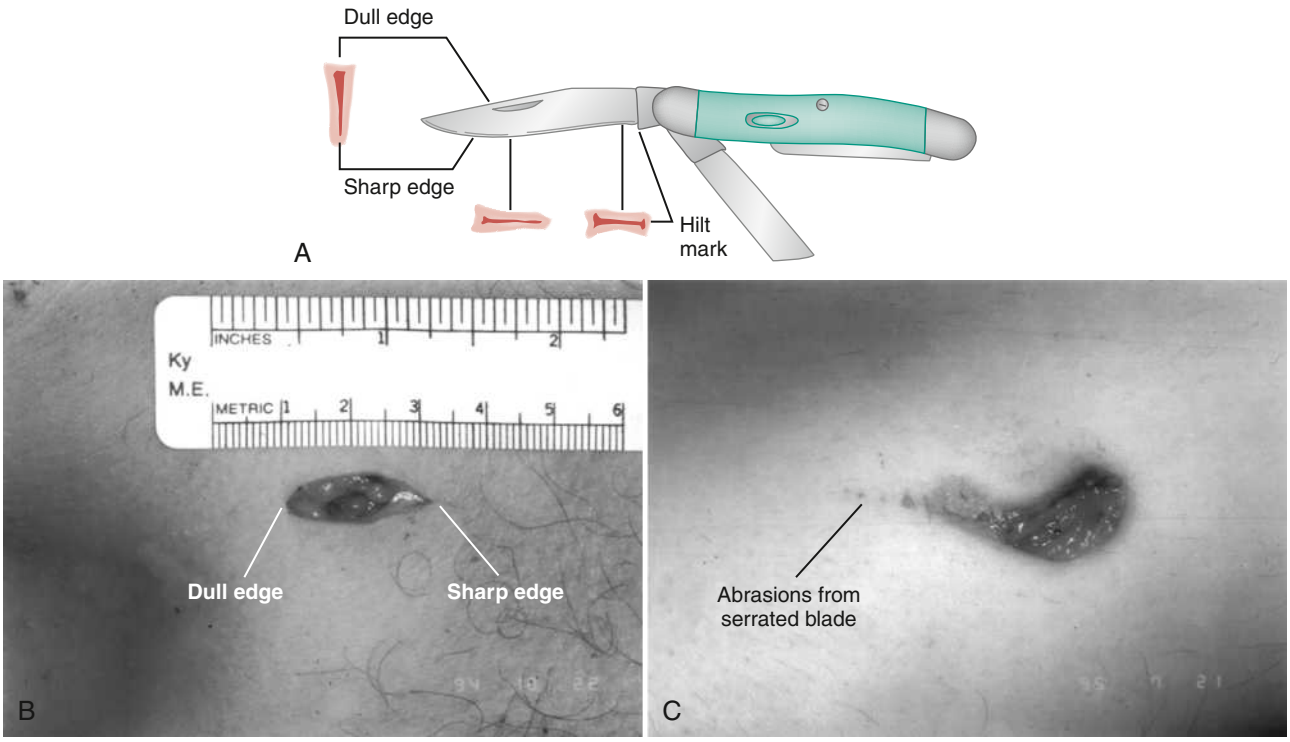

Fig. e11.24 (A) A single-edged knife blade will cause a wound to be formed with a sharp edge and a dull edge. If the blade penetrates to its hilt, a hilt mark may be seen overlying the sharp edge. (B) Single-edged stab wound. (C) Single-edged stab wound made by a serrated blade. Abrasions from the blade's serrated edges are seen on the left margin of the wound.

Fig. e11.25 The presence of multiple, parallel, superficial incised wounds, sometimes termed *hesitation marks*, are indicators of self-inflicted wounds.

BOX E11.2 Characteristics of Self-Inflicted Knife Wounds

- Multiple superficial incisions located on the anterior trunk, arms, and face
- Multiple superficial stab wounds located on the anterior trunk, arms, and face
- Parallel incisions, in close proximity to each other, on the nondominant side of the body
- Sparing of sensitive body areas
- Linear or curved incisions toward the hand inflicting the wound
- Intact clothing covering the wound
- Evidence of prior wounds in repeat offenders

Half of the world's road traffic deaths occur among so-called vulnerable road users, which are motorcyclists, pedestrians, and cyclists.[30] In vulnerable road users struck by motor vehicles, there is evident gender disparity, with more males affected. In addition, infrequent helmet use, riding against traffic, and distractions, such as use of electronic devices while driving, are important factors.[31] Collisions not occurring at intersections, occurring during overnight hours, and collisions by a heavy vehicle were associated with an increased rate of death.[31] In high-income countries, the proportion of deaths in those older than 70 years is noticeably greater than in low- and middle-income countries, likely due to longevity, combined with the greater risks posed by reduced mobility and frailty. Fatalities are high among the elderly, whereas injury rates were highest in adolescents and young adults.[31] Young adults account for over half of global road traffic deaths, with the majority of those deaths occurring in men.[30] Substance use and distracted driving, particularly with cell phone use, are dominant patterns seen in high-risk behavior in motor vehicle collisions (MVCs), and not wearing a motorcycle helmet is deadly for victims of motorcycle collisions. Devastating brain injuries are the leading cause of mortality in MVCs and motorcycle-related deaths. For pedestrians and bicyclists, the collision speed of the vehicle and protective devices are obvious factors that influence injury outcome. Patterns of injury differ according to the mechanism of injury.

Motor Vehicle Collisions

In MVCs, the head and thorax are the most frequently injured body regions. Occupants impact against the dashboard and steering wheel and are more likely to sustain torso injuries. Frontal and near-side crashes are most frequently associated with pulmonary contusion. Occupant weight, body mass index, and number of rib fractures are positively correlated with pulmonary contusion volume. The initial mechanical insult to the chest is followed by a secondary inflammatory response that extends the injury and has

been shown to be predictive of ventilatory support, acute respiratory distress syndrome, and pneumonia. Although women are less often involved in MVCs when compared to men, it has been shown that belt-restrained female drivers involved in an MVC are more susceptible to severe injuries, particularly of the chest and spine, when compared to male drivers.

Motorcycle Collisions

In the United States, there has been an overall decrease in the injuries sustained by young adult motorcyclists and an increase in the injuries sustained by middle-aged and older adult motorcyclists. Motorcycle riders involved in fatal crashes were more often alcohol impaired compared to other vehicle types, particularly those killed at night.[32] Older adult motorcyclists had high injury severity scores compared to younger adults, with head and chest injuries associated with the lowest rate of survival.

Evaluation of Motor Vehicle Collisions

Law enforcement officials investigating an incident involving serious or fatal injuries from a motor vehicle or pedestrian collision may benefit from information regarding injury patterns and the collection of trace evidence from the victim. This information can help determine whether an occupant was a driver or passenger. It may help identify a suspect vehicle involved in a hit and run pedestrian collision or a pedestrian's position (standing or lying) when struck on the roadway.

Determination of a vehicle occupant's role may be simple (e.g., if the driver is pinned behind the steering wheel) or complex (e.g., if the vehicle's occupants are ejected). Many impaired drivers claim to be passengers. Short-lived evidence or pattern injuries that might be destroyed or altered in the delivery of patient care should optimally be preserved and photographed.

An opinion on an occupant's position should be avoided because an occupant's role is difficult to determine based solely on history and physical findings in the ED. Such an opinion is best rendered by someone who has examined the scene, vehicle, other occupants, and trace evidence, has reviewed postmortem examinations, and has had the collision reconstructed to determine vehicle dynamics (Box e11.3).

BOX E11.3 Evidence Collection—Driver Versus Passenger

Victim

Examine for Pattern Injuries

Steering wheel contusion
Radio knob contusion
Window crank contusion
Striated incised facial wounds
Dicing wounds

Examine Clothing for Transferred Material[a,b]

Glass (front and side windows)
Fibers
Pedal imprint on shoe
Dashboard components

Collect Biologic Standards[b]

Hair
Blood

Collect Clothing Standards[b]

Damage

Vehicle

Examine for Pattern Damage

Steering wheel
Radio, knobs, dashboard
Window crank, side door
Windshield (laminated glass)
Side and rear window (tempered glass)

Collect Standards

Glass
Carpets and seats
Gas and brake pedals
Broken dashboard components

Examine for Transferred Material of Pedestrian

Hair on windshield and components
Blood on windshield and components

Examine for Transferred Material on Car Occupants

Fabric fibers
Imprinted fabric pattern

[a] Each article of clothing should be collected in a separate paper bag. This avoids cross-contamination, and wet material will dry. Do not collect evidence in plastic bags because moisture will condense within the bag and may degrade biologic material.
[b] Each article should be marked with the patient's name, item collected, date and time collected, location of collection, name of the collector, and name of law enforcement official to whom the evidence was given. This information will preserve the chain of custody.

Pattern Injuries

Matching pattern injuries with components within a vehicle often reveals an occupant's position during a portion of the vehicle's collision sequence. Common pattern contusions, abrasions, and lacerations are seen from steering wheels, air bags, air bag module covers, window cranks, radio knobs, door latches, dashboard components, and front and side window glass. An occupant's movement and subsequent contact with a vehicle's components are dictated by the forces applied to the vehicle through its interaction with the environment. Vehicle occupants, restrained or unrestrained, will initially move toward the primary area of impact.

A deployed air bag may induce a pattern abrasion to the face, cornea, forearms, or other exposed tissue. Pattern lacerations, specific fracture patterns, and amputations are seen when the deployed air bag module cover impacts the hand or forearm (Fig. e11.26). The correlation of these injuries and transfer of DNA from the driver or passenger to the deployed air bag are helpful in assessing an occupant's role as driver or passenger.

Laminated glass (windshields) and tempered glass (side and rear windows) produce pattern injuries. The windshield has two layers of glass laminated together with a thin layer of clear plastic sandwiched between. Laminated glass breaks into shards on impact and causes linear incised wounds. Tempered or safety glass is a single layer of glass that breaks into small cubes when fractured, imparting a dicing pattern to the skin (Fig. e11.27).

Trace Evidence

Clothing, shoes, and biologic standards (e.g., hair, tissue, blood) may determine an occupant's role. The soles of leather shoes may reveal the

Fig. e11.26 A traumatic partial amputation of the hand resulted from contact with a deploying air bag module cover.

Fig. e11.27 Sliding skin contact with the tempered glass found in a side or rear window creates dicing lacerations.

Fig. e11.28 Imprint of a brake pedal on a leather-soled shoe. This information will assist in determining the occupant's role and whether the patient's foot was on the brake or accelerator pedal at the moment of impact.

Fig. e11.29 Occupant contact with the air bag often results in the transfer of trace evidence. The presence of blood, tissue, hair, and makeup will assist in the determination of the seating arrangement of a particular occupant.

imprint of the gas or brake pedal (Fig. e11.28). Glass collected from within a patient's wound can be matched with a particular window within the vehicle. Air bags can be an excellent source of trace evidence. Examples of transferred evidence include skin, blood, makeup, and hair (Fig. e11.29).

Evaluation of Pedestrian Collisions

Pedestrians impact against various parts of the vehicle and ground and therefore sustain injuries to their arms and legs. The injury severity of pedestrians increases exponentially with increased impact speed of the offending vehicle. Crossing at uncontrolled midblock locations results in greater injury severity compared with crossing at a signalized intersection. Alcohol use is a significant risk factor for pedestrians stuck by motor vehicles because these patients are more likely to cross the street in an unsafe manner and sustain more serious injuries.[33] In pedestrians who were seriously injured or killed, driver failure to yield and driver inattention were cited as significant contributing factors. Pedestrians are at high risk for severe TBI, specifically intracranial hemorrhages and contusions and significant skull fractures.

Pattern Injuries

When struck by the front of a vehicle, a standing adult will sustain bumper injuries, which include open and closed fractures of the tibia and fibula, soft tissue damage, and pattern injuries from vehicle components and hardware.

The height of bumper injuries, measured from the heel and including the height of the patient's shoe, can be correlated with the height of the vehicle's bumper to determine whether the vehicle was braking at the moment of impact. Application of the brake results in the dipping of a vehicle's front end. The presence or absence of braking may help determine the driver's intent. The presence of bumper injuries at one height on one leg and at another height on the other may indicate that the pedestrian was walking or running at the moment of impact, with one leg elevated. Examination may show lateral striations or abrasions when a patient has been dragged.

A victim who is struck from behind may have pattern contusions on the calf or thigh (Fig. e11.30), whereas pattern contusions from a grill on the anterior aspect of the thigh indicate that the pedestrian was standing and facing the vehicle. Pedestrians struck by a glancing portion of a vehicle may also display a pattern injury (Fig. e11.31). Victims who are run over may display a tire tread pattern (Fig. e11.32). Tire marks and the absence of bumper injuries suggest that the patient was supine or prone in the roadway before he or she was run over (Box e11.4).

Fig. e11.30 (A) A pattern imprint contusion on the posterior aspect of a pedestrian's right thigh was the result of contact with the vehicle's grill. The location of the contusion provides information about the configuration of the patient at the moment that the car struck him. The patient was struck from the rear. (B) The grill of the striking vehicle.

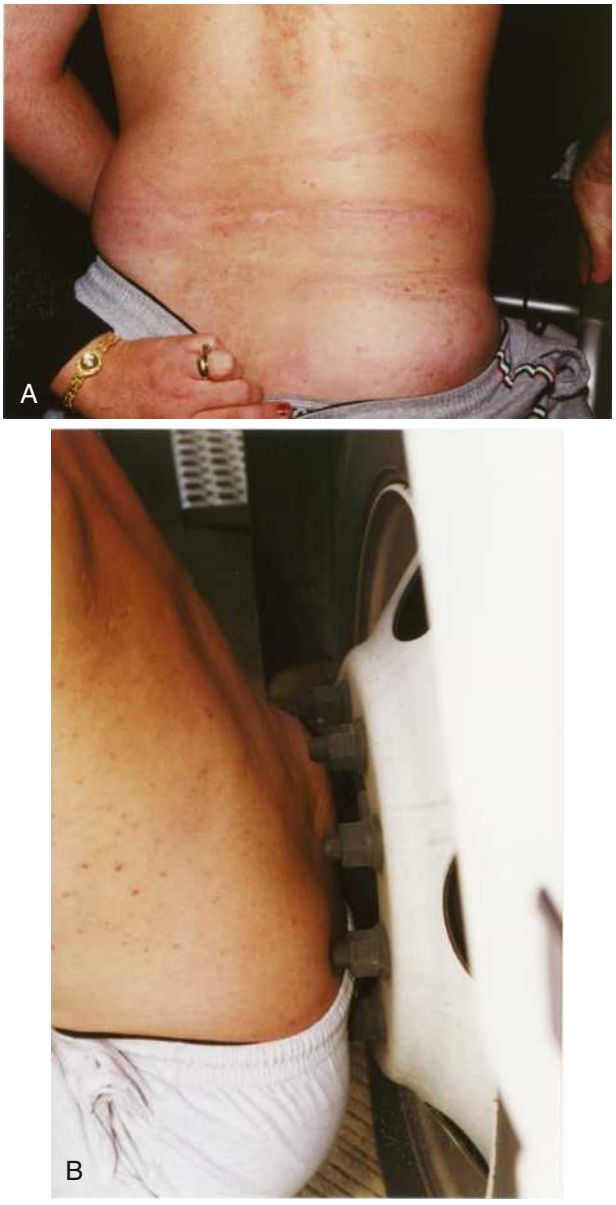

Fig. e11.31 (A) Three horizontally oriented wounds were noted on the back of a pedestrian struck by a semi–tractor trailer on a highway while changing a flat tire. (B) The pattern injury was matched to the lug nuts of the front right wheel.

INTERFACING WITH THE LAW

Law Enforcement Exemptions to the Health Insurance Portability and Accountability Act

Emergency physicians interact with law enforcement more than other medical specialties. Law enforcement often accompany victims of crime to the ED to document their injuries, collect evidence, and investigate crimes. They may request patient information related to the trauma that was sustained.[34]

Title 45, Part 164, of the Health Insurance Portability and Accountability Act (HIPAA) of 1996 permits hospitals to disclose to investigating law enforcement agencies specific information regarding a victim or suspect, without patient consent. Section 45 CFR 164.512 permits the release of protected health information, without a court order, "in response to a law enforcement official's request for such information for the purpose of identifying or locating a suspect, fugitive, material witness, or missing person." A hospital or emergency clinician may disclose the information listed in Box e11.5 only to an investigating law enforcement officer. Physicians should only disclose what is necessary to satisfy law enforcement and permitted under the law.[34] There is also a national security exemption to HIPAA that allows disclosure of patient information to authorized federal officials for the conducting of intelligence and national security activities to avert a serious threat, including terrorism.[34]

In some law enforcement investigations, officers must use photography to collect evidence. Obtaining consent is optimal but may not always be feasible and is not legally required. Such photography or videography should not include patient interactions with medical staff in the course of obtaining medical care.[34]

Mandatory Reporting

The patient-physician relationship is complex for emergency physicians when caring for victims of trauma. Mandatory reporting statutes typically require physicians to report to law enforcement or the state social service agency for a defined public good and override patient confidentiality.[34,35] Such statutes require reporting when there are

Fig. e11.32 Tire tread imprints on the skin indicate that this victim of a hit and run collision was on the ground when he was hit.

concerns for public safety related to infectious diseases, lapses in consciousness that would pose a risk while driving a vehicle, suspicion of abuse or neglect, and threats of harm.[34] Almost all states require clinicians to report when a patient is injured by an assault and the clinicians have reasonable suspicion of child abuse, elder abuse, or interpersonal violence. Every state has a statute that provides some sort of immunity to those that make a good faith report, even when the report turns out to be incorrect. Physicians may be held liable for failing to report. It is important to learn the applicable state law because specific reporting requirements may vary from state to state.[34]

Subpoenas and Court Depositions

One important interface between medicine and law is the courtroom. Most physicians will provide legal testimony during their career. Judicial and administrative proceedings are exempt from HIPAA under specified circumstances.[34] In the event a physician is subpoenaed as a witness, it is prudent to inform the risk management department at the facility where the patient was treated. When contacting the attorney, discuss the parameters of the testimony and learn what questions might be asked during the deposition. Prior to providing testimony, it is important to be familiar with the medical record, including nursing notes. Relevant hospital policies and departmental guidelines should also be reviewed in preparation for a deposition. Documentation in the medical record is paramount, especially because a case may not go to court until years after the patient was evaluated in the ED. It is prudent to document the rationale for major decision making if using macros or templated text, paying close attention so as not to contradict other sections of the chart, and to put patient statements regarding the event in quotations.

In criminal cases, witness testimony is given by the treating provider. Typically, questions will relate to explaining the medical care and injuries in lay terms. For civil cases brought to court by a private law firm, it is possible to charge as an expert witness, with the caveat that providers may be asked to go beyond their knowledge of the case. Most attorneys are aware physicians have busy schedules, so it is possible to ask to be on call, to be the first witness of the day, or to be scheduled for a certain time.

When testifying, it is best to answer questions thoughtfully and confidently. It will be necessary to explain medical jargon in lay terms. If the clinician does not have a direct memory, then referring back to the provided medical record will help. In general, it is best to only answer the question that is being asked and not to answer outside the clinician's scope of care for the patient or outside the clinician's expertise. If the attorney's question is convoluted, it is acceptable to ask that the question to be rephrased. If the clinician is still unsure, then it is best to inform the

BOX E11.4 Evidence Collection—Pedestrian Collisions

Victim

Examine for Pattern Injuries

Examine for Transferred Material of Pedestrian
Hair
Blood or tissue

Examine for Transferred Material on Vehicle
Fabric fibers
Imprinted fabric pattern

[a] Each article of clothing should be collected in a separate paper bag. This avoids cross-contamination, and wet material will dry. Do not collect evidence in plastic bags because moisture will condense within the bag and may degrade biologic material.
[b] Each article should be marked with the patient's name, item collected, date and time collected, location of collection, name of the collector, and name of law enforcement official to whom the evidence was given. This information will preserve the chain of custody.

BOX E11.5 Law Enforcement Exemptions to the Health Insurance Portability and Accountability Act[a]

- Name and address
- Date and place of birth
- Social security number
- ABO blood type and Rh factor
- Type of injury
- Date and time of treatment
- Date and time of death, if applicable
- Description of distinguishing physical characteristics, including height, weight, gender, race, hair and eye color, presence or absence of facial hair (beard or moustache), scars, and tattoos

[a] 45 CFR 164.152.

attorney that the question cannot be answered. Objections may interrupt the deposition. In that situation, it is best to pause and wait for the judge to determine whether the clinician can continue answering.

Forced Blood Draws

Physicians have an ethical and legal duty to the patient's best interest, even if the patient is suspected of committing a crime.[34,36] Law enforcement personnel may bring a patient to the ED to have blood drawn if the patient is arrested for driving under the influence (DUI) of alcohol and/or drugs. If the patient has decision-making capacity and explicitly refuses to give consent to perform the test, then the situation can be difficult to navigate. Patients who are brought to the ED may have agreed in advance to provide a blood sample but can change their mind at any point.[34] Patients who are in custody still have a right to informed consent, refusal of medical treatment, and a right to privacy similar to other patients.[34] The primary mission of the physician is to provide medical care to those that are ill or injured, whereas the responsibility of law enforcement is to public safety.[36] The United States Supreme Court upheld the constitutionality of subjecting a person to an involuntary blood test under certain circumstances and found that it does not violate the due process clause, the person's privilege against self-incrimination or the right to counsel. Neither written nor oral consent from the patient is required. Furthermore, some states, such as California, have implied consent when obtaining a driver's license.

In general, ED personnel should draw blood needed for diagnosis and treatment only. When legally bound by either implied consent or a court order, then ED personnel should make every reasonable effort to draw blood for evidence purposes from the patient who is seeking medical attention. Law enforcement will need an official written request, such as a court order, for the procedure, should bring the necessary specimen collection tubes, and follow chain of custody procedures. Drawing of the blood should be done in a reasonable manner, such as when other blood specimens are being drawn while the patient is receiving medical care, should not interfere with the delivery of emergency medical care to the patient, and should be done without coercion by medical personnel. Chlorhexidine or betadine should be used to clean the skin rather than an alcohol wipe. Some states provide statutory immunity to medical personnel who take such a blood sample without the patient's consent. Additionally, there may be exceptions for patients who are using anticoagulant therapy or have a history of hemophilia. If there are any concerns, then hospital risk management should be contacted.

CHAPTER E11: QUESTIONS AND ANSWERS

1. When documenting a gunshot wound, it is important to do which of the following?
- **a.** Describe the appearance, physical characteristics, and location of wounds.
- **b.** Describe the bullet trajectory.
- **c.** Determine the type of bullet used.
- **d.** Estimate the caliber of the bullet.
- **e.** Interpret the wounds as "entrance" or "exit."

Answer: A. Emergency clinicians should not identify wounds as "entrance" or "exit." Instead, their charting should include a detailed description, using appropriate forensic terminology, of the wound's characteristics and location without speculating about its function or the caliber or type of bullet (projectile) used to create it.

2. A young man is brought to the emergency department following an accidental rifle injury to his right leg. He has an obvious deformity to the extremity on examination with intact sensation and motor function, but pulses are diminished. Plain radiographs of the extremity show comminuted tibial and fibular fractures. Which of the following is/are indicated in his management?
- **a.** Superficial débridement and wound closure
- **b.** CT angiography, prophylactic antibiotics, and operative management
- **c.** Splinting and urgent orthopedic follow-up
- **d.** Emergent fasciotomy
- **e.** Urgent surgical consultation

Answer: B. High-energy gunshot wounds with associated fractures are managed as open fractures and are generally treated with prophylactic antibiotics because contaminants can be sucked into the wound due to cavitation. Operative intervention is required for patients with unstable fractures, fractures with exposed bone, compartment syndrome, or vascular injuries requiring repair. The latter is likely present in this patient given his diminished pulses and should be further evaluated by CT angiography. These patients are also at risk for compartment syndrome and should be closely monitored.

3. An abrasion collar can be associated with which of the following types of wounds?
- **a.** Close-range wound
- **b.** Contact wound
- **c.** Long-range or indeterminate-range wound
- **d.** Intermediate-range wound
- **e.** Shotgun wound

Answer: C. An abrasion collar (also referred to as an abrasion margin, rim, or ring) results from skin indentation as the bullet penetrates the surface. This collar is an abraded area of tissue that surrounds an entry wound as the result of friction between the bullet and epithelium. These usually result from distant or long-range wounds, which are inflicted from far enough away that only the bullet makes contact with the skin. When an abrasion collar is the only visible superficial clinical finding present, the term *indeterminate range* describes the range of fire. Most entrance wounds will have an abrasion collar aside from those on the palms and soles, which usually appear slit-like.

4. A 23-year-old woman presents after having been physically and sexually assaulted by an unknown assailant. In addition to multiple abrasions and brown contusions, she has a bite mark on her left shoulder. Which of the following is not appropriate in your evidence collection procedures and evaluation of this patient?
- **a.** Estimating the age of the contusions based on their color
- **b.** Measuring and documenting each visible injury on a diagram
- **c.** Preserving the condition of the bite mark until after a forensic examination
- **d.** Swabbing the bite mark with a sterile cotton-tipped applicator moistened with sterile water or saline
- **e.** Taking photographs of the bite mark and each injury

Answer: A. When an acute bite mark is identified, take care that critical evidence is not washed away. The skin surface should first be swabbed with a sterile cotton-tipped applicator moistened with sterile saline. Swabbing the area may reveal the assailant's DNA present in dried saliva. Remember, a contusion's color is never a predictor of its age. The emergency clinician may be asked to render an opinion regarding the age of a contusion. Because contusions develop as a result of multiple variables, there is no reproducible standard for dating them.

5. When managing a gunshot wound victim, which of the following is not important for forensic evidence collection?
- **a.** Do not clean the patient's the hands with alcohol or Betadine.
- **b.** If soot is noted on the hands of the victim, cover with paper bags.
- **c.** Maintain a chain of evidence.
- **d.** Place each article of clothing in a separate paper bag.
- **e.** Use metal forceps to handle a bullet to prevent contamination.

Answer: E. Never remove a bullet with metal hemostats or pickups because metal tools can obliterate the microscopic markings (the telltale fingerprint) of the gun from which it was shot. A victim's clothing may hold the answer to critical questions, such as "How far away was the assailant who fired the weapon?" and "Which hole is the entrance and which the exit?" Articles of clothing removed from a wounded patient should be placed in separate paper bags to preserve the trace evidence on them and to avoid accidentally transferring evidence from one article to another (cross-contamination). Always cover a patient's hands with paper bags when the presence of soot is suspected. A gunshot residue test may determine whether a victim or suspect has been in close proximity to a weapon that has been fired. Factors that decrease the sensitivity of gunshot residue tests include washing the skin with alcohol or Betadine.

Emergency Medical Services: Overview and Ground Transport

Emergency Medical Services: Overview and Ground Transport

Thomas H. Blackwell

KEY CONCEPTS

- Published in 1966, *Accidental Death and Disability: The Neglected Disease of Modern Society* by the National Academy of Sciences–National Research Council was instrumental in emergency medical service (EMS) maturation in the United States.
- There are multiple models for EMS systems, including public and private services, those operating at basic and advanced levels of care, and those including single or multiple tiers of response capability.
- There are four levels of prehospital providers recognized nationally—emergency medical responder (EMR), emergency medical technician (EMT), advanced emergency medical technician (AEMT), and paramedic, which is the most advanced level.
- The community paramedic provider focusing on population health issues such as access, chronic disease, and decreasing utilization and readmission is now being considered by many communities.
- Advances in emergency medical dispatching and positioning resources at locations and during specified times where expected call volumes are prevalent are innovations that are being implemented to decrease response times and improve outcomes.
- Regulatory oversight for EMS systems lies at the individual state level, and medical direction for individual public or private services resides at the local level.
- Direct medical oversight involves real-time interaction with the prehospital providers via face-to-face or radio communications. Indirect medical oversight involves off-line processes such as protocol development, quality improvement, and education.
- Advances in prehospital care of medical patients have included analgesics and anxiolytics that can be administered intranasally, negating intravenous routes, noninvasive measures to support patients in respiratory distress, alternative adjuncts in place of endotracheal intubation for managing airways, and tourniquets for controlling hemorrhage.
- More advanced diagnostics (such as 12-lead electrocardiography and use of stroke screens) have assisted in transporting patients to appropriate facilities based on their illness and acuity.

FOUNDATIONS

Development of Emergency Medical Services

Before the advent of civilian ambulance services, the sick and injured were transported by any means available, including passerby motorists, wagons, farm machinery, delivery carts, buses, and taxicabs. The military was instrumental in developing systems for transporting wounded soldiers off the battlefield. Figure e12.1 depicts the early Larrey ambulance used during the Napoleonic Wars, the Rucker wagon used during the American Civil War, and a modern ambulance in use today. In 1865, the Commercial Hospital in Cincinnati established the first hospital-based ambulance service. Four years later, the first city service began at New York's Bellevue Hospital.

The beginning of the interstate system of highways in the mid-1950s, excessive speed limits, and poor automobile construction resulted in widespread injuries and deaths across the United States. To address this growing problem, the 1965 President's Commission on Highway Safety recommended the National Accident Response Program and the results from a national survey by the National Academy of Sciences–National Research Council were used to draft the 1966 white paper entitled *Accidental Death and Disability: The Neglected Disease of Modern Society.* This document described the hazardous conditions for the provision of emergency care at all levels and outlined the necessary building blocks for future maturation of emergency medical services (EMS). Congressional legislation eventually directed the United States Department of Transportation (DOT)–National Highway Traffic Safety Administration (NHTSA) to develop a program for improving emergency medical care.

During the 1960s, emergency cardiac care included field defibrillation programs in Belfast, Northern Ireland, and cardiac arrest research in several cities, including Columbus, Ohio, and Miami, Florida. In 1969, the first National Conference on EMS convened, resulting in the development of a curriculum, certification process, and national registry for the emergency medical technician–ambulance (EMT-A). Interested physicians and nurses soon began providing more advanced educational courses and expanding the scope of practice for EMTs, which led to the paramedic provider.

The EMS Systems Act of 1973 (P.L. 93-154) was passed by Congress and authorized funding that dramatically improved regionalization of EMS systems. In 1984, efforts to improve pediatric emergency care occurred when Congress adopted the Emergency Medical Services for Children (EMS-C) initiative through the Health Services, Preventive Health Services, and Home Community Based Services Act of 1984 (P.L. 98-555). A study by the Institute of Medicine (now the National Academy of Sciences, Engineering, and Medicine [NAS]) released in 1993 promoted the integration of EMS-C not just into existing EMS systems but into comprehensive systems of care provision, including injury prevention, primary and definitive care, and rehabilitation services.

In 1996, NHTSA published *Emergency Medical Services Agenda for the Future,* which broadly outlined the principles required for future EMS development. All components of an EMS system, both operational and clinical, were identified and discussed. This document has been used by many individuals and organizations as a valuable reference for planning, administration, and forecasting the future of EMS delivery. More than 40 years after the 1966 white paper publication, the NAS released a report on the status of emergency care entitled *The Future of Emergency Care in the United States Health System* which focused on three separate yet related topics: (1) emergency care: at the breaking point, (2) EMS at the crossroads, and (3) emergency care for

Fig. e12.1 Larrey's flying ambulance (A), Letterman's Rucker wagon (B), and the modern ambulance used today (C). (A, Courtesy the National Library of Medicine, History of Medicine Division. B, Courtesy the Library of Congress, Prints and Photographs Division, LC-88171-2585 DLC.)

children: growing pains. A major focus included the need to strengthen the integration of EMS into the entire health care system because lack of such coordination often results in patients being diverted to inappropriate or distant facilities. The recommendation was to ensure that emergency medical and trauma care is organized into a coordinated, regional system such that patients receive care at the most appropriate facility on the basis of their injury or illness. The concern for inadequate funding for EMS systems operations and disaster response was also addressed. In addition to recommending that Congress develop regionally funded, multiyear demonstration projects that provide seamless systems of care, workforce strengthening, evidence-based practices, and disaster preparedness, the NAS recommended that an advisory committee be created to work with the Centers for Medicare and Medicaid Services to improve reimbursement. In 2019, the Centers for Medicare and Medicaid Services Innovation Center released a Request for Applications for interested EMS systems to participate in a new initiative called Emergency Triage, Treat, and Transport (ET3) which will investigate reimbursement for alternative transport destinations (primary care physician or urgent care) or to treat on scene by a provider or telehealth connection.[1] Finally, the NAS report recommended that the care of children be integrated into the overall EMS system, with pediatric emergency care training enhanced to maintain defined competencies.

In 2014, plans were initiated to update the 1996 Agenda and in 2019, the *EMS Agenda 2050: A People-Centered Vision for the Future of Emergency Medical Services* was released.[2] This report describes the future of EMS being people-centered, evidence-based, and functionally a component of the overall health care delivery system. Figure e12.2 lists the six guiding principles included in the Agenda.

In 2019, *Pediatric Readiness in Emergency Medical Services Systems* was published and cosponsored by the American Academy of Pediatrics, American College of Emergency Physicians, Emergency Nurses Association, National Association of EMTs, and the National Association of EMS Physicians.[3] This document outlines important recommendations for EMS systems to be pediatric ready, and future efforts will include a national assessment of all EMS agencies nationally.

Specific Issues

Emergency Medical Service Systems

Multiple EMS system designs exist, all predicated on the type of community served. Whereas this is a local decision, all states incorporate an administrative office that governs or oversees the provision of EMS activities. The role of the state office includes planning, licensing services and providers, and establishing or enforcing the scope and standards of practice. Other functions may include disaster preparedness and response activities, public health initiatives, record keeping, data collection, and auditing or investigating programs or providers. A description of EMS systems for the 200 most populous cities in the United States is periodically published in the *Journal of Emergency Medical Services*. For simplicity, the following categorization of systems is used: private and public agencies; basic life support (BLS) and advanced life support (ALS) services; and single-tiered, multitiered, and first responder systems.

Private and Public Agencies

Where local government has not assumed primary responsibility for EMS services, communities may depend on private providers. Financial responsibility varies but usually depends on federal reimbursement (Medicare or Medicaid) and user fees. A local government subsidy may or may not supplement the operation. If multiple providers are serving one jurisdiction, calls may be allocated by rotation or specified zone coverage. Dispatching varies by system but may be by the provider or by a central agency. Medical direction is often provided by a contracted physician or physician oversight board.

Hospital-based EMS systems are few in number and may be managed by a single hospital or hospital corporation. Not all hospital-based EMS programs are considered private, in that the hospital may be a division under local or state government or operate under a public authority. Financial responsibilities and dispatching are similar to private models outlined previously. An emergency physician from a sponsor or base hospital typically provides medical direction.

A public utility model is a hybrid between private and public design that allows local government to contract with a private or public

EMS AGENDA 2050
A People-Centered Vision

In 2050, EMS systems are designed to provide the best possible outcomes for patients and communities–every day and during major disasters. They collaborate with community partners and are integral to regional systems of care that are data-driven, evidence-based and safe. EMS clinicians have access to the resources they need, including up-to-date technology and training. **To achieve this vision, EMS systems in 2050 will be designed around six guiding principles.**

ADAPTABLE AND INNOVATIVE

Technologies, system designs, educational programs and other aspects of EMS systems are continuously evaluated in order to meet the evolving needs of people and communities. Innovative individuals and organizations are encouraged to test ideas in a safe and systematic way and to implement effective new programs.

INHERENTLY SAFE AND EFFECTIVE

The entire EMS system is designed to be inherently safe in order to minimize exposure of people to injury, infections, illness or stress. Decisions are made with the safety of patients, their families, clinicians and the public as a priority. Clinical care and operations are based on the best available evidence, allowing systems to deliver effective service that focuses on outcomes determined by the entire community, including the individuals receiving care.

SUSTAINABLE AND EFFICIENT

EMS systems across the country have the resources they require to provide care in a fiscally responsible, sustainable framework that appropriately compensates clinicians. Efficient EMS systems provide value to the community, minimize waste and operate with transparency and accountability.

INTEGRATED AND SEAMLESS

Healthcare systems, including EMS, are fully integrated. Additionally, local EMS services collaborate frequently with community partners, including public safety agencies, public health, social services and public works. Communication and coordination across the care continuum are seamless, leaving people with a feeling that one system, comprising many integrated parts, is caring for them and their families.

SOCIALLY EQUITABLE

Access to care, quality of care and outcomes are not determined by age, socioeconomic status, gender, ethnicity, geography or other social determinants. Caregivers feel confident and prepared when caring for children, people who speak different languages, persons with disabilities or other populations that they may not interact with frequently.

RELIABLE AND PREPARED

EMS care is consistent, compassionate and guided by evidence—no matter when or where it is needed or who is providing the care. EMS systems are prepared for anything by being scalable and able to respond to fluctuations in day-to-day demand, as well as major events, both planned and unplanned.

THE FUTURE STARTS NOW

Visit ems.gov to learn more about EMS Agenda 2050 and help make the vision a reality.

ems.gov

Fig. e12.2 EMS Agenda 2050 guiding principles. (From: EMS Agenda 2050 Technical Expert Panel. EMS Agenda 2050: A People-Centered Vision for the Future of Emergency Medical Services (Report No. DOT HS 812 664). Washington, DC: National Highway Traffic Safety Administration; 2019.)

provider. The service selected, usually through a request for proposal and competitive bidding process, becomes a contracted entity that agrees to provide the specified services (ALS, BLS, or both) and, depending on the arrangement, bills the patient directly or receives uniform reimbursement. A subsidy may or may not be provided by the local jurisdiction, dispatching may be performed by an existing public safety organization or by the parent company, and medical direction is usually performed by a specified individual subject to contractual terms.

When municipal governments were faced with planning and establishing EMS systems, many decided that fire departments would be well-equipped to provide EMS in addition to fire services. Fire stations are strategically located throughout the community and personnel are already used to providing emergency response and public services. Firefighters can be cross-trained as firefighters-paramedics or dedicated to performing either fire or EMS functions separately. Public EMS systems that were not incorporated into fire departments evolved into their own separate entity, referred to as a municipal third-service system. Such agencies are endorsed and supported by local government. Many cities have been successful in combining police, fire, and EMS under a global public safety agency, with all department heads or chiefs reporting to one administrator. Financially, public EMS systems may be supported by a per-capita tax base, which may or may not be supplemented by user fees. Regardless of design, medical oversight for a municipal EMS system may be provided by a physician appointed and contracted by the municipality, a local hospital, an advisory council or medical society, or a medical oversight board.

Basic Life Support and Advanced Life Support Service

Basic life support describes the provision of emergency care without the use of advanced therapeutic interventions. Skills include airway management (oral and nasal airways, bag-mask ventilation, extraglottic airways), cardiopulmonary resuscitation (CPR), hemorrhage control, fracture and spine immobilization, and childbirth assistance. Defibrillation with an automated external defibrillator (AED) is often included by many BLS systems. Services are provided by emergency medical responders (EMRs) or emergency medical technicians (EMTs), and medical direction may or may not be a requirement depending on individual state regulations. Few urban communities across the United States operate solely at the BLS level. Many rural and some suburban EMS services rely on volunteers who may not wish to become advanced-level providers. Because these services may have low call volumes, it becomes difficult for personnel to maintain advanced skills. Also, such communities may not have access to medical supervision or hospital sponsorship for ALS care.

The effectiveness of ALS for medical and traumatic emergencies is debatable, although systems categorized as ALS offer a more comprehensive level of service by highly educated providers, usually certified at the advanced emergency medical technician (AEMT) or paramedic level. Provider skills include advanced airway interventions, intravenous line placement, medication administration, cardiac monitoring and 12-lead electrocardiographic (ECG) interpretation, and certain invasive procedures.

Most EMS systems in cities operate at this level of care; however, the number of paramedics in any jurisdiction has come under scrutiny, in that cities with more paramedics per capita tend to have lower survival rates. Although this may seem counterintuitive, one explanation might be that the number of patient encounters per paramedic decreases and skill performance degrades when more providers are competing for the same number of experiences.

Single-Tiered, Multitiered, and First Responder Systems

In a single-tiered system, every response regardless of call type receives the same level of personnel expertise and equipment allocation (all BLS or ALS). Multiple-tiered systems use a combination of ALS and BLS levels, depending on the nature and potential severity of the call. Differences in cost and effectiveness between a mixed ALS-BLS service and an all-ALS service have been debated. A single-tiered ALS response may prove to be cost-effective in specific locales, ensures the capability of providing a consistent advanced level of care to all patients regardless of illness or injury severity, and obviates the potential for undertriage or overtriage by 911 telecommunicators. Alternatively, a multitiered system may meet the needs of individual communities and could be less costly because EMTs are usually compensated less than paramedics. This design also has the potential to preserve ALS resources for higher priority calls.

Regardless of single- or multiple-tier design, EMS systems usually include first responder services as part of their structure. The first responder, usually a police officer or firefighter, is the nontransport BLS or ALS provider who responds to the scene of an emergency to provide initial care before definitive medical care and transportation assets arrive. The first responder quickly assesses the scene and patients, determines whether additional resources are required, initiates patient care, and provides information to responding personnel prior to their arrival.

The design of an EMS system is targeted toward providing quality patient care in the briefest time after unexpected injury or illness. A desirable and cost-effective design might include BLS nontransport first responders with short response times (average 2 to 4 minutes) having the capability of providing early defibrillation and airway support, coupled with ensuing ALS care and transport services.

Levels of Provider and Scope of Practice

At the federal level, NHTSA and their partner stakeholders are responsible for developing all education and standards related to providers and their scope of practice. In 2000, the *Emergency Medical Services Education Agenda for the Future: A Systems Approach* was published and set forth the processes required to improve EMS education delivery. As components of this document, the Core Content (released in 2004) includes all knowledge and skills for EMS practice; the Scope of Practice Model (released in 2007 and revised in 2019) defines the knowledge and skills for the four provider levels; and the Education Standards (released in 2009) outlines objectives, competencies, behaviors, and judgements for developing more broad and flexible curricula. Two additional components included educational program accreditation and a national certification process for providers (both released in 2013). Although the National Association of State EMS Officials (NASEMSO) has been collaborating with multiple stakeholders and federal partner organizations to assist states in implementing this agenda, it is still incumbent on individual state legislation to determine provider levels recognized, initial and continuing medical education requirements at each level, testing, and time intervals for course completion and recertification. Suggested hours of training at each level of provider are listed in Table e12.1.

Emergency Medical Responder

The EMR, formerly referred to as *medical first responder,* is typically the first to arrive on the scene of an incident. Initial scene and patient assessment along with limited lifesaving interventions is the primary function. Along with CPR and basic airway management skills, the EMR should be able to control hemorrhage, manually secure an airway, stabilize fractures, perform CPR, and operate an automatic external defibrillator (AED). The EMR also assists the EMT or paramedic with ongoing care following their arrival.

Emergency Medical Technician

The EMT, formerly referred to as the *EMT-Basic,* is the minimum level required to staff an ambulance and is commonly used for

TABLE E12.1 Emergency Medical Services Provider Level, Training, and Skills

Provider Level	Commission on Accreditation of Allied Health Education Programs Recommended Hours of Training	Skill Set
Emergency medical responder (EMR)	Initial: 40 didactic and laboratory hours	Initial scene and patient assessment and stabilization Basic airway skills CPR Hemorrhage control Spinal motion restriction
Emergency medical technician (EMT)	Initial: 110 hours that include didactic, laboratory, clinical, and field experience	First responder skills plus: Triage and detailed patient assessment Automatic external defibrillation May assist in some systems, such as use of epinephrine autoinjectors for anaphylaxis and albuterol for wheezing
Advanced emergency medical technician (AEMT)	Initial: 200 to 400 hours that include didactic, laboratory, clinical, and field experience	EMTS skills plus: Endotracheal intubation Manual defibrillation Intravenous line placement Limited pharmacologic treatments May assist in some systems, such as laryngeal mask airway
Paramedic	Initial: 1000 or more hours that include didactic, laboratory, clinical, and field experience	AEMT skills plus: Cardiac rhythm recognition Expanded pharmacologic treatments Needle decompression of a tension pneumothorax Needle or surgical cricothyrotomy Transthoracic cardiac pacing

AED, Automated external defibrillator; *CPR,* cardiopulmonary resuscitation.

nonemergency and convalescent transport services or paired with a higher-level provider for ALS care. In addition to the skills of the EMR, the EMT is also involved with triage, more detailed patient assessment, and transportation.

Many but not all states have expanded the EMT scope of practice to include extraglottic airway insertion; use of continuous positive airway pressure; epinephrine administration for anaphylaxis, naloxone, chemical nerve agent antidote autoinjections; and administration of aspirin, nitroglycerin, and albuterol by handheld nebulizer or metered-dose inhaler.

Advanced Emergency Medical Technician

The AEMT, formerly referred to as the *EMT-Intermediate,* was established to allow a more comprehensive approach to care when paramedic services are unavailable or unobtainable due to a limited workforce. Many states recognize the AEMT certification, but others designate alternative but comparable levels depending on specific skills and procedures. This level is useful for rural systems because it provides some ALS care for less cost and education time. The scope of practice for the AEMT varies across the United States. In addition to all EMT skills, most systems allow the AEMT to establish an intravenous line, to manually defibrillate, and to administer limited medications.

Paramedic

Paramedics are the most advanced prehospital providers. Their scope of practice includes a wide variety of therapeutics and procedures including 12-lead ECG rhythm interpretation, expanded pharmacologic treatments, and advanced airway interventions. Invasive and lifesaving procedures include needle decompression of a tension pneumothorax, needle or surgical cricothyrotomy, and transthoracic cardiac pacing.

Initial training courses for all levels of providers include didactic, clinical, and field education, each escalating in complexity for higher levels of certification and all focusing on technical and professional competencies. Additional coursework programs exist for paramedics that expand the scope of practice, including the flight paramedic for fixed or rotor wing services, the community paramedic who serves in a population health capacity, and the critical care paramedic for high-risk adult and pediatric transfers. With the expansion of EMS technology and management career options, many paramedic educational programs have advanced from 1-year certificate curricula to 2-year associate or 4-year baccalaureate degrees. Since 2018, as a means to ensure quality prehospital education and consistency, any individual applying for national paramedic certification must have graduated from a program accredited by the Commission on Accreditation of Allied Health Education Programs.[4]

In keeping with the spirit of the EMS Agenda for the Future, which specifically calls for integration of health services and prevention attributes, some systems have implemented programs that engage interprofessional health providers into the existing structures of care. Examples include embedding a nurse triage system at the 911 access level, where low-acuity complaints as determined by evidence-based algorithms are transferred to alternative call centers. Here, nurses determine and arrange appropriate care at a clinic or facility other than an emergency department (ED).[5] Another example that is becoming popular is having prehospital providers, usually at the paramedic level, provide patient evaluation services to pre-identified patients with chronic conditions such as hypertension,

diabetes, congestive heart failure, and substance abuse. These programs, referred to as *community paramedics, mobile integrated health,* or *advanced practice paramedics,* among others, often include interprofessional providers (nurses, social workers, case managers), and are designed to prevent or reduce the need for EMS calls and decrease ED utilization for targeted patients or frequent users.

Material Resources

Before the mid-1960s, few if any regulations governed system design, operations, and equipment. As EMS development progressed, guidelines for emergency vehicle specifications were adopted by the DOT and equipment lists were proposed. Today, collaborative efforts from multiple professional organizations continue to publish documents that recommend design, equipment, and medications for ambulances.[6]

Medications

During the 1980s, many believed that prehospital drug administration was unjustified and simply delayed hospital transport. Although there was a profound paucity of outcomes-based research into the use of various medications and practices in the prehospital environment, this has improved in recent years. There is significant evidence for early defibrillation and certain advanced cardiac life support medications carried by most ALS services. The wide variety of alternative medications is less uniform. This includes medications for respiratory conditions and anaphylaxis, altered mental status, pain, nausea and vomiting, and hypoglycemia. Medications are traditionally administered on the field by the parenteral route, but the intranasal route is becoming more popular. The beneficial aspects are that absorption is rapid with an onset of action similar to that of parenteral administration. Medications that are commonly administered intranasally are naloxone for narcotic overdose, midazolam for pediatric seizure, and fentanyl for pain control.[7,8]

Equipment

Basic ambulance equipment includes items necessary for emergency procedures (i.e., airway support, hemorrhage control, fracture immobilization and spinal motion restriction, childbirth), personal protection, basic rescue capabilities, and patient movement. Additional patient care equipment is predicated on the level of provision outlined by the system design (ALS or BLS and procedures or other forms authorized by the medical director). Many ALS systems have adopted the equipment necessary for the acquisition of a prehospital 12-lead ECG and there are now mobile stroke ambulances equipped with a CT scanner and/or telemedicine capability to provide earlier diagnosis of acute cardiac and cerebrovascular conditions.[9,10] This information often guides destination protocols to deliver these patients directly to acute care facilities that incorporate staffed 24-hour percutaneous cardiac intervention (PCI) or neurointervention services.

Ambulances

Three basic designs for ambulances are recognized by the DOT: type I, type II, and type III. Both type I and type III ambulances incorporate a modular patient compartment mounted on a conventional truck or van chassis, respectively. The type II vehicle is a standard van. A larger additional-duty vehicle, mounted on a business-class chassis, has become popular in recent years because this configuration requires less periodic maintenance and offers extended service time. Each ambulance manufacturer promotes various interior cabinetry, and all include sufficient lighting, outlets for 110-volt equipment, suction and oxygen systems, and external audible and visual warning devices. Most ambulances are marked with various colors and design schemes that serve as additional safety features and display the six-pointed blue star, or Star of Life, surrounding the staff of Aesculapius, which is recognized worldwide as the standard symbol for EMS.

Communications

Integral to prehospital care systems, EMS communications involve multiple components, all interlinked to support expedient patient care. Effective communication systems include public information and education programs regarding general access to care, technology to ensure simplified access, a means of call prioritization and management of available resources, protocols for providing prearrival patient care instructions for certain life-threatening conditions, ability to communicate with allied agency and hospital personnel, educational opportunities for telecommunicators, and quality improvement processes.

Access

Since 1973, the 911 universal emergency access telephone number has been adopted by most communities throughout the United States. Basic 911 service simply connects a caller to a central communications center or public safety answering point (PSAP). Most primary PSAPs are under the domain of law enforcement. Although many of these handle all public service (police, fire, and EMS) calls, many larger cities have secondary PSAPs for fire and EMS. Enhanced 911, or E911 provides additional information by immediately displaying the caller's telephone number and address.

Emergency Medical Dispatch

Dispatching encompasses multiple elements that assist patients in receiving immediate medical care. The emergency medical dispatcher (EMD) is responsible for ascertaining the primary medical condition and severity. Communication centers that model their dispatch response protocols by priority use a finite list of common chief complaints, each having associated predetermined questions. Answers to these questions ultimately dictate a predefined response mode such as emergent, urgent, and nonurgent. Depending on the response assigned and system configuration, an ambulance (BLS or ALS) and possibly a first responder resource are dispatched in an emergency or nonemergency mode. When critical conditions are identified, the EMD should proceed to give specific prearrival instructions to assist the caller in providing critical interventions before EMS arrival. These include procedures such as opening and clearing an airway, performing CPR, controlling hemorrhage, and assisting with childbirth. Such assistance dramatically narrows the response time interval for receiving emergency medical care.

Systems Status Management and Flexible Deployment

System managers, especially those who operate under performance contracts, must ensure that response resources are available and proximate to where calls may actually arise based on historical data. This system of supply and demand has proved beneficial in managing resources and decreasing response times. On the basis of historical data, high-performance or peak-demand periods of the day coupled to service areas or call location can be identified so that coverage plans or ambulance posting assignments may be instituted. Such mechanisms place ambulances at predetermined locations where potential calls are likely to occur. For example, during regular business hours, prediction models may recommend that ambulances be positioned within the central areas of a city where most of the population is located versus evening and night hours when the population is mostly located in the suburbs or outlying areas of a city. Response vehicles often incorporate an automatic vehicle locator that functions as a telemetry unit or a global positioning satellite system that provides a site interface with the computer-aided dispatch and mapping system. Knowing where each vehicle is located assists the EMD with staging or redeploying vehicles during periods of high call

volume or when units are limited. Routing software is usually used, and more sophisticated systems use programs that incorporate additional factors. These may include traffic patterns based on time of day and street configurations so that closest ambulances to a call are not based on straight lines but as streets are configured.

Field Communications

At an incident scene or during transport, providers usually have the capability of communicating with hospital staff. A consultative patient report may be given to receive medication or intervention orders or simply for arrival notification. Additional information may include cardiac telemetry or transmission of a 12-lead ECG. EMS providers should also have the capability of communicating with all allied public safety agencies for mutual aid purposes, mass casualty situations, or disaster responses. If air medical services are available, EMS and fire personnel should have the capability of communicating with the helicopter pilot for landing zone instructions and crew members for patient condition and care reporting.

OVERSIGHT

Federal

Various federal agencies participate in the oversight of EMS development and refinement. The lead agency is the EMS Division of NHTSA under the DOT. In 2007, the National EMS Advisory Council was formed to provide advice and recommendations to NHTSA from consumers, advocates, and stakeholders. Additional federal support comes from the EMS for Children Program under Maternal and Child Health, Department of Health and Human Services. In an effort to better coordinate federal agencies involved with state, local, tribal, or regional EMS, Congress formed the Federal Interagency Committee on EMS in 2005. The purpose of this organization is to simplify the processes and efforts by which federal agencies support EMS by identifying state and local EMS needs and recommending the addition, expansion, or improvement of programs. Although it is not regulatory, the National Association of EMS Physicians is an international organization of physicians and prehospital professionals interested in promoting research, innovation, and excellence in prehospital care delivery.

State

Each state incorporates a governmental agency that oversees EMS. Duties typically include enforcement, regulation, and implementation of EMS rules adopted by state legislature, possibly including a medical oversight or advisory board. Another nonregulatory organization, NASEMSO, assists in developing policy, providing support, and ensuring leadership and resources for EMS development at the state, regional, and local levels. Table e12.2 lists contacts for agencies and organizations involved in EMS development.

Local

Medical Director

An EMS medical director is a physician with specialized interest and knowledge of patient care activities unique to the prehospital environment. Medical oversight must extend from the communications center through all components of field care, including the hand-off at the receiving facility. Typically, a contractual arrangement for services provides the physician with administrative authority to implement patient care protocols, to interact with all aspects of the system, and to remove a provider from practice if medical care or behavior is substandard. Published guidelines describing the activities and performance of an EMS medical director have been prepared by the National Association of EMS Physicians and the NASEMSO. On September 23, 2010, the American Board of Medical Specialties approved EMS Medicine as the sixth subspecialty available to candidates who apply through the American Board of Emergency Medicine with the first certification examination being administered in October 2013 and every other year thereafter. The Core Content of EMS Medicine is available on the ABEM website.[11]

Medical direction consists of off-line (indirect) and on-line or on-scene (direct) oversight. Off-line medical oversight includes protocol development, personnel education, prospective and retrospective patient care review, and other quality improvement processes. Direct medical oversight involves real-time interaction between a physician or designee and the field provider either by telephone, radio, or in person.

Indirect Medical Oversight

Medical accountability for patient care activities is the basis for indirect medical oversight and functions either before a patient is encountered (prospective) or after patient disposition has occurred (retrospective). Patient care guidelines and protocol development for EMTs and EMDs, initial and continuing medical education, medical-legal policies, and quality and performance improvement processes are important elements.

Perhaps the most important duty of the medical director is to develop patient care protocols, which are preestablished practice guidelines that define the standard of care for most illnesses, injuries, and medical conditions encountered in the prehospital setting. Operational issues such as hospital designation and destination policies along with approval of facility capabilities, termination of resuscitation, and patient transport refusal may be included. Depending on state regulations, protocols may include standing orders for particular clinical situations in which providers may perform certain procedures or administer medications for predefined patient conditions before communication with hospital personnel. Protocol development should be driven by evidence-based medicine, system resources, and patient needs, and it should include guidelines for triage and care of specific populations of patients, including trauma patients, newborns, and children.[12]

Regardless of local communication protocols, providers should always be able to discuss a case with a physician for clarification or guidance when clinical questions or controversial situations arise. Furthermore, hospital notification is important when critical patients are being transported.

Medical directors should be familiar with and actively involved in local, regional, and state educational programs for initial and continuing education courses for all levels of EMT certification. Course curriculum development and administration, evaluation, and revision processes should be understood. Systems that incorporate their own educational programs allow modifications that reflect intrinsic needs of the system and the providers.

Field personnel and telecommunicators should be given regularly scheduled courses that are current to improve competency in knowledge and skills. Instructional formats and resources to accomplish educational objectives may include didactic classroom or distance learning lectures, webinars or podcasts, skill laboratories, simulation experiences, and direct field observation. Standardized, evidence-based core content is important for consistency and quality of care.

Once patient care protocols are developed and implemented, there must be mechanisms, such as retrospective patient care report review or direct field observation, for evaluation of individual and system performance and patient outcome for various conditions. Deviations from specific protocols may reflect problems with individual EMTs, on-line medical direction personnel, or the protocol itself, each requiring education and reevaluation. Deficiencies, both operational and clinical, should be identified for appropriate remediation, which may be in the form of counseling, educational instruction, or revisions of system design or patient care protocols. Competency, knowledge retention, and skill performance are measurable parameters. Time standards (e.g., out-of-chute time [time from ambulance notification to deployment], response time, scene time, hospital turnaround time, and overall call or task time) are equally important measures because these may indirectly affect patient care and outcome.

Direct Medical Oversight

Direct medical oversight is the concurrent direction of EMTs providing patient care. This may be in the form of radio or telephone communications or by direct scene observation and may be considered centralized or decentralized. In a centralized system, a selected hospital is designated the lead facility (base station hospital, resource hospital, or sponsor hospital) and is responsible for providing all direct medical orders and notification regardless of the receiving facility. In a decentralized system, each hospital functions as a base station, providing direction to EMTs transporting patients to their facility.

Personnel responsible for direct medical oversight must be knowledgeable about the entire EMS system, receiving facilities, protocols, provider capabilities, medication formulary and equipment, administrative and operational issues, and medico-legal implications for certain presenting situations. These physicians and nurses must understand the austere environment of EMS and what can and cannot be accomplished in the field setting. Systems whose protocols include standing orders may require direct communication only for specific reasons. Thus, while medical and administrative protocols may guide EMTs through most circumstances, physician consultation may assist with more challenging dilemmas such as medico-legal issues, termination of resuscitation, behavioral patients, patient refusal of care and/or transport, or ethical dilemmas. Direct medical oversight is usually invaluable for notification and staff preparation when critical or potentially critical patients are being transported.

Table e12.3 lists the various levels of EMS oversight.

MEDICAL CARE AND CONTROVERSIES IN MANAGEMENT

Airway Support and Respiratory Emergencies

Interventions

Respiratory complaints account for a significant number of EMS responses. Basic measures to control and support a patient's airway include manual maneuvers (e.g., chin lift or jaw thrust), oral and nasopharyngeal devices, and bag-mask ventilation. At a more advanced level that can still be performed by basic providers, interventions may include use of extraglottic airway devices (e.g., laryngeal mask airway, laryngeal tracheal airway, i-gel), which afford a faster than and equally successful placement as traditional endotracheal tube insertion.[13,14] Early studies comparing survival from cardiac arrest in patients whose airway was managed with an extraglottic device versus endotracheal intubation demonstrated minimal differences or slightly improved outcomes than with endotracheal intubation.[15] Recent studies have shown better results in terms of number of attempts at airway placement, unrecognized misplacement, and complications with extraglottic device use during cardiac arrest.[16,17] Additional adjunctive techniques for decreasing complications during airway management include apneic oxygenation, preoxygenation using a non-rebreathing mask or noninvasive positive-pressure ventilation, head elevation, and delayed sequence intubation using prolonged sedation prior to paralytics.[18,19]

Drug-assisted intubation (DAI) and rapid sequence intubation (RSI) procedures are well established in ground and air transport services. There is debate on the safety, effectiveness, and complications associated with this procedure, especially with more widespread use of extraglottic devices. Despite the controversy and ongoing comparative studies evaluating the best approach for airway management in patients ill or injured, most would agree that to have a successful airway management program, evidence-based protocols should guide practice and the educational and quality management components must be meaningful and comprehensive. For programs using DAI or RSI procedures, the experiential component should include regular operating room time and/or simulator sessions. Ideally, training would also occur in an ED setting where patients requiring emergent intubation would potentially have the full complement of confounding variables (e.g., combative status, full stomach, blood and vomit in the airway). Such training may be difficult or impossible to achieve, particularly the ongoing maintenance of skills, especially in rural communities. Unless EMS systems perform a large number of intubations, use of an extraglottic device for tracheal intubation should be strongly considered, especially given the growing evidence of the importance of uninterrupted chest compressions which may be discontinued during an endotracheal intubation procedure.[19]

Traditionally used in the hospital setting, prehospital continuous positive airway pressure (CPAP) has been shown to decrease intubation rates and improve patient outcomes.[20] Field use requires strict protocols that outline indications and contraindications, clinical applications, mental status assessment, hemodynamic status, and mechanisms for transfer of the patient and devices upon hospital arrival.

Medications

Most advanced programs have adopted the use of clinically proven medications for bronchospasm, chronic obstructive pulmonary disease, and anaphylaxis, but no studies have demonstrated a benefit for administration of these medications in the prehospital setting. Whereas some studies might be considered unethical (e.g., a prehospital study of epinephrine for anaphylaxis), others (e.g., out-of-hospital use of beta$_2$-agonists or steroids for asthma or diuretics for pulmonary edema) could easily be performed. Pending further studies, most systems have adopted the position that these medications do not harm patients in the prehospital setting, may be helpful, and may provide comfort and clinical improvement for most patients experiencing varying degrees of respiratory distress. Fortunately, the use of CPAP and inhaled bronchodilators has been approved for use at the EMT level by some states.

Cardiovascular Emergencies

Interventions

Early research demonstrated the effectiveness of early defibrillation for termination of ventricular fibrillation and improvement of survival rates from sudden cardiac death. Advances in technology have improved such that defibrillators, traditionally used by paramedics, are now used by a variety of first responders and bystanders. Public access defibrillation programs are continuing to be implemented throughout the country, with devices being placed in high-volume, populous, and secluded areas, such as airports and airplanes, casinos, churches, office buildings, transit buses, and other locations identified as high risk.[38] Emerging technology includes cellular phone applications that alert trained bystanders when a cardiac arrest is identified by the 911 center and the use of drones to deliver defibrillators directly to the scene.[21,22] The acquisition and transmission of prehospital 12-lead ECGs has become standard practice and has resulted in minimizing delays in time to intervention (thrombolytic administration or PCI).

A factor now recognized to improve survival from cardiac arrest is uninterrupted or minimally interrupted chest compressions.[23] Each interruption of compressions (e.g., while intubating, checking for pulses, analyzing rhythms) decreases coronary perfusion pressure, which in turn decreases cellular respiration. Additionally, eliminating ventilations may result in more bystanders willing to perform continuous chest compressions.

Although the statistics for cardiac arrest survival across the United States are dismal, those who survive often suffer some degree of hypoxic encephalopathy. Early studies supported the use of induced hypothermia in patients who achieve a return of spontaneous circulation after cardiac arrest; however, recent evidence has not demonstrated beneficial effects for long-term survival.[24] Such conflicting evidence may be due to confounding variables such as optimum target temperatures, methods of inducing hypothermia, duration of cooling, initiating the process in the field environment, and methods to sedate and rewarm.[25] Extracorporeal CPR (ECPR) is an emerging trend where prehospital systems may identify candidates for extracorporeal membrane oxygenation based on initial rhythms, rhythms refractory to shock, duration of arrest and no-flow states, and time on scene.[26,27]

Medications

Traditional cardiac medications recommended by advanced cardiac life support are used by most ALS systems and include epinephrine, including push dose vasopressors, for hemodynamics; atropine for heart blocks; and amiodarone, lidocaine, and magnesium for dysrhythmias. Previously debated, there is no evidence to suggest that amiodarone should replace lidocaine for ventricular fibrillation for adult and pediatric cardiac arrest.[28,29] The use of prehospital fibrinolytic agents for STEMI has not gained wide acceptance and may be a useful intervention only for systems having prolonged transport times or if hospitals may not have PCI available. Perhaps a more plausible EMS response to STEMI patients is a rapid response, early recognition, acquisition and interpretation of a 12-lead ECG, stabilization of hemodynamics, and notification to a PCI facility.

Traumatic Emergencies

Interventions

Interventions for specific medical emergencies, such as cardiac arrest (i.e., defibrillation, intubation, intravenous fluids, and medication administration), may be effectively performed while on the scene or before hospital transport. Alternatively, it is widely accepted that most interventions for traumatic injuries should be performed during transport to the hospital, and all efforts should be made to reduce on-scene time. Only two interventions should be considered for critical injuries: (1) control of the airway to reverse hypoxemia and to prevent aspiration and (2) hemorrhage control. Although it is a routine part of prehospital trauma care, tracheal intubation is not known to be beneficial for severely injured adult and pediatric patients.[30,31] There are many potential issues that may predict morbidity and mortality when managing trauma patients. With airway stabilization, paramedics must be proficient in rapid decision making to determine the need, potential success, and complication risk; the procedure must be expedient with minimal scene time delays, preferably performed during hospital transport; ensuring correct placement by multiple measures; and ensuring continued correct placement during all patient movements. In addition, providing the correct minute and tidal volumes is equally important. Inadvertent hyperventilation may impair cardiac output and cause further tissue damage. Patients sustaining blunt head injury pose special problems that must be considered. Attempting to intubate head-injured patients may result in dental or soft tissue damage in those patients with clenched teeth, and intracranial pressure may be exacerbated from an intact gag reflex or from subsequent regurgitation. Studies on the use of RSI in these patients reveal that patients may experience significant hypoxia and bradycardia during the procedure, along with hypotension depending on induction agents used, all resulting in worse outcomes. Thus, the role of RSI in prehospital airway management in trauma patients is in question, as it is for medical patients. The extraglottic airway devices may be the best method for prehospital airway management in trauma patients due to ease and time required for insertion.

Emergent hemorrhage control is also essential in reducing mortality in severe trauma. For internal bleeding, limiting the total prehospital time and transfer to definitive surgical care is paramount. Recent evidence on the battlefield has demonstrated the effectiveness of tourniquet application to extremity wounds.[32] These devices have application in the civilian setting, are quick and easy to apply, and do not result in the complications once thought to exist. In addition, there is evidence to support the use of tranexamic acid and gauze packing impregnated with hemostatic agents such as chitosan for trauma patients.[33,34] Use of these products for an injured patient with uncontrolled hemorrhage may lessen the need for blood products and can improve outcomes.

BOX E12.1 Emergency Medical Treatment and Active Labor Act Requirements for Patient Transfers

Complete certification (risks and benefits) of transfer
Informed consent obtained from the patient or family
Appropriate transportation (equipment and personnel) arranged
Treatment and stabilization performed
Acceptance from receiving facility ensured
Appropriate patient care data sent (faxed or with patient)

The issue of intravenous fluid administration has become more controversial over the years. Traditionally, high-volume intravenous fluid for hemodynamic instability resulting from traumatic injury was the accepted standard. However, there has been a paradigm shift to restrictive or hypotensive resuscitation for penetrating truncal injuries, because there is evidence that restoration of hemodynamic stability with fluid resuscitation before definitive surgical hemostasis may lead to increased morbidity.[35]

INTERFACILITY AND SPECIALIZED TRANSPORTS

Transportation between health care facilities may occur for several reasons, including patient preference, unavailable diagnostic or therapeutic resource availability at the transferring facility, and managed care requirements that patients be cared for in predesignated hospitals after stabilization. Hospital corporations engaged in networks or alliances that share resources and services depend on interhospital transport systems to convey patients to allied institutions for specialized tests or procedures. Likewise, critical patients admitted to less specialized facilities may need to be transferred to specialized or tertiary care facilities. Whereas long-distance transport may be best accomplished by fixed-wing air medical services, regional or local transports should use rotor-wing or ground systems.[36] These may be provided by either local EMS resources or those owned and operated by the hospital.

An interfacility transfer that is medically indicated must fall under a set of requirements referred to as the Emergency Medical Treatment and Active Labor Act (EMTALA).[37] Although the EMS system providing the transport plays a key role, these guidelines primarily involve particular information and obligations that must be satisfied by the transferring and receiving facilities before transfer. An unstable patient should not be transferred to another facility unless the transferring hospital is incapable of providing standard care and the receiving hospital has capacity and does have the capability to manage the condition and foreseeable complications. Box e12.1 lists various requirements that should be completed before a patient is transferred to another facility (see Chapter e7).

Depending on the patient's condition, specialized transport services may function at the BLS or ALS level, providing emergency or nonemergency transportation. Patient transfers considered ALS may include interhospital (either ED or intensive care unit) neonatal or high-risk infant, critical cardiac, and trauma transports. Personnel configuration depends on system design and level of care provided. Many programs use a nurse-paramedic combination. Patients requiring specialized care may need the services of specifically trained individuals, such as respiratory therapists, neonatal nurses, or other specialized critical care personnel. The presence of a physician is not mandatory but may be useful in selected cases.

As with any EMS activity, all interfacility transports should be reviewed for appropriateness of transfer and medical care provided. In 2019, the American College of Emergency Physicians reaffirmed the policy statement on EMTALA and patient transfers.[38]

ACKNOWLEDGMENTS

I would like to once again thank Marty for understanding the time commitment for this project, and would like to express how proud I am of my sons Joey and Alex for completing medical school and also entering the specialty of emergency medicine.

CHAPTER E12: QUESTIONS AND ANSWERS

1. Which of the following describes an EMS system that is contracted to provide services?
- **a.** Public utility
- **b.** Third-service municipal
- **c.** Private
- **d.** Fire-based
- **e.** Hospital-based

Answer A. A public utility model is a hybrid between private and public design that allows local government to contract with a private or public provider.

2. Which of the following best defines direct medical oversight in the prehospital setting?
- **a.** Concurrent direction of EMTs providing patient care
- **b.** Development of prehospital care policies
- **c.** Implement quality improvement program
- **d.** Use of prehospital patient care protocols
- **e.** Use of standing field treatment protocols

Answer: A. Direct medical oversight is the concurrent direction of EMTs providing patient care, which can be at the scene or online over radio or cell phone.

3. Which of the following recognized the need to formally develop EMS in the United States?
- **a.** Highway Safety Act of 1973
- **b.** The EMS Agenda for the Future
- **c.** *Accidental Death and Disability: The Neglected Disease of Modern Society*
- **d.** 1965 President's Commission on Highway Safety
- **e.** The Future of Emergency Care in United States Health System

Answer: C. The National Academy of Sciences–National Research Council published this document as a result of the growing concern for EMS and hospitals not being prepared to respond to the growing number of injuries resulting from traffic accidents on the nation's highways.

4. Which of the following prehospital interventions has been shown to improve patient outcome?
- **a.** Defibrillation
- **b.** Endotracheal intubation for children
- **c.** Endotracheal intubation in severe head trauma
- **d.** Intraosseous needle placement
- **e.** Needle cricothyrotomy

Answer: A. Rapid defibrillation has been shown to improve outcomes for patients in cardiopulmonary arrest; other interventions have not shown proven benefit in the prehospital setting.

5. The EMS Agenda 2050 describes a vision for EMS that is defined by which of the following?
- **a.** Availability of ambulance resources
- **b.** Centralized resources that can be deployed
- **c.** Community-based
- **d.** People-centered

Answer: D. The EMS Agenda 2050 describes a vision for EMS that is people-centered along with six guiding qualities: inherently safe and effective, integrated and seamless, socially equitable, reliable and prepared, sustainable and efficient, adaptable and innovative.

Air Medical Transport

Air Medical Transport

Ira J. Blumen and Howard Rodenberg

KEY CONCEPTS

- Air medical transport (AMT) is a critical component of a comprehensive health care system and a vital link for rural communities and critical access hospitals to distant emergency care.
- Boyle's law and Dalton's law have the greatest impact and explain the development of hypoxia and most common altitude-related symptoms. Other stresses of flight that can affect the patient or crew include temperature fluctuations, dehydration, noise, and vibration.
- Although most flight programs do both primary (scene flights) and secondary (interfacility) response, ground ambulance remains the primary means of out-of-hospital and interfacility patient transport.
- The helicopter offers several advantages over other transport vehicles, including reduction in travel time by up to 75%, ability to avoid common ground delays (traffic, obstacles, and so on), and ability to fly into locations that may be inaccessible to other modes of travel.
- All air medical services require involvement of a medical director responsible for supervising, evaluating, and ensuring the quality of medical care.
- As a general rule, helicopters are less useful in urban settings because of the proximity of health care facilities.
- Helicopter emergency medical services (HEMS) represents the only modality by which nearly 28% of United States residents have timely access (within 1 hour) to level I or level II trauma centers.
- HEMS may benefit in other time-critical situations, including ST-elevation myocardial infarction (STEMI) patients going to a catheterization laboratory and acute stroke patients going to regional stroke centers.
- Safety is the predominant concern of air medical operations. *Helicopter shopping*, the practice of a requesting EMS agency or hospital calling numerous HEMS programs after other programs have declined the flight because of bad weather, must be avoided.

FOUNDATIONS

Background and Importance

Air medical transport (AMT) is a critical component of a comprehensive health care system, EMS system, and a vital link for rural communities and critical access hospitals to distant emergency care. It is an essential tool to support the regionalization of specialty care for trauma, stroke, cardiac emergencies, burns, pediatric critical care, and more. Many emergency physicians routinely rely upon medical helicopters to transport critically ill or injured patients from smaller rural or community emergency departments (ED) to tertiary care centers.

AMT dates back more than a century to World War I. As early as 1915, the French evacuated soldiers from Serbia using airplanes as ambulances. In 1918, the United States military converted an airplane for the first recorded United States (US) air ambulance to accommodate a litter patient in the rear cockpit. During World War II, more than 1.1 million sick and wounded soldiers were airlifted to the United States during the last 3 years of the war. The Korean War introduced the helicopter to AMT, and more than 20,000 battlefield medical evacuations were flown during the conflict. Utilizing the Bell 47 helicopter, wounded soldiers were strapped to litters outside the helicopter and transported to Mobile Army Surgical Hospitals (MASH units). During the Vietnam War, Operation Dustoff transported nearly 1 million wounded from the front lines in larger helicopters staffed with medics to initiate care en route.

AMT had a significant impact on the wounded soldier when considering transport times and mortality. World War I saw battlefield transport times between 12 and 18 hours. Of those surviving transport, mortality was 20%. During World War II, the average time from injury to definitive care was 6 to 12 hours, with a mortality rate of 5.8%. In Korea, the time was 2 to 4 hours, with a 2.4% mortality rate. In Vietnam, no soldier was more than 35 minutes from definitive care, and overall mortality was 2.6%.

Encouraged by the military experience, United States civilian AMT began in 1969 with a hospital-sponsored fixed-wing air medical program. The first US civilian helicopter emergency medical services (HEMS) program was established in 1972.

Aviation Physiology

A working knowledge of aviation physiology is vital to understanding the effects of AMT on pilots, medical personnel, and patients.

Gas Laws

There are four gas laws important to aviation physiology: Boyle's law, Charles' law, Dalton's law, and Henry's law (Tables e13.1 and e13.2). The cornerstone of aviation physiology begins with Boyle's law, which describes the behavior of gases in an enclosed space. Boyle's law is also a contributing factor to hypoxia along with Dalton's law. No one is exempt from the effects of hypoxia at altitude, and the most threatening feature is its insidious onset and the knowledge that the onset and severity of symptoms may vary by individual.

Additional Stresses of Flight

Other stresses of flight that can affect the patient or crew include temperature fluctuations, dehydration, noise, and vibration. Temperature changes may produce increases in metabolic rate and oxygen consumption. As altitude increases and temperatures drop, the amount of moisture in the air decreases significantly.

To prevent dehydration during long-distance fixed-wing AMT, fluid intake (oral or intravenous) must be monitored carefully, and all patients should receive humidified medical oxygen. Noise and vibration may represent the most ubiquitous stresses encountered in AMT, and both may interfere with patient care or the function of medical equipment. Hearing protection should always be worn during aircraft

TABLE E13.1 The Gas Laws

Gas Law	Principle	Clinical Implication
Boyle's law	• The volume of a unit of gas is inversely proportional to its pressure. • As altitude increases and atmospheric pressure decreases, the molecules of gas grow apart, and the volume of gas expands. • With descent (increasing atmospheric pressure), gas volumes contract. • The result is the expansion and contraction of gases within the closed spaces of the body.	• Squeeze injuries from contraction of air and associated soft tissues can occur on descent, resulting in barotitis, barosinusitis, and toothache. • Reverse squeeze injuries occur on ascent, leading to an increased volume of the air trapped within the space. Examples include the conversion of a simple pneumothorax into a tension pneumothorax and rupture of a hollow viscus. • Medical equipment containing closed air spaces, such as intravenous (IV) tubing and pumps, air splints, ventilators, and endotracheal tube and laryngeal airway cuffs, may also be affected by altitude. • Responsible in part for hypoxia at altitude due to fewer molecules of oxygen present per volume of inhaled gas.
Charles' law	• As the volume of a unit of gas rises, the temperature of that volume falls.	• Explains why the ambient temperature decreases with increased altitude.
Dalton's law	• The total barometric pressure at any given altitude equals the sum of the partial pressures of gases in the mixture. • Oxygen still constitutes 21% of the atmospheric pressure at altitude.	• A decrease in arterial oxygen tension with increasing altitude, resulting in hypoxia. • Initial physiologic responses to hypoxia include tachypnea and tachycardia. • With prolonged exposure, cerebral hypoxia causes headache, nausea, drowsiness, fatigue, unconsciousness, and death.
Henry's law	• The mass of gas absorbed by a liquid is directly proportional to the partial pressure of the gas above the liquid.	• Sudden decompression at altitude may result in dysbaric injuries. • In scuba diving, rapid ascent can result in gas coming out of solution within the bloodstream, resulting in decompression sickness.

TABLE E13.2 Effects of Altitude on Oxygenation

Altitude (ft)	Barometric Pressure (mm Hg)	P_{O_2} (mm Hg)	$P_{A_{O_2}}$ (mm Hg)	$P_{a_{CO_2}}$ (mm Hg)	Oxygen Saturation (%)
Sea level	760	159.2	103.0	40	98
8000	565	118.4	68.9	36	93
10,000	523	109.6	61.2	35	87
15,000	429	89.9	45.0	32	84
18,000	380	79.6	37.8	30.4	72
20,000	349	73.1	34.3	29.4	66
22,000	321	67.2	32.8	28.4	60

$P_{A_{O_2}}$, Partial pressure of alveolar oxygen; $P_{a_{CO_2}}$, partial pressure of arterial carbon dioxide; P_{O_2}, partial pressure of oxygen.

operations by patient and crew. Prolonged exposure to environmental extremes may result in fatigue, motion sickness, disorientation, ear damage, and deterioration in task performance.

SPECIFIC ISSUES IN AIR MEDICAL TRANSPORT

Administrative Structure of Air Transport Systems

Air medical services in the United States may be structured in different ways. There has been tremendous growth of medical helicopters in the United States over the last two decades. Data extracted from the ADAMS Database[1] estimates that in 2019 there were 228 HEMS programs flying more than 927 dedicated aircraft throughout the nation.[2] Since the early 2000s, the number of dedicated HEMS aircraft has doubled. During that time, what had been the most common HEMS business model in the United States has changed. The original and "traditional" nonprofit hospital-based operation, sponsored by a single hospital or a consortium of institutions, is now less common than the for-profit community-based programs or hybrid programs. Nearly 70% of the helicopters are for-profit ventures, operated by privately owned (private equity firms) or publicly traded companies. Public service agencies may also sponsor air medical services or partner with private companies; vehicles used by these programs are often multifunctional aircraft that serve in medical, search and rescue, fire suppression, and law enforcement roles. The Military Assistance to Safety and Traffic (MAST) program operated by the United States Armed Forces provides additional HEMS resources to civilians, but in recent years their role for civilian support has been generally limited to Hawaii and Alaska.[1] Together, the public service and MAST helicopters supply more than 120 additional aircraft for patient transport in the United States. There is no accurate accounting of the number of fixed-wing air ambulance companies or airplanes. Although some hospitals sponsor fixed-wing AMT, it is more common for these programs to be private fee-for-service operations.

Types of Transports

Air medical transports may involve primary or secondary response. Primary responses ("scene flights") are when the aircraft responds directly to the scene of an accident or illness and transports the patient directly to an appropriate receiving facility. Aircraft involved in secondary responses (interfacility transport) move patients from outlying hospitals to facilities offering higher levels of care. AMT flights may also be

Fig. e13.1 Confined spaces and weight restrictions in many helicopters may limit the number of transport personnel or medical equipment that can be carried and may make it more challenging to perform procedures. (Courtesy Ira Blumen, MD, UCAN [University of Chicago Aeromedical Network], UChicago Medicine, 2020.)

classified according to the level of care provided. This may be critical care transport, specialty care transport, or advanced or basic life support.

Air Medical Aircraft

Although ground ambulance remains the primary means of prehospital and interfacility patient transport, AMT has a definite role in the health care delivery system. However, no one aircraft is ideal for the needs of all air medical programs or patients. In addition, certain flight conditions and situations may also influence aircraft and transport consideration.

Helicopters (Rotor-Wing Aircraft)

An estimated 320,000 patients are flown each year by dedicated HEMS operations in the United States. The helicopter offers several advantages over other transport vehicles. Traveling "as the crow flies" at speeds of 120 to 180 mph, helicopter transport time is often 75% less than that for an equivalent distance by ground. The service area of helicopter programs is generally up to 150 to 200 miles from its base of operations, but average transports can be significantly fewer miles. Rotor-wing aircraft have the ability to avoid common traffic delays and ground obstacles and can access rural and remote locations that may be inaccessible to other modes of travel. Helicopter landing zone requirements are a disadvantage compared with ground ambulances but offer an advantage over airport requirements.

Disadvantages to HEMS can include noise, vibration, thermal variances, and other stressors on patients and crew. Weather considerations may at times significantly limit the availability of helicopter transport. Although some medical helicopters can transport two patients, most are configured to transport only one patient. In smaller helicopters, confined spaces and weight restrictions may limit the number of transport personnel or medical equipment that can be carried and may make it more challenging to perform procedures. (Fig. e13.1).

Many helicopter programs operate only under visual flight rules (VFR). When the weather conditions (ceiling and visibility) fall below established program minimums, a flight request may be declined for safety reasons. However, an increasing number of programs are equipping their helicopters and training their pilots in instrument flight rules (IFR) to allow safe travel in less favorable weather conditions. IFR flight may be facilitated to fixed locations such as hospital helipads that have developed IFR approaches, but it does not facilitate travel to the scene of illness or injury.

Airplanes (Fixed-Wing Aircraft)

Fixed-wing aircraft provide increased range, greater speed, and often more patient, crew, and equipment capacity than most rotor-wing vehicles. Decreased cabin noise and turbulence creates fewer patient management problems and cabin pressurization combats the physiologic impact of altitude and the gas laws. Fixed-wing operations are limited, however, to areas that have airports with runways of appropriate length and refueling facilities. During fixed-wing transports, patient transfers require multiple vehicles for each leg of the transport (i.e., hospital to ground ambulance to airplane).

Various fixed-wing aircraft are available for medical transport. These range from unpressurized light planes with single- or twin-piston engines to pressurized turboprops and jets. The selection of the ideal aircraft depends on the nature of the air medical mission.

Air Medical Flight Crew

Air medical crew members represent the broad spectrum of health care providers who commonly provide advanced skills, medication, and equipment for adult and pediatric patients not available to local ground EMS (GEMS).[3-5] The medical literature details decades of studies and reviews of various enhancements brought directly to the patient, which have grown to include advanced airway management,[6-11] blood products,[12-16] tranexamic acid (TXA),[17-20] point-of-care ultrasound,[21-23] and extracorporeal membrane oxygenation (ECMO).[24-27]

AMT services that provide critical care transport, advanced life support, or specialty care transport must staff the vehicle with a minimum of two medical personnel to provide direct patient care.[28] The majority of AMT programs in the United States provide critical care transport teams composed of one registered nurse and an additional crew member (paramedic, second nurse, respiratory therapist, or physician). Most common is the nurse/paramedic crew.[1] AMT crew configuration may also be mission dependent. Some programs will use specialty teams to transport pediatric, neonatal, or high-risk obstetrics patients. Other programs will add a specialty care provider to their "routine" team for these transports.

Flight nurses generally have extensive experience in intensive care units (ICUs) or emergency departments (EDs). They may be specialized within the transport team to care for adult, pediatric, or neonatal patients. Paramedics often make their greatest contribution in the transport of critical patients from the scene of illness or injury. Respiratory therapists bring expertise in airway and ventilator management and oxygen delivery systems. Flight physicians may be residents or attending physicians. Today, only a small number of the US HEMS programs use a physician as a dedicated or alternate member of the flight crew. However, in many other countries, especially in Europe, physician-staffed HEMS remains a dominant crew configuration.[29]

The AMT environment imposes unique considerations on the air medical flight crew. Most medical care procedures are more difficult to perform in an AMT vehicle than in ground-based or in-hospital settings. Auscultation of the heart and lungs, palpation of pulses, performance of cardiopulmonary resuscitation, endotracheal intubation, radio communications while wearing a face mask, and recognition of visual alarms may all be impaired. In addition, fatigue (many crews work 24-hour shifts), motion sickness, an unpredictable pattern of work activity, and the high risk involved in AMT operations may affect task performance.

Medical Direction

All air medical services require the active involvement of a physician as medical director, responsible for supervising, evaluating, and ensuring

the quality of medical care provided by the AMT team. Emergency clinicians play a significant role, with nearly 70% of all US air medical directors having a background in emergency medicine, according to a survey done by the Air Medical Physician Association (AMPA). The medical director must have the final authority over all clinical aspects of the air medical service and should ensure that the flight crew has adequate training and qualifications to optimize patient care. An increasing number of flight programs are using high-fidelity simulation to train their medical crews to the unique transport environment, but access to simulations labs and cost (fiscal and personnel) may be prohibitive for some programs.

Medical care policies and procedures should be established, including specific provisions for on-line and off-line medical control. AMPA and the National Association of Emergency Medical Service Physicians (NAEMSP) have established guidelines for the medical director of an air medical service.

Safety

Safety is the predominant concern of air medical operations, and ensuring a safe flight is a fundamental responsibility of every flight program. Safety must also be an overriding consideration in weighing the risks and benefits of AMT. The role of aircraft pilots and mechanics is essential to the airworthiness of the vehicle, and medical personnel must also be proficient in both routine and emergency operations in and around the aircraft. Checklists aid in safe practices, but alone may not detect significant operational concerns. Crew fatigue and other self-imposed stresses that could affect safety (such as the use of prescription or over-the-counter medications, tobacco, and alcohol) must be scrupulously avoided.

Weather requirements ("minimums") must be strictly enforced. On receipt of a flight request, the pilot must verify the weather conditions and the condition of the aircraft. To ensure impartiality, the pilot should not be told of the patient's condition or acuity. The pilot maintains the unquestioned right to decline a mission because of aircraft or weather considerations. These decisions should not be questioned or influenced in any way by administrators, flight crew, or other parties.

The practice of "helicopter shopping" has been a major factor in several fatal HEMS accidents. Helicopter shopping refers to the practice of a requesting emergency medical services (EMS) agency or hospital calling numerous HEMS programs until one agrees to accept a flight without disclosure to the accepting HEMS operator that other programs were called and declined the flight because of bad weather or other safety concerns. The practice was so common that in 2006, the FAA issued a letter to all state EMS directors describing helicopter shopping and requesting that they take action to prohibit this practice. Numerous state and national organizations have addressed this serious problem through position papers, educational videos, and other resources.[30-31] Although there may be circumstances when a subsequent program called can safely undertake and complete the flight, it is essential that they are made aware of all the facts surrounding the request, including previous denials from other HEMS providers.

The risk of an accident and patient safety are often of concern when considering HEMS transport for a patient. Cost-benefit analysis, however, has demonstrated that the risk of crash-related patient mortality is so low that the impact on calculations of HEMS use and overall effectiveness is minimal. In addition, available data suggest that after adjustment for patient acuity, transport by HEMS is associated with lower risk of adverse events than transport by ground ambulance.

Landing Zones

Helicopter landing zones are inherently dangerous places. The most obvious risk of injury is impact by rotor blades. This danger is heightened during ground operations, because the main blades dip lower to the ground at the slower rotor speeds associated with engine start-up and shutdown. Tail rotor blades can be virtually invisible when moving at full speed, explaining why no one should be towards the rear of an operating helicopter. Injuries also may occur as a result of debris being propelled through the air by "rotor wash," increased noise levels and an inability to hear warnings, and slippery surfaces found on exposed landing sites.

Fig. e13.2 Landing zone (LZ) safety is paramount to delivery of patients to hospitals. Designated rooftop or ground level LZs are appropriately lit and secured, with fixed coordinates and predesignated liftoff and approach patterns. (Courtesy Ira Blumen, MD, UCAN [University of Chicago Aeromedical Network], UChicago Medicine, 2020.)

Many hospitals have designated rooftop or ground-level helipads that are appropriately lit and secured (Fig. e13.2), with fixed coordinates and predesignated liftoff and approach patterns. However, most primary (scene) responses occur at temporary sites. Ground personnel must be trained to designate and secure a safe landing zone for helicopter operations. HEMS programs have an obligation to help train ground staff on proper landing zone setup and operations (Boxes e13.1 and e13.2).

Helicopter flights that go directly to the scene of an accident can pose unique risks from hazards near the landing zone and the risk is heightened at night.[32] In response to this concern, some prehospital providers and flight programs have found it beneficial and safer to use a hospital helipad for rendezvous. This practice raised concerns about Emergency Medical Treatment and Active Labor Act (EMTALA) responsibilities to provide a medical screening examination for these patients. In May 2004, the Centers for Medicare and Medicaid Services (CMS) resolved this issue, noting that the use of a helipad on hospital property does not trigger EMTALA provisions as long as the helipad is being used only as a stopping place for EMS personnel to rendezvous with AMT to facilitate transport of a patient to the closest appropriate facility.

Other adjuncts to landing zone safety and night operations in general are night vision goggles (NVGs) and terrain avoidance warning systems. A 2017 survey of over 750 dedicated HEMS aircraft found that 97% were equipped with NVGs.[2]

Integration of Air Medical Transport Within Emergency Medical Service Systems

Integration of AMT within a comprehensive EMS system begins with the establishment of geographic service areas. As a general rule, helicopters are less useful in urban settings because of the proximity of

BOX E13.1 Landing Zone Safety

- Vehicles and personnel should be kept at least 100 ft (30 meters) from the landing zone.
- Spectators should be kept at least 200 ft (61 meters) from the landing zone.
- No smoking or running is permitted within 50 ft (15 meters) of the helicopter.
- All items (e.g., intravenous lines, poles) should be kept below shoulder height.
- The flight crew opens and closes aircraft doors.
- The flight crew directs and supervises the loading and unloading of the patient and equipment.
- Ground personnel should use eye and ear protection.
- Approach the helicopter *only* when signaled to do so by the pilot or an onboard crew member.
- Approach and depart the helicopter *only* forward of the rear cabin door and in a crouched position with your head down.
- Never approach or depart from the rear of the helicopter.
- Stay clear of the tail rotor; it is virtually invisible and extremely dangerous.
- If the aircraft is parked on a slope, approach and depart on the downhill side (greatest clearance under the blades).
- Keep the landing zone clear of (or hold on to) all loose articles (e.g., hats, scarves, sheets, pillows).
- Protect patient from the dust and debris.
- Follow the flight crew's instructions at all times.
- In disaster situations and mass casualty incidents, victims, witnesses, and spectators may become hysterical or exhibit signs of an acute situational reaction. These individuals must be kept clear of the landing zone and helicopter at all times. Injured victims who exhibit this behavior should not be triaged for helicopter transport, or they should be transported only with adequate physical or chemical restraints in use.
- If you do not know if an action is safe, ask before you act.

BOX E13.2 HEMS Landing Zone Requirements

Landing Area

- Landing zone should be as close as possible to the scene or hospital entrance but not so close that it may interfere with ground operations or patient care.
- Landing zone should be at least 100 × 100 ft (30 × 30 meters) in area.
- Landing zone should be as flat and level as possible.
- Landing zone *must* be clear of debris.

Hazards and Obstructions

- Identify all potential hazards that may be on the ground or near the approach/departure path of the landing zone.
- Landing zone should be clear of wires, poles, trees, buildings, vehicles, and spectators.
- Road cones, ropes, tape, and barricades are *not* recommended for use near landing zone.
- Perimeter of landing zone should be at least 50 ft away from potential obstructions and hazards.
- Landing zone should be located *upwind* from any hazardous material incident.

Approach and Departure Path

- Path should point into the wind and be free of obstruction to an altitude of 500 ft (152 meters) above the surface.
- Path should not pass over command posts, treatment areas, or operationally congested areas on the ground.

Day Operations

- Use radio communications and hand signals.
- Stand with your back to the wind.

Night Operations

- Use radio communications and lighting to designate landing zone.
- Spotlights should be directed at the top of possible hazards, *not* toward the approaching or departing aircraft.
- Position a portable light, vehicle headlights, emergency vehicle flashing lights, flare, or chemical stick at each corner, with a fifth light upwind.
- Nonessential lights should be turned off.

Light Sources

- Lights *must* be clear of landing zone.
- If portable, lights *must* be well secured.
- *Never* point lights toward an approaching or departing helicopter.

Wind Indicator

- Indicator may be a windsock, flag, flare, or smoke.
- Indicator must be clear of landing zone.
- If portable, indicator must be well secured.

Courtesy Ira Blumen, MD, UCAN (University of Chicago Aeromedical Network), UChicago Medicine, 2020.

health care facilities and a lack of open and safe landing zones. However, HEMS and fixed-wing service areas may be determined based on program mission description, aircraft range and speed, and the placement of specialty centers and receiving facilities. Population and incident data can be used[33] and HEMS base locations can be optimized considering either percentage of the population covered or average response time for the entire population.[34] Using mathematical modeling, a Norway study determined that optimally placed bases could reach their entire population in 45 minutes or less.[35] A Pennsylvania trauma registry analysis of nearly 145,000 transported patients concluded that HEMS became faster than GEMS at 7.7 miles from the trauma center with variations for traffic, weather, and geographic region.[36] A 2019 study from France had a significantly different conclusion, finding that HEMS should be chosen over GEMS when the distance is farther than 35 km (22 miles).[37]

Paramedics, emergency medical technicians, and other public safety personnel should be provided with guidelines specifying when HEMS should be considered. These protocols are best developed by EMS medical directors in close collaboration with their air medical colleagues.

SPECIFIC DISORDERS

Although virtually all types of patients have been transported by air medical services, available data do not allow prospective identification of which patients will benefit from flight. Many questions about the triage of patients to air or ground transport, the efficacy of air medical care, and the precise effects of AMT on morbidity and mortality in medical and surgical conditions remain unanswered. There are many studies indicating which patients can be cared for in the air medical environment, what skills and equipment can be used, and that medical flight is generally associated with safe patient care and a low incidence of adverse effects. Unfortunately, there is a relative paucity of clinical investigation addressing potential solutions to the problems of triage and appropriate use. A general approach to the need for AMT is illustrated in Box e13.3.

In response to the controversy over whether HEMS transport improves patient outcomes, the NAEMSP Air Medical Services Task Force began in 2000 to annotate HEMS outcomes studies published since 1980. This ongoing project has been updated every 3 to 5 years through the Critical Care Transport Collaborative Outcomes Research

BOX E13.3 Criteria for Air Medical Transport

- Distance to the closest appropriate facility is too great for safe and timely transport by ground ambulance.
- Patient's clinical condition requires that the time spent in transport be as short as possible.
- Patient's condition is time critical, requiring specific or timely treatment not available at the referring hospital.
- Potential for transport delay associated with ground transport is likely to worsen the patient's clinical condition.
- Patient requires critical care life support during transport that was not available from the local ground ambulance service.
- Patient is located in an area inaccessible to regular ground traffic, impeding ambulance egress or access.
- Local ground units are not available for long-distance transport.
- Use of local ground transport services would leave the local area without adequate EMS coverage.
- For interfacility medical transport, the requesting physician based on his/her best medical judgment and information available at the time of transport determined the need for AMT.
- For scene medical transport, the requesting authorized out-of-hospital provider based on applicable policy, his/her best medical judgment and information available at the time of transport determined the need for AMT.

Trauma

A significant volume of AMT literature addresses the use of HEMS for trauma victims and scene response. Methodological heterogeneity precludes formal meta-analysis of the AMT outcomes data. However, existing data consistently show significant improvement in trauma outcomes with HEMS,[38-43] especially from rural areas.[44,45] A large study assessing over 469,000 transferred patients found that despite improvements in trauma care over a decade, patients had improved survival if transported by HEMS.[46] Another study found higher survival in patients who were transported by HEMS versus GEMS who received CPR within 1 hour of hospital arrival.[47] Noting that HEMS represents the only modality by which nearly 28% of US residents have timely (within 1 hour) access to level I or level II trauma centers emphasizes the vital role of AMT in the care of the injured patient. Caution should be exercised in definitive statements about the criteria for and the value of AMT because such statements can be interpreted only in light of the overall local environment in which the transport system exists.

Rapid transfer of injured patients to a trauma center is essential to increase survival.[48] For many patients, factors other than speed (such as the provision of advanced levels of care over that provided by ground personnel) are hypothesized to be responsible for AMT's benefits even when GEMS transport was faster.[5,49] However, these advanced skills may result in prolonged scene times, often for patients with higher injury severity scores (ISS), which may impact overall outcome.[50] HEMS patients were more likely to have hypotension, a Glasgow Coma Scale (GCS) score less than 9, and an Abbreviated Injury Scale (AIS) score of 5.[51] Despite this, they found that in adult patients with isolated severe TBI, HEMS was associated with improved survival.[51]

AMT is unlikely to improve outcome in those whose injuries are either trivial or grave. Therefore, the decision to request HEMS is ideally based upon the clinical, logistic, and geographic considerations consistent with recommended guidelines for HEMS dispatch that should be region or system specific.[52-54] In a 7-year review of referrals to HEMS or GEMS in a rural trauma system from nontrauma facilities to a tertiary trauma center, distance was the most influential factor associated with the use of HEMS; however, injury severity and prehospital EMS transport were also significant predictors of HEMS use regardless of the distance to the trauma center.[54,55]

The Air Medical Prehospital Triage (AMPT) Score has been introduced as a triage tool to identify patients most likely to benefit from HEMS over GEMS while potentially reducing costs to the health care system.[56] Reviewing over 2 million subjects from the National Trauma Databank, it was concluded that the AMPT score identifies patients with improved survival following HEMS transport. As an air medical triage tool,[57,58] the AMTP suggests HEMS be considered for a score greater than or equal to 2 points, using the following scoring system[57]:

- GCS less than 14 = 1 point
- Respiratory rate less than 10 or greater than 29 breaths/minute = 1 point
- Unstable chest wall fractures = 1 point
- Suspected hemothorax of pneumothorax = 1 point
- Paralysis = 1 point
- Multisystem trauma (>2 body regions injured) = 1 point
- Any physiologic plus any anatomic criterion from National Field Triage Guidelines = 2 points

Overutilization of HEMS is a significant concern, as is overtriage to trauma centers. After decades of studies looking at trauma triage, even the best guidelines have trauma center overtriage rates as high as 50%. The "problems" with trauma triage have a direct impact on the issue of HEMS "overuse." If it is not possible to predict with accuracy which patients need to be transported to a trauma center, it is not possible to identify with any greater certainty which patients should be flown, resulting in overtriage of HEMS.[59] A 10-year review of HEMS and GEMS transport of trauma patients in the United States was completed to identify possible trends. The study found that the use of HEMS had significantly decreased (17% in 2007; 10.2% in 2015) without any significant change in mortality (7.6%). The authors suggested a more effective utilization of available resources. At the same time, they concluded that the overtriage of patients with minor injuries remained relatively unchanged.[60] A 2-year retrospective chart review found overtriage ranging from 35% (early discharge) to 85% when a more stringent definition was applied.[55] Another concern may be undertriage of patients for whom a HEMS response was canceled and who were later transported to a trauma center.[61] An 8-year study from North Carolina concluded that overtriage was low, suggesting a high incidence of undertriage.[62]

Overutilization is also a concern in the pediatric population. A New Jersey study concluded that in this group, the overutilization was likely secondary to the scarcity of hospitals capable of managing pediatric trauma.[63] Multiple studies have demonstrated that the principal determinants of triage to HEMS transport were primarily distance to a major trauma center and clinical factors relating to the type and severity of injury.[64,65] In a national cohort study that adjusted for nonrandom assignment of transport mode, only severely injured children

with ISS greater than 15 were found to benefit from HEMS.[66] Yet in a study reviewing 127,489 HEMS and GEMS transported pediatric trauma patients, nearly 40% of children transported by air had only minor injuries.[67]

The protocols of many EMS systems, trauma regions, and HEMS programs include a guideline for HEMS to be dispatched only for potentially salvageable patients. In general, HEMS would not be dispatched for out-of-hospital traumatic cardiac arrest (OHCA). However, several international studies have suggested that there is a potential for improved outcomes.[68,69] In a large Polish retrospective analysis of 2139 OHCA patients, ROSC was achieved in 1119 cases, including more than 70% after arrival of the HEMS team.[69] These data suggest possible benefit of HEMS dispatch to traumatic OHCA cases when additional skills, procedures, and equipment are brought to the scene; however, how this practice translates to other areas of the world remains in question.

AMT of injured patients by airplane has also been reviewed in the literature with the focus on longer distance transport. In general, fixed-wing AMT is determined to be beneficial when transporting patients hundreds or even thousands of miles to definitive trauma care.

Burn Victims

An estimated 80% of all burn patients in North America suffer less than 20% total body surface area burns. Although these patients may benefit from a burn center, without coexisting inhalation injury or other injuries, they may not require HEMS transport. Studies have demonstrated that up to a third of burn transports by HEMS were unnecessary and 25% were discharged from the ED after burn consultation and treatment.[70-72]

Cardiac Disorders

Most AMT studies on cardiovascular disease focus on ST-elevation myocardial infarction (STEMI) patients because these represent the largest group of nontrauma air transports. The ability to study HEMS-related outcomes benefit in acute coronary syndrome (ACS) is limited by the lack of validated scores that can be used to stratify risk and predict outcome.

AMT extends the geographic referral base of primary angioplasty centers and can conceivably shorten door to percutaneous coronary intervention (PCI) time by transporting STEMI patients rapidly from scenes or hospitals without PCI capability to a referral center. Procedures that have the potential to reduce time to PCI should routinely be evaluated.[73] An Ohio study found procedural changes could reduce delays, including requesting HEMS before an accepting cardiologist or hospital was confirmed, limiting IV infusions to only those essential for the transfer, and training flight crews to minimize bedside time.[74]

There is also evidence to support HEMS dispatch to rural or wilderness areas for field-diagnosed STEMIs. A 2015 study focused on scene transports from rural Belgium that assessed the use of HEMS for 342 STEMI patients.[75] Compared with GEMS, using calculated geographic information (GIS), they found that the use of HEMS resulted in savings of 60 minutes (range 47 to 72 minutes) for STEMI patients undergoing primary PCI. Similarly, positive time savings were found in a report from North Carolina, where HEMS use for scene cases saved at least 15 minutes.[76] In contrast, a prospective multicenter study out of France found the HEMS transport of STEMI patients was five times less effective than ground transport in maintaining the 90-minute first medical contact to primary PCI, particularly for transfer distances less than 50 km (31 miles).[77]

Stroke

Acute stroke patients can be just as time sensitive as trauma or ACS cases. With the advent of time-critical reperfusion therapy for ischemic stroke, HEMS has played an increasing role in the regionalization of acute neurologic care. Early studies demonstrating safety of transport of patients receiving thrombolytics during transport or post-thrombolysis stroke patients has been complemented by case series illustrating the increasing use of helicopter interfacility transport for stroke.

Although it is more common for flight programs to transport patients from smaller hospitals to regional stroke centers, case reports and series have demonstrated the utility of air medical dispatch for primary (scene) transport of patients with strong suspicion of stroke. In both scenarios, it has been demonstrated that HEMS can make important contributions when "time is brain" to facilitate the timely administration of tissue plasminogen activator and/or a neurointerventional procedure.[78] With appropriate education and criteria, ground EMS can effectively triage and identify patients who would likely benefit from HEMS scene response. This is especially important in the rural population, where HEMS can significantly reduce prolonged prehospital transport times. A 2015 report of more than 25,000 HEMS-transported stroke patients found that 96% of the HEMS patients reached tertiary care within 2 hours, which would not have been possible by GEMS.[79] In another proof-of-concept scenario, HEMS was used in interventional stroke management in much the same manner as an organ harvest—transporting physicians to the patient to improve time to procedure.[80]

High-Risk Obstetrics Patients

With appropriate triage, the speed of air transport of the high-risk pregnancy to an obstetric referral center can counter the risk of delivering an infant in an aircraft's confined space. Case series demonstrate that high-risk obstetric patients transported by air from distant hospitals have outcomes equal to patients presenting directly to an obstetric referral center. Common reasons for obstetric transport include preterm labor, premature rupture of membranes, hypertensive disorder of pregnancy, and other maternal life-threatening disorders.

Neonates and Children

The use of AMT to extend the geographic reach of neonatal care centers is reported in many settings. AMT allows infants with medical complications born in remote areas to achieve outcomes equal to those of infants born in urban centers. Although speed of transport may be important, the emphasis for neonates is often more on the transport team than on the mode of transport. Neonatal transport teams often spend more time at the bedside to resuscitate and stabilize the newborn prior to transport.

Many areas depend on AMT to deliver critically ill or injured children to regional pediatric centers. AMT has been shown to be safe for the transport of even the most critical children requiring mechanical ventilation[81] or extracorporeal membrane oxygen support.[25] Although various diagnoses may benefit from speed of transport, one retrospective study looked at patients transferred with suspected testicular torsion and concluded that HEMS offered no advantage over GEMS.[82]

LIVES SAVED, EFFICACY, AND COST-EFFECTIVENESS

Cost-benefit is an ongoing issue for AMT. The crux of the problem lies in the inability to precisely identify in a prospective manner which patients will truly benefit from fixed-wing or rotor-wing flight, especially when outcome improvements are part of regionalized specialty care systems. As a result, in many cases there is little if any guidance regarding when air medical dispatch is indicated. With use of endorsed guidelines and position papers for air medical dispatch, EMS regional authorities should collaborate to generate the best criteria for their own systems, with constant refinement guided by rigorous review.

Over the years, numerous studies have evaluated the survival benefits of HEMS, yielding results between 1.1 and 12.1 additional survivors for every 100 HEMS transports.[83-85] Cost-effectiveness determinations are not straightforward. It is difficult to calculate true cost-effectiveness for transports that are not likely to occur (as with high-risk obstetrics cases at risk of precipitous delivery) or that would deliver patients outside critical time windows (as for stroke or cardiac transports) in the absence of AMT. Cost-efficiency is also difficult to demonstrate when there are no comparison options (such as transport from coastal islands or locations without road access) or when integrated ground and air transport systems have already become established in ways that effectively prohibit head-to-head comparisons of risks and outcomes (as is true in most of the United States). If we accept that HEMS represents the only mechanism by which more than 80 million American citizens have timely access to mortality-improving high-level trauma center care, it is obvious that some form of air transport is a "must-have" for some EMS regions, and calculations of cost-efficiency fall away in favor of service provision.

FUTURE OF AIR MEDICAL TRANSPORT

AMT faces many challenges. The dramatic increase in the number of medical helicopters in the United States since the early 2000s and the number of HEMS accidents has heightened concerns for their inappropriate use. AMT works best and provides the most benefit when it is integrated into an overall system of out-of-hospital care and interfacility transport and when systems are in place to educate requesting agencies and professionals. Understanding the risks and benefits of HEMS, guidelines need to be in place to determine the appropriate use of these often-limited HEMS resources and ground resources.

Currently, the major challenge facing helicopter transport outcomes research is to identify triage variables that can prospectively (i.e., at the time of transport vehicle selection) guide use of air medical resources. In recent years, advances in ground-based EMS and the availability of critical care ground ambulances for interfacility transports have offered an appropriate transport option when an advanced level of care is needed but speed of transport is not a determining factor. Nonetheless, the regionalization of specialty services, development of new therapies that are highly time-sensitive, and inflexible geography mean that there will always be a role for AMT in emergency care. Thus, the major challenge for the AMT community is to determine not whether but rather in whom there is benefit to air medical flight.

CHAPTER E13: QUESTIONS AND ANSWERS

1. Which of the following statements is true regarding air medical transport (AMT)?

a. AMT does little to improve outcomes when used for STEMI transport from rural areas.

b. AMT scene response for acute stroke is limited by emergency medical service (EMS) providers' inability to effectively triage and identify patients who would likely benefit from HEMS scene response.

c. Faster times to a trauma center are not required for outcomes benefit from AMT.

d. The emphasis for AMT of neonates is often more on the *mode* of transport than on the transport team.

Answer: C.

2. Safety is a critical consideration for all air medical operations. Which of the following statements is true?

a. If the patient's condition is severe, it is prudent to request service from several AMT providers in the face of marginal weather.

b. Spectators should be kept at least 200 feet away from the landing zone.

c. The use of a hospital helipad for emergency medical service (EMS) rendezvous triggers the Emergency Medical Treatment and Active Labor Act (EMTALA).

d. Vehicles and personnel should be kept at least 50 feet away from the landing zone.

Answer: B.

3. A working knowledge of aviation physiology is vital to understanding the effects of AMT on pilots, medical personnel, and patients. Which of the following statements is correct regarding the aviation physiology gas laws?
   - **a.** Boyle's law explains the physiologic effects of expansion and contraction of gases within the closed spaces of the body that may occur with altitude change.
   - **b.** Charles' law can be shown as Pt = P1 + P2 + P3…Pn.
   - **c.** Dalton's law accounts for the gas changes that result in decompression sickness.
   - **d.** Henry's law explains why the ambient temperature decreases with increased altitude.

Answer: A.

4. Which of the following statements is correct with regard to landing zone safety?
   - **a.** During night operations, spotlights should be toward the approaching aircraft.
   - **b.** If the aircraft is parked on a slope, approach and depart on the downhill side.
   - **c.** In a rear-loading helicopter, it is safe to approach or depart from the rear of the helicopter.
   - **d.** Vehicles and personnel should be kept at least 50 ft from the landing zone.

Answer: B.

5. Determining which patient(s) might benefit from AMT is a critical decision for prehospital and interfacility personnel. Which of the following would represent a safe and appropriate request for AMT?
   - **a.** Any burn victim being transferred to a regional burn center
   - **b.** Based on distance for pediatric trauma patients, regardless of the type and severity of injury
   - **c.** The preferred HEMS program has turned down the flight due to weather conditions but there are other programs that can be called
   - **d.** When the distance to the closest appropriate facility is too great for safe and timely transport by ground ambulance

Answer: D.

Disaster Preparedness

Carl H. Schultz and Romeo Fairley

Disaster Preparedness

Carl H. Schultz and Romeo Fairley

KEY CONCEPTS

- Comprehensive emergency management consists of four phases: mitigation, preparedness, response, and recovery.
- Mass casualty planning should account for the breakdown of traditional transportation and communications systems during a disaster.
- Field personnel should be specifically trained in mass casualty triage and stabilization because austere field conditions change management strategies.
- All plans must protect caregivers and rescue personnel.
- Critical incident stress management is highly desirable after an event and should be planned for in advance. Psychological triage tools, such as Psy-START, may help.
- Planners should establish and exercise a hospital-based incident management system.
- Disaster planning needs to include policies to address the needs of vulnerable populations such as children, disabled, and the elderly.
- Multiple United States government agencies support disaster response, including the National Disaster Medical System, the Department of Defense, the Department of Veterans Affairs, and the Centers for Disease Control and Prevention.

FOUNDATIONS

Disasters occur in all areas of the world and cause harm to populations, property, infrastructure, economies, and the environment. Harm to populations includes death, injury, disease, malnutrition, and psychological stress. Recent catastrophes include earthquakes in Italy (2012) and Nepal (2015) (Fig. e14.1); devastating tsunamis in Japan (2011); severe flooding in Sudan (2013) and Venice, Italy (2019); hurricanes in the Philippines (2013) and the United States (2017); tornados in China (2015); the spread of Zika in South America (2015–2016); wildfires in California (2017 and 2018) and Australia (2019); the Ebola outbreak in West Africa (2014–2016) and Democratic Republic of Congo (2019); and the pandemic of severe acute respiratory syndrome coronavirus-2 (COVID-19) (2020–2021).[1]

Increasing population density in floodplains, seismic zones, and areas susceptible to hurricanes, as well as the effects of climate change, point to the probability of future catastrophic disasters with large numbers of casualties. Additional factors that indicate an increasing probability of mass casualty incidents include terrorist activity; production and transportation of toxic and hazardous materials; risks associated with fixed-site nuclear and chemical facilities (illustrated by damage to the Fukushima nuclear power plants after the 2011 Japan earthquake and tsunami); and the possibility of catastrophic fires and explosions. As an example, the United States Geological Survey has identified volcanoes in the western United States and Alaska that are likely to erupt in the future, including Mt. Hood, Mt. Shasta, and the volcano underlying Mammoth Lakes in California. Because of the rising population density in these areas, hazards from volcanic activity are increasing. An entire town, containing several hundred residents, required evacuation during the 2018 Kilauea volcanic eruption.

Given this probability and the increasing role of emergency medicine in disaster mitigation, preparedness, response, and recovery, this chapter discusses disaster planning and operations with emphasis on the role of the emergency clinician. The emergency clinician has extensive responsibilities for community disaster preparedness and disaster medical services, including response to terrorism. In position and policy documents, the American College of Emergency Physicians (ACEP) outlines the scope of emergency medicine's involvement in preparedness and response to disasters and terrorism, stating that "emergency physicians should assume a primary role in disaster preparedness and response, throughout all phases of the disaster life cycle."[2] Organized emergency medicine has also facilitated creation of national disaster and terrorism-related core competencies for emergency department (ED) personnel and emergency medical service (EMS) professionals, most recently including similar education for emergency medicine residents.[3]

A committed ED alone is insufficient to provide hospitals with a successful disaster preparedness program. Institutional commitment by every hospital department and the administration is necessary to coordinate effectively with system-wide resources for disaster management. Addressing this need is one of the major factors behind the federal government's emphasis on creating and maintaining health care coalitions (HCC). An integrated comprehensive health care system response is especially critical for providing care when demand exceeds available resources, a concept referred to as *hospital surge capacity*. A partial listing of sources for general disaster medicine information can be found in Table e14.1.

In 2016, the Office of the Assistant Secretary for Preparedness and Response (ASPR) released their guidance for health care disaster preparedness through 2022.[4] Four key capabilities are outlined:

1. Creating a foundation for health care and medical readiness
2. Health care and medical response coordination
3. Continuity of health care service delivery
4. Medical surge

The first two HCC capabilities involve organizational creation and maintenance. HCCs act as multiagency coordination groups and allow for collaboration on the mitigation of, preparation for, and response to disasters and emergencies. HCC members include individual health care and response organizations (acute care hospitals, emergency medical service agencies, public health entities, long-term care facilities, etc.) within a defined region. An emergency operations center should be established for use by the HCC. Prearranged mutual aid agreements within the HCC allow sharing of resources among members during times of crisis or hospital evacuation. The Centers for Medicare and

Fig. e14.1 Large-scale catastrophes, such as this earthquake in Nepal (2015), have the potential to cause much injury and psychological stress. (Voice of America. "Dead count rises in Nepal." Available at: https://www.amerikaninsesi.com/a/2739517.html.)

Medicaid Services require physician involvement in HCCs, and emergency physicians working at hospitals may consider participating in HCC planning and community disaster management operations.

Surge Capacity

The concept of surge capacity has emerged as a way to manage an event that produces a sudden influx of casualties with medical and health needs that exceed current hospital resources. This can be due to either the volume or types of victims. The three basic components of the surge capacity system are commonly referred to as the three "Ss": staff (hospital personnel), stuff (supplies and pharmaceuticals), and structure (physical location and management infrastructure). A complete discussion of surge capacity is beyond the scope of this chapter but has been published elsewhere.[5]

Within the context of surge capacity, new protocols exist that address allocation of resources when the medical and health needs of a population exceed current inventory. The issues involve creation of an equitable system for scarce resource allocation strategies, including, but certainly not limited to, the expansion of the emergency department or the assignment to an intensive care unit as was done during the COVID-19 pandemic.[6] Although no universally accepted approach currently exists, the Institute of Medicine has published a consensus-based document that suggests approaches to optimize patient outcomes in a resource-constrained environment.[7]

Definitions

One of the challenges facing those responsible for disaster preparedness is that no standard definition of *disaster* exists. In the most general terms, one can define a disaster as a severe supply and demand mismatch where the need for resources exceeds the supply. This suggests that a disaster is defined more by the resource and need discordance than the actual size of the event. These response capabilities can change in diverse environments or even in the same location at different times of the day or day of the week. A multiple-vehicle collision with 6 critically injured patients and 12 patients with minor injuries could overwhelm both the EMS system and the hospital in a small rural community. In an urban area with multiple hospitals that participate in a trauma system, this same event could be managed with routine resources. Thus, it is the functional impact on the specific entity that is the key concept in determining whether a disaster exists. For example, many would consider a plane crash a disaster, yet it may not even approach overwhelming the resources of the local responders. Because disaster medicine is multidisciplinary and depends on the integration of multiple levels of responders, the use of a common, precise terminology is essential.

Classic Terminology

The words *internal* and *external* refer to a hospital setting to help distinguish whether an event has occurred within the hospital grounds (internal) or in the community (external). This concept distinguishes between preparing for casualties to arrive at the hospital and managing casualties or resources within the hospital. This geographic distinction between internal and external may be useful, but it has severe limitations. Many events can be both internal and external to the facility at the same time (e.g., major earthquake or hurricane). Furthermore, simply identifying the location of the event does not answer the critical question: How are response capabilities affected? The key consideration is what actions are required to mitigate and then to rectify the situation.

Some definitions have been based on the number of casualties. As previously described, the absolute number of patients is much less important than whether their medical and health needs exceed the resources to care for them at a given point in time. The attack on the World Trade Center in 2001 (Fig. e14.2) illustrates this point. Although over 2000 victims died in the collapse of the twin towers, the actual impact on the overall health system of New York City was relatively mild. The capacity of the system to care for citizens living in New York remained intact. In contrast, Hurricane Katrina in 2005 resulted in a similar number of deaths, but caused such massive destruction, including the loss of medical and health infrastructure, that federal disaster medical assistance teams (DMATs) were deployed to Louisiana to provide medical personnel and supplies.

Hazard Vulnerability Analysis

An all-hazards approach is a common feature in disaster planning. This concept dictates that the bulk of planning should be designed for all disaster scenarios instead of for specific types of hazards (such as fire, flooding, tornados, etc.). However, an important consideration in disaster planning is an awareness of the types of events to which the hospital or community is vulnerable. The classic example is the increased risk from earthquakes in the central United States resulting from the combination of the New Madrid fault and the limited seismic safety requirements for

Fig. e14.2 The World Trade Center attack of 2001 overwhelmed local resources and necessitated state and federal help.

buildings in that area. A hazard vulnerability analysis (HVA) can be used by an HCC and individual facilities to appropriately plan resources. An HVA is based on the likelihood of an event, the potential destructive force of an event, and the preparedness level of the entity for an event. The Kaiser system has developed an HVA template (www.calhospitalprepare.org/hazard-vulnerability-analysis). The major nonmilitary threat to life and property in the United States is probably a large earthquake in a densely populated area or a terrorist attack, although the threat from flooding is increasing. The COVID-19 pandemic has demonstrated that with the increasing rate of globalization and population density growth, an emerging infectious disease represents a new and expanding risk.[1]

SPECIFIC ISSUES IN DISASTER MANAGEMENT

Triage

The term *triage* derives from the French verb *trier*, meaning to sort. The concept of triage was used as far back as Napoleon's time to assign priorities to treatment of the injured when resources were limited. Priority is given to the most salvageable patients with the most urgent conditions. Some EDs continue to use triage in the hospital setting, although this daily practice has little in common with triage during disaster conditions. For those EDs that continue to use standard triage, it is intended to identify the most seriously ill patients with time-dependent conditions and to ensure that they receive rapid care. The goal of disaster triage is clearly different—to do the most good for the most people. There is a shift from focus on individual patients to focus on the entire affected population. It can be difficult for physicians to realize that achieving the goal of maximizing benefit to an entire population of patients may necessitate letting some patients die with comfort care only. Under true disaster conditions, cardiopulmonary resuscitation should not be performed.

Routine Multiple-Casualty Triage

To assist in the understanding of triage techniques, it is useful to consider a routine out-of-hospital event with multiple casualties (e.g., a multivehicle collision). In such situations, rescue personnel often use a simple triage and rapid treatment (START) technique that depends on a quick assessment of respiration, perfusion, and mental status.[8] These three assessments can be remembered by the mnemonic RPM (*r*espirations, *p*erfusion, and *m*ental status). To initiate this sorting process, all victims who are able to walk are asked to move away from the incident area. These patients are classified as green, or "walking wounded," and are reassessed after the more immediately critical patients are triaged.

The Pediatric Triage Tape (PTT) and JumpSTART have been proposed for the triage of children. JumpSTART is a modification of the START triage protocol that includes an additional step of five rescue ventilations for children presenting apneic and modification of criteria for hypoventilation and tachypnea, as well as for a decrease in mental status (Fig. e14.3). The PTT uses criteria that change in proportion to increasing victim size. The parameters for a child 50 to 80 cm in length are illustrated in Figure e14.4. In an evaluation of five triage tools using a large trauma database, JumpSTART performed best for children under 8 years of age with CareFlight triage performing best overall.[9] Although START, JumpSTART, the PTT, and CareFlight appear to be useful tools, only START has been evaluated in an actual disaster situation. As such, no pediatric triage system has proven clear superiority over any other, and therefore, recommendations on choice of pediatric triage system should be left to individual jurisdictions. Proper education and team training may be more important than triage system choice.

As illustrated in Figure e14.5, a rescuer using START triage can assess each patient in seconds, quickly checking respiratory rate, pulse, and ability to follow commands (mental status), and divide the patients into the remaining three categories: red (immediate), yellow (delayed), and black (deceased). The only patient care interventions provided during this process are the opening of an obstructed airway and direct pressure on obvious external hemorrhage. At this point, patients are generally transported to a hospital for definitive care. Most often, patients arrive with a color-coded triage tag and are reassessed and retriaged by the hospital staff (Fig. e14.6). An outcomes-based evaluation of the performance of START triage in an actual disaster (2002 Placentia Linda train crash) demonstrated acceptable levels of undertriage (100% sensitivity of the red category and 90% specificity of the green category). However, significant amounts of overtriage occurred. Use of START also appropriately prioritized the transport of victims, with patients triaged as red arriving at hospitals earlier than patients triaged as yellow or green.

Given the significant number and variability of proposed disaster triage systems, a multidisciplinary group in the United States attempted to standardize these platforms by developing the Model Uniform Core Criteria in 2011. These core criteria promulgated a set of principles to guide creation of mass casualty triage algorithms. Based on these guidelines, this group also proposed a potential national triage system for the United States. The result, derived by consensus, was referred to as SALT (*s*ort, *a*ssess, *l*ifesaving interventions, and *t*reatment or transport). It differs from START mainly in the assessment of respirations (i.e., relies on a qualitative evaluation of respiratory distress rather than a number), the requirement for performance of certain lifesaving interventions (chest decompression), and an unstructured estimate of survivability. The algorithm is more complicated than START, and no current data exist evaluating its sensitivity, specificity, or other performance characteristics after use in an actual incident. As such, it is not currently possible to make recommendations for the use of SALT triage. For anyone considering implementing an adult mass casualty triage algorithm, we recommend using START triage until more evidence emerges describing the performance of SALT triage in actual disasters.

Catastrophic Casualty Management

Triage during a disaster differs from triage performed in routine out-of-hospital and hospital settings. The number of victims is vastly increased, while medical resources are severely limited or initially absent. Patients may remain on scene for an extended period and may require periodic reassessment, which will be challenging. If hospitals remain accessible, patients tend to seek care at the closest one, a phenomenon known as convergence. Hospitals close to the disaster scene are overwhelmed, whereas hospitals located only a few miles away may receive few if any patients. The triage process will then be decentralized, occurring at multiple sites, or compartments, simultaneously throughout the disaster zone. Rather than a single scene or localized disaster, this can be thought of as a compartmentalized disaster.

To address this situation, researchers developed the Secondary Assessment of Victim Endpoint (SAVE) system of triage. The SAVE triage system is designed to identify patients who are most likely to benefit from care available under austere field conditions or in a resource-poor environment. When combined with the START protocol, SAVE triage is useful for any scenario in which multiple patients experience a prolonged delay in accessing definitive care.

The SAVE methodology is designed for use by health care providers under two conditions: (1) for those working within the disaster zone that begin caring for patients immediately but may not be able to transport patients to a definitive care facility for days, and (2) for those caring for patients within hospitals where demand for resources exceeds supply. This second situation can occur as hospitals attempt to increase surge capacity. It is immediate and dynamic rather than delayed and static.

The SAVE triage methodology divides patients into three categories: (1) those who will most likely die despite available care, (2) those who will survive without care, and (3) those who will benefit from austere field interventions. Only those patients expected to improve receive care beyond basic or comfort measures. The decision to place patients in a particular group is based on field outcome expectations derived from existing survival and morbidity statistics. An example is a situation in which three victims require chest tubes (two victims require one tube each and one victim requires two tubes), but only two chest tubes are available. The SAVE principles guide providers to place their last two chest tubes into the two victims who need one rather than into the single victim requiring two tubes.

Since nuclear, biologic, and chemical terrorism has become a threat, triage systems have been modified to address these situations. These systems attempt to incorporate the added threats from exposure and contamination into the triage process. One such method for biologic casualties triages many individuals to home observation rather than hospitalization to optimize resource use and to minimize the spread

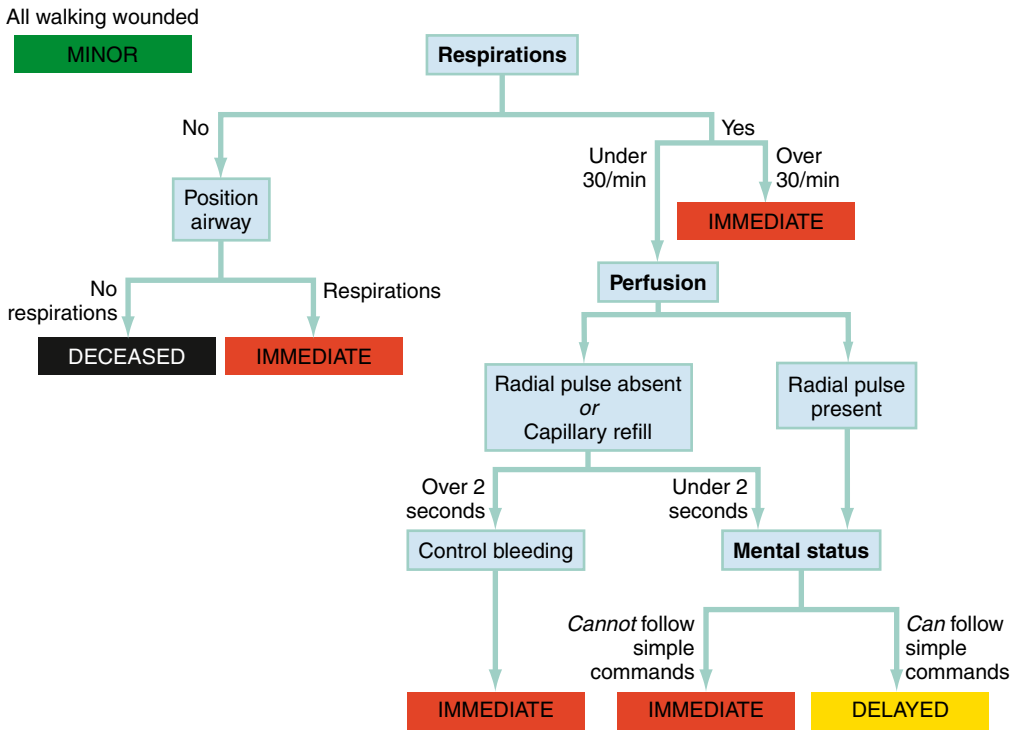

Fig. e14.5 Simple triage and rapid treatment (START). Victims who can walk are identified first and triaged into the "minor" category. Those remaining are triaged using the algorithm. (Modified from: Triage—START and SAVE. In: Medical disaster response training course syllabus, Dana Point, CA: Medical Disaster Response; 1993.)

of the infectious agent. This strategy has been used effectively during the COVID-19 outbreak. In addition, responders require protection from secondary contamination or exposure; therefore, part of the triage algorithm should include a risk assessment and determination of whether and what type of personal protective equipment should be donned before patients are assessed. This was illustrated during the 2014 to 2016 Ebola outbreak when health care providers initiated Ebola exposure screening procedures during initial patient contact before engaging in patient evaluation and treatment. A similar approach was also utilized initially in the COVID pandemic. Once community spread developed, however, this practice was replaced by the assumption that all patients were infected. In a combined event scenario, such as an incident involving a radiologic dispersion device, rapid patient assessment is critical to prevent patient deaths from traumatic injuries while awaiting medical care from responders concerned about their own health and safety.

Also associated with disaster incidents are large numbers of psychological casualties. These individuals have not received physical injuries or toxic exposures but experience significant psychological trauma and are at risk for posttraumatic stress disorder and other psychiatric illnesses. The emergency plan should include a mechanism to provide psychological triage, such as PsySTART, that can rapidly assess individuals to identify those at risk for serious and prolonged illness and assure that they have access to mental health care. Responders effectively used PsySTART immediately after Hurricane Sandy and Typhoon Haiyan.[10]

While performing triage, the emergency clinician should consider the effects of extreme age, underlying disease, and multiple injuries when assessing the potential prognosis for a given patient. Treatment of many nontraumatic emergencies can be accomplished with field interventions that do not consume extensive resources. Patients with such illnesses should usually be triaged to the treatment area.

Vulnerable Triage Populations

Certain groups of patients, such as children, the elderly, the disabled, and homeless persons, may have special needs that present challenges to routine triage. For example, if a person is too young to follow commands or is deaf, the individual would not be able to respond to a command to walk away from an incident site for reasons that may not indicate severe injury. Triage schemes should attempt to accommodate language and cultural barriers, as well as physical and psychological limitations that result in social or medical vulnerabilities.

Special Triage Categories

To maximize human resources, disaster victims who would normally be triaged to the observation area can be triaged to the treatment area if they possess special skills valuable to the medical team (e.g., medical expertise and translation skills). By increasing the number of functional team members, the effectiveness of the overall response will improve. The guiding principle supports the disaster triage goal of maximizing benefit to the most people.

Care of Populations with Functional or Access Needs

Within the general population, groups of unique individuals exist that are at greater risk for injury, death, and property loss resulting from a disaster. These vulnerable populations include children, the elderly, racial and ethnic minorities, the disabled, those residing in institutions such as skilled nursing facilities, and the mentally ill. Challenges in the management of these populations with functional or access needs during a disaster include: (1) lack of mobility; (2) difficulty tracking victim movement during evacuations and issues of reunification with responsible family members; (3) inability to understand English or to comprehend instructions issued by local authorities; (4) fear of deportation if requesting aid or other resources from state or federal authorities; and (5) poor access to transportation resources. A detailed

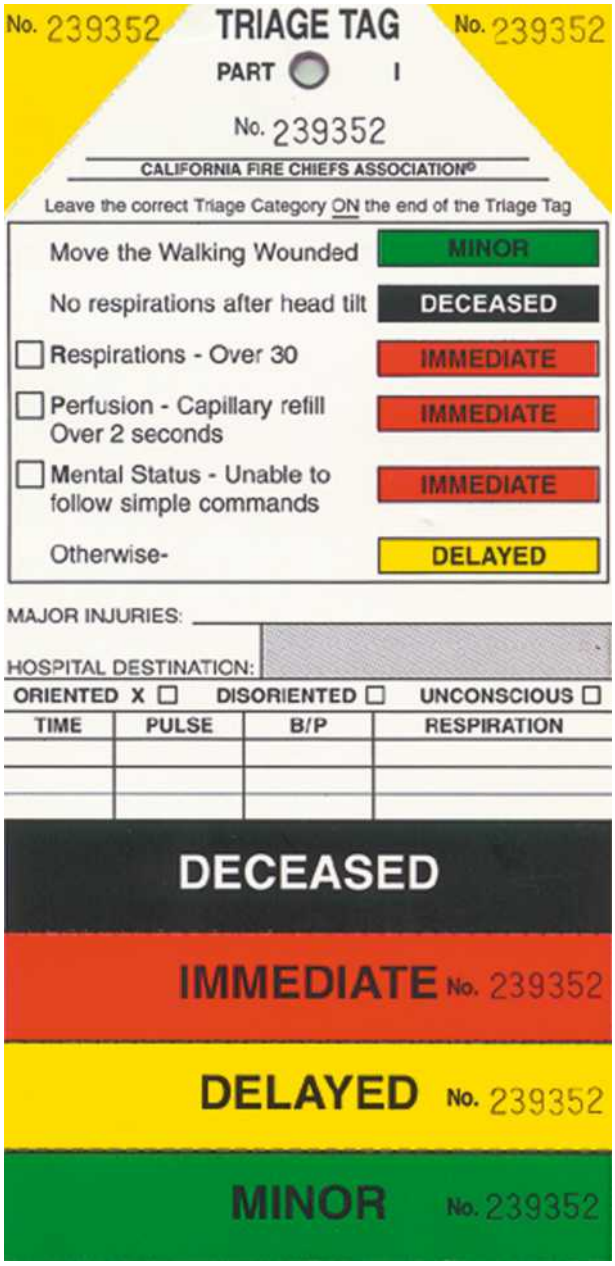

Fig. e14.6 Triage tag to be used in multicasualty or disaster patient assessments.

discussion on the disaster management of these populations is beyond the scope of this chapter but available elsewhere.[11] Those responsible for disaster planning should ensure that policies and procedures are developed that address the unique needs of such groups.

Out-of-Hospital Response

Emergency Medical Services System Protocols

To prepare adequately, hospitals should be familiar with and involved in the development of county or regional plans. For example, some EMS systems use automatic systems such that each hospital may be expected to accept a fixed number of critically ill or injured and minor patients without advanced notification.

Incident Management System

Some form of an incident management system is a standard component of emergency command and control throughout the United States.

TABLE E14.2 Incident Command System Elements

Incident Commander	• Responsible for overall management of incident • Not physician • Can appoint command staff to manage public information, safety, and interagency coordination
Operations Section	• Manages incident tactical activities • Manages the resources assigned to staging areas • Medical care and triage fall within this section
Planning Section	• Collects, evaluates, and disseminates information about incident operations and the status of resources • Develops incident action plans • Conducts planning meetings
Logistics Section	• Provides facilities, services, and material in support of the incident • Procures equipment and supplies • Provides food and medical support • Arranges for transportation needs
Finance Section	• Maintains records on personnel and equipment • Provides payments to vendors for supplies and use of equipment • Determines the cost of various alternatives for strategic planning

It provides a flexible management structure on which to organize a response.[12] The federal version, known as the National Incident Management System (NIMS), is incorporated into the National Response Framework (NRF) and provides strategic guidance on the United States government's involvement in disaster response. All states must use an incident management system compliant with the NIMS.[13,14] A tool commonly utilized to implement the NIMS approach is the incident command system (ICS).

By standardizing an organizational structure and using a common vernacular, the ICS provides a management configuration that is adaptable to events involving a multiagency or multijurisdictional response. At the most basic level, there are five functional elements in the organizational structure: incident command, operations section, planning section, logistics section, and finance section. The key components of these elements are listed in Table e14.2. Each section has a chief to provide leadership and can be expanded and subdivided into branches and divisions. Physicians should understand they will not serve in the incident command position so they may remain available to provide medical care. ICS requires a chain of command and aims to limit the scope of control to roughly five individuals. The principles of an ICS can be adapted to the hospital setting through implementation of a hospital incident command system (HICS).[15] With this type of organizational infrastructure and the flexibility to expand and collapse functions as needed, an orderly and efficient response to any incident can be accomplished, with fluid improvisation as needed. When an event involves multiple jurisdictions, a unified command is established that coordinates a common and consistent action plan to make the best use of available resources. The Joint Commission standards require use of an incident management system in health care facilities.

Organization of the Out-of-Hospital Disaster Scene

The disaster site is organized into several distinct areas. The command post is the nerve center of the operation and contains the incident commander and section chiefs. For events with a discrete scene, ambulances, personnel, and supplies should be staged outside the event

perimeter. Responders can then direct resources inside the perimeter as needed, preventing the uncontrolled convergence of assets to the disaster site that can result in potential disruption of activities and blocking the exodus of patients. If air evacuation is needed, a safe landing zone must be identified. A casualty collection point and morgue should be designated with operational resources (such as restrooms, food preparation areas, and sleeping quarters) for personnel strategically placed adjacent to the scene as needed. The media should have restricted access. Security personnel are required to control access to the entire scene. In conjunction with an ICS, this structure brings order to the response.

Planning and Hospital Response

Comprehensive Emergency Management

The comprehensive emergency management all-hazard approach to disaster preparedness has been a Joint Commission requirement since January 2001. Comprehensive emergency management consists of four phases: mitigation, preparedness, response, and recovery.[16] Although the National Response Framework describes five phases (prevention, protection, mitigation, response, and recovery), most emergency managers endorse the four-phase model and this chapter will employ such an approach for consistency. Mitigation involves taking actions to reduce the impact of identified hazards. Enhancing the seismic structural design of hospitals is one strategy to mitigate the impact of large earthquakes on the health care system. Preparedness includes initiation of strategies and activities before an event occurs to improve capability, such as stockpiling food/water and creating an evacuation plan. Response includes assessment of the situation and coordination of resources. Finally, recovery consists of a return to normal operations with a review of the response and provision of long-term psychological support to the victims and rescuers. As required by the Joint Commission, a hospital's disaster or emergency management plan needs to address events that occur both inside (internal) and outside (external) the institution.[16]

Hospital Disaster Response Plan

A disaster event can disrupt daily, routine hospital functions. This can represent an infrastructure failure (e.g., loss of electric power and water) or a threat to the safety of patients and hospital personnel (e.g., labor dispute or approaching hurricane). Because the response varies from postponement of elective surgery to facility evacuation, every hospital department needs to participate in the planning process.

Most disasters experienced by hospitals are local in nature. Hospital function is typically unimpaired. The majority of problems encountered relate to creating surge capacity for the sudden increase in volume and acuity of arriving patients, or for those with illnesses not usually treated at that facility (e.g., burns, radiation exposure, or severe acute respiratory syndrome). At a minimum, the disaster plan should clearly delineate the circumstances in which the plan is activated, as well as: (1) identify the command structure with defined lines of authority and responsibility; (2) describe a response strategy for each anticipated incident; (3) estimate an incident's impact on safety and hospital function, providing for evacuation if necessary; and (4) list essential information such as critical telephone numbers (e.g., elevators, key personnel, and pay telephones), community agencies (EMS, police, and public health), and a redundant source of vital supplies (water, oxygen, and drugs).

Events occurring in the community may result in a sudden surge of patients requiring emergency care. This type of incident has no direct impact on hospital structural integrity or function. However, the need to rapidly increase capacity may require implementation of different patient management strategies (i.e., temporary creation of alternative care sites on hospital grounds), as was done to accommodate patients with COVID-19. Participation in the planning and execution of the hospital disaster response is an important administrative responsibility. A member of the ED must have a leadership role in the planning and implementation of the disaster plans. Available data guiding development of disaster strategies are incomplete, but an effective disaster response can be created by reviewing the essential components of disaster plans and the previous experience of other hospitals.

The First 72 Hours. In a large-scale disaster, each individual hospital may need to remain self-sufficient for 48 to 72 hours or longer. Disaster medical assistance teams (DMATs) and urban search and rescue (USAR) teams will deploy, but their time to arrival on scene may be variable. Therefore, an alternative source of rapidly available, sophisticated medical care is necessary. Local responders able to initiate treatment of patients soon after the event can best provide such care. One model embracing this concept is the Medical Disaster Response Project, developed by emergency clinicians in Southern California. This model was used to create the current national plans utilizing the Medical Reserve Corps and Strategic National Stockpile.

Local responders and volunteer citizens rescue up to 90% of victims with serious but survivable injuries in the first 24 to 48 hours. Therefore, special medical teams such as DMATs and urban search and rescue teams may not significantly affect survival from acute injuries if they arrive after more than 48 hours. A recent analysis has questioned the cost-effectiveness of internationally deployed search and rescue teams.[17] The traditional view holds that deploying field hospitals to distant disaster zones does not improve outcomes. Due to the widely acknowledged success of their mission, the results reported by the Israeli Field Hospital after deployment to the Haitian Earthquake in 2010 may change this for acute events. In a more protracted event such as the COVID-19 pandemic, load balancing patients across an HCC or medical system may be a more effective approach if the risk of intrafacility spread is minimal. Otherwise, creating a single "SARS" hospital and supporting it with on-site alternative care facilities may be safest to protect the integrity of the health care system.

Basic Components of a Hospital Comprehensive Disaster Response Planning Process

Interdepartmental Planning Group. The interdepartmental planning group (frequently referred to as the disaster or emergency preparedness committee) is composed of representatives from all departments vital to the hospital's response. This group has the responsibility of completing the HVA and disaster mitigation activities. Commonly included departments are administration, finance, medical staff, nursing, security, pharmacy, and facilities management. Additional input may occasionally be necessary from outside agencies such as the fire department, EMS agencies, and the suppliers of goods and services.

The committee should be structured to ensure that the plan is properly constructed, tested, and executed. Hospital resources are needed to support the planning process and testing of the plan, and a detailed educational program should exist for all affected hospital staff. The Joint Commission requires the emergency plan to be reviewed annually.[16]

Resource Management. A full inventory of the hospital's resources is necessary, including equipment, space, and personnel. It is also necessary to develop contingency plans with redundancy to compensate for lost resources (e.g., failure of hospital computers during a power outage or cyber-attack). Augmentation of such resources is critical to the successful enhancement of the hospital's surge capacity. Discussion within an HCC on utilized vendors can prevent a single vendor from being overwhelmed in a disaster scenario.

Hospitals located near companies using large amounts of hazardous materials are required by Title III of the Superfund Amendments and Reauthorization Act to participate in local emergency planning

committees (LEPCs).[18] LEPCs are similar to HCCs but are broader in scope and include non–health care community representatives.

Command Structure. The HICS implements an organized approach to disaster management by establishing lines of authority and decision responsibility. This system designates a command center where the disaster response can be coordinated and creates a clear chain of command based on positions, not individuals. This prevents confusion if certain individuals are missing, a common situation on nights and weekends or in cases of a community-wide disaster during which hospital personnel may become victims.[15] The command center should contain sufficient equipment to support command and control functions, even if the center must be moved as a result of hospital damage.

Media. The media can be an important source of information but can also significantly disrupt the hospital's disaster response. Arrangements should be made in advance for a designated individual to coordinate all media interactions and for these briefings to occur in a predetermined location. Frequently referred to as the public information officer (PIO), media coordinators should inform reporters of the time they will receive their next update so that they do not intrude on response operations while trying to obtain information. A strong media liaison can facilitate dissemination of important information to the public, such as that no blood shortage exists to prevent individuals from flooding the hospital to donate blood. In fact, crisis and emergency health risk communication is now an important part of managing the disaster response and can have a significant impact on the public's perception of events.[19] Security should be involved in managing the media response to the hospital and in preventing media from interfering with essential hospital functions. During the Loma Prieta earthquake in 1989, for example, a news helicopter occupied a nearby community hospital's only landing zone, impairing the ability of landing a medical helicopter.

Communication. Communication systems are probably the most important but also most vulnerable component of a disaster plan. Redundant systems are essential. Those responsible for mobilizing the emergency response require access to at least one other communication system besides the landline telephone (which is frequently one of the first systems compromised during a disaster). Telephone service will cease as lines are disrupted or deliberately restricted by the phone company. Cellular phones may function within a local area, but failure is likely if more distant sites within the city are dialed. Hospital radios designated for disaster use should be secured in place using bolts or other devices to prevent damage from violent movements, such as falling to the floor, during an earthquake. Two-way radios are often used, as are independent fax lines and cellular phones. Other options are satellite phones and HAM radios provided by organized volunteers that are part of established national organizations. Recently, use of social media has proven beneficial.[20] Survivors of the 2011 Japan earthquake used social media to provide early information to the outside world on conditions within the disaster zone. Runners are useful for intrahospital communication if all else fails. A mass communication system is essential to easily distribute information to personnel and receive responses such as availability to return to work. Several commercial emergency notification systems exist using email, text messaging, and voice calls.

Personnel. The disaster plan should include a roster of all critical positions with relevant personnel and establish a reliable method for their mobilization. Several individuals should be assigned to each position in preparation for absences. Studies have shown that up to 80% of staff will not come to work during a disaster.[21] A protocol for managing volunteers is also crucial. A large group of volunteers spontaneously descending on a hospital (convergent volunteerism) can be as disruptive as the disaster.

Credentialing of volunteer health professionals in a timely manner so hospitals can use their services during a disaster remains a challenge. A federally supported program known as the Emergency System for Advance Registration of Volunteer Health Professionals (ESAR-VHP) attempts to address this problem. It provides a system for credentialing of volunteer health care providers (at the state level) in advance of a disaster so that they will have emergency privileges should the need for their services arise. There remain significant challenges with such a system, including whether sufficient numbers of providers will participate, how quickly they can deploy, how qualified they will be, and whether they will have competing obligations during a disaster. An alternative system that permits hospitals to recognize each other's credentialing process through a shared database shows promise and has been endorsed by a publication from the Agency for Healthcare Research and Quality. Not only will this alternative system facilitate participation by most health care providers, but it also permits hospitals to grant emergency privileges within minutes after a disaster. Aspects of this system are in use to support emergency staffing during the COVID-19 pandemic while other components are evolving.

Patient Management. A systematic approach to patient management is necessary to maximize resources. This includes protocols for decontamination, triage, prioritization, evacuation, and family reunification. Alternative use of hospital facilities should be anticipated, such as the conversion of a parking lot into a clinic area for suturing of lacerations or a decontamination zone. If hospitals are not functional and no backup plan exists, immediate advanced medical care will not be available, and people may die. Planners should include a backup system to provide medical care at alternative nonhospital care sites. Provisions for patient identification and treatment documentation are also important to facilitate federal and third-party reimbursement at the conclusion of the disaster.

Hospital Evacuation. On rare occasions, the hospital structure or critical infrastructure will be damaged, forcing facility evacuation. After hospital damage, immediate access to structural engineers is important. In the Northridge earthquake, eight hospitals in the Los Angeles area sustained enough damage to force evacuation of at least one patient. Four institutions completely evacuated their facilities in the first 24 hours, including two hospitals that met the most current structural earthquake standards. Further structural damage was subsequently identified, and two additional hospitals were forced to evacuate completely in the next 2 weeks. Ultimately, four of these hospitals were permanently closed and demolished.

Hospitals are also vulnerable to flooding. A study of Hurricane Harvey's (2017) impact by the Texas Hospital Association showed that twenty hospitals were closed or evacuated. Significant problems included loss of power, lack of potable water and other critical supplies, insufficient staff, and structural damage. It was also difficult to obtain vehicles for transportation of patients to other facilities. Nonmedical vehicles were sometimes used to evacuate stable patients.

In the event that evacuation of the hospital is necessary, evacuation routes and relocation destinations that have been planned in advance maximize safety and efficiency. Some hospitals use the ED as a "landing zone" for hospital evacuations (i.e., patients move from inpatient beds to the ED and then are transported out). When resources are plentiful, patients in critical condition are assigned the highest priority for evacuation and transport. Less ill patients receive a lower priority. When time is limited (e.g., in the event of an imminent structure collapse), the reverse strategy applies. The least critically ill patients receive the highest priority for evacuation; this maximizes patient evacuation in a constrained timeframe.

Generator problems are frequent; they either fail altogether (as they did during the Loma Prieta earthquake) or supply insufficient power to meet emergency needs (as during the Northridge earthquake). Evacuation plans must not require elevators for this reason. Though several commercial devices exist to aid patients down stairwells, none has ever been documented as superior to backboards, sheets, and other readily available hospital equipment.

Training Exercises. Disaster exercises are one of the more effective ways of familiarizing hospital staff with their responsibilities. All hospital departments should participate, and community agencies should be involved. The Joint Commission requires two drills a year; these should mimic incidents that are likely to occur, based on the hospital HVA. Methods to assess the effectiveness of these exercises as measures of overall hospital disaster preparedness are improving, such as those provided in the toolkit by Agboola et al.[22]

Toxic Disasters (Hazardous Material)

Hospitals located near major chemical industries, transportation corridors, or probable terrorist targets (e.g., major theme parks or nationally symbolic buildings) should be aware of potential hazardous material incidents. Such facilities should be prepared to decontaminate large numbers of individuals. Coordination of decontamination resources through the HCC can significantly increase community preparedness. Effective decontamination of victims and the need for safety measures on the part of rescue personnel to prevent secondary contamination are critical. Decontamination equipment should be stored near the ED and the staff trained in its use. When such an emergency occurs, there is little time to search the hospital for necessary supplies.

Patients contaminated with hazardous materials should first be brought to a designated decontamination area containing a warm-water shower with a container to hold drainage water. In a rapidly evolving event with mass casualties, collection of wastewater after decontamination is not a priority and drainage into the sewer system is acceptable. Victims should remove all clothing and valuables, and these should be bagged, identified, and stored. Contaminated patients should never be brought into regular patient care areas due to the danger of contaminating other patients, hospital staff, and equipment. In 1994, paramedics unsuspectingly transported a patient contaminated with a degradation product of dimethyl sulfoxide to an ED in Riverside, California. Before the presence of the hazardous material was detected, six health care workers were exposed, including an emergency clinician. The emergency clinician experienced a near-fatal exposure and required intubation and an extensive stay in the hospital's intensive care unit. Uncontrolled spread of the toxin resulted in evacuation and temporary closure of the ED.

Closing off air intake vents by hospital personnel is appropriate for rooms containing contaminated patients so that toxic products do not enter the ventilation system and circulate to other areas of the hospital. Rescue personnel and hospital staff should be protected by gowns, gloves, masks, and, if necessary, supplied air respirators. The goals are to reduce the initial level of external contamination, to contain the contamination that remains, and to prevent further spread of these potentially dangerous substances to other patients and staff members (secondary contamination).

Chemical, Biologic, Radiologic, Nuclear, and Explosive Terrorism

In addition to the familiar threat from hazardous materials, there is another challenge: a potential attack by terrorists using biologic, radiologic, chemical, or explosive (CBRNE) weapons (see Chapter e15). Although somewhat similar to hazardous materials situations, management of patients exposed to weapons of mass destruction (WMD) requires additional knowledge and skills. While expertise in the management of patients targeted by unconventional weapons is important, emergency clinicians should also be familiar with the treatment of blast injuries. Events characterized by the use of high-explosive devices, including suicide bombers, remain the most probable type of terrorism.[23]

The most likely radiation source used by terrorists will probably not come from the detonation of a nuclear weapon. Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are likely the source of choice. They do not explode and give no warning of their presence. Terrorists can dismantle such devices and incorporate the radioactive source into an explosive radiologic dispersion device (dirty bomb). Providers should recognize the presentation of patients suffering from radiation exposure to make the diagnosis. In addition to damage from radiation, these casualties may also suffer blast injuries. Initial treatment of such victims, if they are critically injured, should address stabilization of the blast injuries first before the radiation exposure is considered. Patients who are irradiated but not externally or internally contaminated pose no threat to ED personnel.

One of the greatest challenges with respect to WMD is the detection of biologic weapons. Patients exposed to biologic agents often initially present with vague symptoms associated with influenza-like illnesses (ILI). Decontamination is not a priority unless the exposure is immediate; standard precautions are generally sufficient.

Unlike radiologic or biologic weapons, chemical agents produce symptoms quickly. The challenge is decontamination and treatment. Their accurate diagnosis may also be challenging given the clinical overlap with other natural, pharmaceutical, or chemical entities. For example, Sergei and Yulia Skripal were poisoned with what was eventually found to be a targeted attack with a Novichok (nerve) agent, but their symptoms were originally diagnosed as an overdose on a fentanyl-contaminated product. At least 2 other people were contaminated during the process, and one died. Approximately 80% of mass casualty decontaminations are performed at hospitals. PPE is essential for responders and hospital "first receivers" due to the risk of exposure during the decontamination process.

Disaster Stress Management

Emergency health care providers experience high levels of stress when responding to the needs of disaster victims. If the stress exceeds the capacity of normal coping mechanisms, it can potentially interfere with job performance and produce symptoms, including depression, sleep disturbances, increased use of alcohol and drugs, irritability, and anxiety. Posttraumatic stress disorder (PTSD) can result. In an attempt to reduce the psychological impact of these events on medical responders, various therapeutic techniques have been introduced throughout the years and are collectively known as critical incident stress management. This formal process of resolving emotional conflict using mental health professionals is now widely practiced.[24]

In general, the longer the delay between exposure to the critical incident and subsequent psychological intervention, the smaller the chance for a successful outcome. Therefore, the critical incident stress management process is designed for rapid implementation. During the incident, stress management staff or even a colleague can provide on-scene intervention. The goal is to assist the health care worker in regaining emotional control by facilitating communication of feelings and reactions through listening and support. A recently validated tool, PsySTART, can be used to rapidly identify disaster victims or health care workers at risk for long-term mental health impact due to a stressful exposure.[25]

If a critical incident has profoundly affected participants and if symptoms are still present many hours later, urgent assistance is provided in the form of defusing. Mental health or peer support staff coordinate the critical incident defusing process. The focus is on providing feedback information and allowing for venting of emotions. This process often takes place in private to protect confidentiality. If the psychological stress is severe, the process transitions to formal care provided by psychiatrists or psychologists. Data from previous experiences suggest that such intervention can assist providers in maintaining job performance and satisfaction.

Personal Preparedness

Personal preparedness is critical to survival in disasters. FEMA maintains a course called "Are you ready?" to assist people in preparing and

TABLE E14.3 Disaster Kit Components

Battery powered radio	Sanitation items (toothbrush, toilet paper, moist towelettes, concentrated soap)	Can opener
Extra batteries	Matches (in waterproof container)	Photocopies of insurance, identification cards, essential documents
Flashlight	Extra clothing (cold weather as needed)	Cash and coins
First aid kit and manual	Cooking utensils (pot, cup, plate, fork/spoon)	Medications (2-week supply)

protecting themselves in an all-hazard approach.[26] The steps of personal preparedness include: (1) know the risks inherent for a location; (2) purchase appropriate insurance; (3) develop an emergency action plan; and (4) assemble a disaster kit. In a disaster, sources of information include the local Emergency Alert System, local news access (websites, television stations, radio stations), and National Oceanic and Atmospheric Administration Weather Radio.

The emergency action plan should be reviewed, practiced, and updated on a regular basis. All members of a household, including children, should have a strong understanding of the emergency action plan. Planning experts suggest that individuals have knowledge of evacuation routes from home, work, school, and the city. Along with escape routes, a rally point should be designated in case of family separation. Emergency action plans should also include how to care for pets or vulnerable people (such as children or the elderly). A basic understanding of how to turn off utilities (such as gas or water) to a home may be necessary in case of structural damage.

A disaster kit is the cornerstone of personal preparedness. The disaster kit should be kept in a consistent and safe location at home with easy access by all members of the household. Guidelines recommend keeping 72 hours' worth of nonperishable food, water, and supplies for personal survival. An average estimate for water needs is one gallon per person per day. Special consideration should be given to vulnerable populations such as infants (formula, diapers, bottles, toys), pets (food, medications), and the disabled (hearing aids, oxygen canister, wheelchair, etc.). Table e14.3 outlines the basic requirements of a disaster kit.

Disaster Management and Response Organizations within the United States Government

Department of Homeland Security

The Department of Homeland Security (DHS), a cabinet-level department formed after the terrorist attacks of September 11, 2001, is the federal government's lead organization for emergency management activities in the United States. The Federal Emergency Management Agency (FEMA) was incorporated into DHS and retained its name. DHS has a coordinating responsibility for the entire spectrum of disasters irrespective of their size or etiology. DHS assists state and local organizations to mitigate, prepare for, respond to, and recover from emergencies and is a source of funding for these endeavors. In 2003, President Bush directed that DHS develop a National Incident Management System and a National Response Plan. Existing federal plans, including the National Response Plan, were then incorporated into the National Response Framework. The National Response Framework includes 15 Emergency Support Functions (ESFs). Each has a primary (lead) federal agency and many supporting agencies. ESF #8, titled Public Health and Medical Services, is of key importance to the health care community. The primary agency is the Department of Health and Human Services (HHS). Examples of functions within ESF #8 include coordination of health care personnel, supplies, pharmaceuticals, surveillance and reporting, and mass fatality management. To illustrate, HHS facilitated the distribution of large quantities of remdesivir to states so equitable hospital distribution could occur, supporting treatment of COVID-19 patients.[27]

Urban Search and Rescue (ESF #9 of the National Response Framework)

When a building collapses, various challenges confront rescue and medical personnel. Some victims require field amputations to facilitate extrication. The use of urban search and rescue (USAR) teams and effective emergency medical care may improve the outcomes of such lifesaving efforts, but limited data exist supporting these activities. The role of USAR teams has recently been questioned and the cost-effectiveness of their interventions remains unclear. This national system of multidisciplinary task forces is designed for rapid deployment to the sites of collapsed structures. The medical team's responsibilities include caring for task force members, victims recovered by search and rescue activities, and the search team's dogs. There are also weapons of mass destruction (WMD) USAR teams trained by FEMA to respond to nuclear, biologic, and chemical terrorist attacks.

Department of Health and Human Services

On December 19, 2006, President Bush signed the Pandemic and All-Hazards Preparedness Act (S. 3678) into law and created a new position, the Assistant Secretary for Preparedness and Response (ASPR), within HHS. The office of the ASPR oversees the department's responsibilities for emergency preparedness and response activities, including the National Disaster Medical System (NDMS) and the Hospital Preparedness Cooperative Agreement Program, the coordination of the Medical Reserve Corps, ESAR-VHP, the Strategic National Stockpile, and the Cities Readiness Initiative. HHS also funds several grant programs designed to enhance emergency preparedness by states. These include the Public Health Emergency Preparedness and Hospital Preparedness Program cooperative agreements. Funding for these programs have decreased since 2013. Although a temporary increase in financial support has occurred due to the COVID-19 disaster, the future of this important funding stream is uncertain.

National Disaster Medical System

NDMS is a federally coordinated initiative designed to augment the emergency medical response capability of the United States in the event of a catastrophic disaster. This system is a cooperative program of four departments in the federal government: the Department of Defense (DoD), HHS, DHS, and the Department of Veterans Affairs (VA). Although oversight of NDMS has moved between federal departments, HHS currently has the lead for this program. NDMS provides an interstate medical mutual aid system linking the federal government, state and local agencies, and private sector institutions to address the medical needs of victims of disasters. The three distinct NDMS elements focus on field medical response, patient transport, and definitive care. Its field medical response element includes dozens of volunteer civilian DMATs that supplement the local medical infrastructure, as well as disaster mortuary operational response teams (DMORTs), veterinary

medical assistance teams (VMATs), and various specialty teams (e.g., Trauma and Critical Care Teams).

In a disaster, NDMS is activated when state resources are overwhelmed, and the governor makes a request for federal assistance. The DMATs and other teams must meet specific NDMS standards. Throughout the NDMS, emergency clinicians are taking key roles in defining training standards, the deployment of clinical services, the administration of field operations, and in developing the concept of a civilian-federal disaster response capacity during national emergencies. DoD manages patient transfers and provides patient transport from an impacted area to a designated definitive care site. The VA and DoD's Federal Coordinating Centers (FCCs) manage the provision of definitive care by directing patients requiring treatment to health care facilities that have memoranda of understanding with NDMS. Teams of medical, logistic, and administrative staff have been deployed by NDMS continuously since the beginning of the COVID-19 pandemic to assist with critical staffing needs.

Centers for Disease Control and Prevention

The Centers for Disease Control and Prevention (CDC), based in Atlanta, is a United States federal agency under HHS. Its major responsibilities include preparing for and responding to public health emergencies (e.g., disasters) and conducting investigations into the health effects and medical consequences of these events. The major aims of CDC researchers are to assess the risks of death and injury and to develop strategies to prevent or to mitigate the impact of future disasters. Other responsibilities of CDC staff in the area of emergency preparedness and response include: (1) rapid assessment of the health and medical needs of disaster victims in the immediate post-disaster period; (2) development and maintenance of national systems for acute environmental hazard surveillance; and (3) provision of epidemiologic, sanitary, laboratory, and other relevant scientific support services to agencies involved in disaster planning and response. CDC played a major role in helping United States public health officials prepare for identification and management of individuals potentially exposed to Zika virus, including pregnant patients, during the 2016 outbreak and the COVID-19 pandemic in 2020.

Department of Veterans Affairs

The Department of Veterans Affairs has not traditionally been regarded as a disaster response entity. However, one of the VA's four legally mandated missions is emergency management. A unique feature of the VA is that its facilities and personnel are situated nationwide, and these are used to support federal health and medical assistance to state and local governments during disasters. In addition to the vast pool of human resources, the VA provides large amounts of the pharmaceuticals and expendable supplies for on-site disaster support. The VA's assistance is coordinated through DHS and HHS, as the lead federal agency for health and medical response. In addition to the VA's role in the federal disaster response and as the largest integrated health care system in the nation, it has a well-developed hospital emergency management program. Professional emergency managers are located at VA medical centers throughout the country. They also manage the majority of NDMS FCCs. In conjunction with other federal agencies, the VA has developed a number of emergency management planning and operations tools. Many of these are open source and available to the public.[28]

Department of Defense

Although the primary mission of the armed forces is defense of the homeland from foreign threats, the DoD has formed the Northern Command, or NorthCom, to assume responsibility over all military forces that operate within the United States in response to external threats and in support of civil authorities. The stated purpose of NorthCom is to assist the DoD to better manage natural disasters, attacks on American soil, or other civil difficulties. It provides for a more coordinated military support to civil authorities, such as the Federal Bureau of Investigation (FBI), FEMA, and state and local governments. Another important asset at the state level is the National Guard. Each governor has authority to activate the National Guard for its disaster response and recovery missions. National Guard assets also include WMD civil support teams (CSTs). CSTs provide significant capabilities to advise civilian authorities and assist local and state agencies that may be overwhelmed by a large-scale terrorist attack or where specific technical capabilities to identify WMD materials are required. CSTs are federally funded National Guard units established under Presidential Decision Directive 39.

FUTURE DIRECTIONS

The field of disaster medicine has become a major subspecialty within emergency medicine. Standing committees, membership sections, and formal fellowship recognition for the specialty now exist within the ACEP and the Society for Academic Emergency Medicine. There are also numerous national and international forums for the presentation of disaster medical research. Disaster medicine fellowships and advanced degree programs established in the United States and elsewhere continue to attract applicants.[29] Standardized disaster core competencies and associated curricula are now available for residency programs within the United States and endorsed by such organizations as the Council of Emergency Medicine Residency Directors.[3] The quality of disaster medicine textbooks and journals is improving.

In the 21st century, disaster medicine will continue to develop as a professional activity and unique academic specialty. The evolving forces of climate change, increasing population density in disaster-prone regions (as was demonstrated during the COVID-19 pandemic), and terrorism will only enhance demand for this expertise. Encouraging and supporting disaster medicine research activity will become crucial to identifying solutions and interventions to resolve these challenges. Providing regulations that facilitate research activity by deployed medical teams would substantially improve such efforts. Finding sustainable funding sources to support and enhance disaster medicine preparedness and response activities remains one of the most significant challenges.

CHAPTER E14: QUESTIONS AND ANSWERS

1. How can one characterize application of the Secondary Assessment of Victim Endpoint (SAVE) triage guidelines?
   - **a.** Triage decisions are based on patient outcome expectations.
   - **b.** It is applicable to day-to-day hospital operations.
   - **c.** Patients are sorted immediately after the incident.
   - **d.** The guidelines provide detailed management of psychogenic cases.

Answer: A. The SAVE system is designed specifically for care in an austere environment. It triages patients into (1) those who will die regardless of treatment, (2) those who will live regardless of treatment, and (3) those who would benefit from austere intervention. The triage decisions are based on field outcome expectations from existing survival and morbidity statistics.

2. Which of the following best describes the National Disaster Medical System (NDMS)?
   - **a.** It does not include private sector institutions.
   - **b.** It does not involve the Department of Veterans Affairs (VA).
   - **c.** The medical response element consists of Department of Defense (DoD) personnel.
   - **d.** The Department of Health and Human Services (HHS) has oversight.

Answer: D. The NDMS is a federally coordinated initiative that is a cooperative program between the DoD, VA, DHHS, and Department of Homeland Security (DHS) with oversight provided by DHHS. The NDMS provides a system of coordinated mutual aid agreements among federal, state, local, and private institutional entities for resource and personnel provision in times of disaster. The medical response element includes dozens of volunteer civilian medical teams that supplement the local medical infrastructure.

3. What is accurate advice that one would give to those planning a disaster response?
   - **a.** Critical incident stress debriefing is best conducted 1 or 2 weeks after the event.
   - **b.** Medical resupply systems are the most vulnerable component of a disaster plan.
   - **c.** One of the Department of Veterans Affairs (VA) system's four legally mandated missions is emergency management.
   - **d.** The Federal Emergency Management Agency (FEMA) has a coordinating responsibility for the entire spectrum of disasters.

Answer: C. One of the VA health system's four mandated missions is emergency management. Although controversy exists, critical incident stress debriefing, if used, should be implemented as early as possible. The Department of Homeland Security (DHS) has full-spectrum disaster coordinating responsibility. Communications systems are likely the most vulnerable systems.

4. Which of the following statements is *not* a feature of comprehensive emergency management?
   - **a.** An incident management system consistent with NIMS should be implemented.
   - **b.** Health care facilities should perform a hazard vulnerability analysis to assess community risks.
   - **c.** Most incident management systems are characterized by five functional elements: incident command, operations, logistics, planning, and finance.
   - **d.** The four phases of comprehensive emergency management (CEM) are pre-event, event, post-event, and recovery.

Answer: D. The four phases of CEM are mitigation, preparedness, response, and recovery. These phases represent a continuum over time, and more than one phase may be in effect at the same time (e.g., even during the response phases, recovery actions may take place.)

5. After an earthquake, what resource would be expected to provide the most rapid and effective search and rescue activity finding the most victims who would most likely survive?
   - **a.** Urban search and rescue teams
   - **b.** Private citizens
   - **c.** Disaster medical assistance teams
   - **d.** National Guard Civil Support Teams

Answer: B. Uninjured survivors perform the most rapid and effective search and rescue activity after an earthquake. These private citizens will recover most victims who ultimately survive. Although formal urban search and rescue teams will eventually arrive, they do not find many victims and it is unknown how many survive. National Guard Civilian Support Teams and disaster medical assistance teams do not perform search and rescue activities.

Weapons of Mass Destruction

Kristi L. Koenig and Romeo Fairley

KEY CONCEPTS

- Emergency department (ED) preparedness for a radiation incident should address decontamination (an external freestanding decontamination unit is best), triage, staff safety, personal protective equipment (PPE), and diagnostic procedures that emphasize radiation monitoring. It is important that emergency personnel know their radiation safety officer.
- External decontamination of radioactive particles can be achieved by removing clothing and washing the skin with soap and water.
- Management of acute, life-threatening conditions (such as major traumatic injuries) takes priority over radiation-associated issues.
- Aerosol dispersal is a likely route that terrorists may use to deploy biologic weapons, so victims will present primarily with respiratory complaints.
- In addition to influenza-like illness (ILI) symptoms, anthrax typically causes mediastinal widening, pulmonary consolidation, and pleural effusions best seen on chest computed tomography (CT) scans.
- Smallpox can spread in a hospital environment; thus, patients thought to have smallpox should be admitted to locations isolated from the rest of the hospital.
- Decontamination is a key activity in the management of patients exposed to chemical agents and frequently first occurs on emergency department arrival.
- Nerve agents are organophosphates; patients exposed to these agents are treated with large doses of atropine (repeated frequently), pralidoxime, and benzodiazepines.
- Patients with blast injuries can have subtle and delayed presentations of life-threatening conditions.

FOUNDATIONS

Besides managing the injuries and illnesses from common disasters such as earthquakes and airplane crashes, emergency clinicians should also have competence in treating victims generated by terrorist attacks with chemical, nuclear, biologic, or high-energy explosive weapons. Conventional explosives remain the most common weapon used by terrorists; however, the risk from nuclear, biologic, and chemical agents may increase over time. The nomenclature for these weapons is not standardized. The military uses the acronym CBRNE, pronounced "see-burn-ee," referring to *c*hemical, *b*iologic, *r*adiologic, *n*uclear, and *e*xplosive agents. This chapter uses weapons of mass destruction (WMD) because of its wide acceptance and familiarity.

The results of an attack with WMD, although admittedly of low probability, are potentially catastrophic. According to a World Health Organization (WHO) estimate, 50 kg of anthrax spores aerosolized above a city of five million people would result in 100,000 deaths, with an additional 150,000 people seriously infected. The cost of managing 100,000 cases of anthrax exposure is estimated at between $6.4 and $26.2 billion. These types of estimates have led to authorities establishing emergency preparedness as a priority.

Children are particularly vulnerable to these weapons.[1] They are closer to the ground based on height and breathe at a faster rate than adults, increasing their relative exposure to aerosolized agents.[2] Some chemicals, such as sarin, are heavier than air, so they tend to accumulate at the level where children are more likely to inhale them. Children have a greater surface area–to–volume ratio and their skin is thinner. This makes them more susceptible to agents that act on or through the skin. They have smaller fluid reserves and higher metabolic rates. Therefore, they are more vulnerable to dehydration from vomiting and diarrhea and suffer increased toxicity from a given exposure, such as to radioactive iodine (^{131}I).

The use of biologic and chemical agents as weapons dates to biblical times, although the threat from radiation and nuclear detonation is relatively new. Assyrians poisoned the wells of their enemies with rye ergot in the 6th century BC. During World War I, the Germans effectively used chlorine and mustard agent against the advancing Allied armies. The Japanese killed hundreds to thousands of Chinese citizens with bubonic plague during World War II by spraying towns with fleas infected with *Yersinia pestis*. In 2013, the Syrian government attacked cities within its own country using chemical nerve agents, resulting in an estimated 1300 deaths and 3600 injuries. United States government reports indicate that the Syrian government again used chlorine gas in May 2019.

WMD have been predominantly deployed by the military during times of conflict. Toward the end of the twentieth century, however, nonaffiliated terrorist groups began using WMD directed at civilians to achieve political ends. The Aum Shinrikyo used sarin gas in the 1995 Tokyo subway attack that killed 11 people.[3] Terrorists initiated an anthrax attack using the United States mail in 2001 that resulted in 11 deaths.[4] In 2018 and 2020, the fourth-generation nerve agent Novichok was reportedly used during a presumed assassination attempt, leading to four hospitalizations.[5] As of early 2020, no one has used radiologic or nuclear devices in a successful mass terrorist attack; however, several highly radioactive sources have been stolen from American medical facilities, and a Russian dissident, Alexander Litvinenko, was assassinated with a radiologic agent (^{210}Po) in 2006 while living in London.

Many agents are potential candidates for weaponization, and some represent a substantial risk (Box e15.1). Management strategies for patients exposed to WMD are frequently similar to strategies for hazardous materials exposure. However, several features associated with WMD make these events unique (Box e15.2). Additional knowledge and skills are required in the evaluation and treatment of WMD victims. These plans represent only one small part of an overall comprehensive emergency management strategy for all hazards (see Chapter e14). Names of departments, bureaus, and agencies that can assist with planning and response to WMD events are listed in Table e15.1.

BOX E15.1 Potential Agents of High Concern for Use as Weapons of Mass Destruction

Chemical

Nerve agents
- Sarin
- Soman
- Tabun
- VX

Mustard agent
Novichok agent

Biologic

Anthrax
Plague
Smallpox
Botulism
Viral hemorrhagic fever
Tularemia

Radiologic

Simple device
Dispersal device

BOX E15.2 Features of Weapons of Mass Destruction Threat

Fear of unknown or unfamiliar
Lack of training for hospital personnel
Lack of equipment, including personal protective equipment (PPE) and diagnostic aids
Potential for mass casualties
Psychological casualties
Crime scene requiring evidence collection and interaction with law enforcement
Potential for ongoing morbidity and mortality (dynamic situation)

SPECIFIC DISORDERS

Nuclear and Radiologic Devices

Foundations

Terrorists selecting radiation as a means to inflict casualties are unlikely to use nuclear weapons. These devices are heavily guarded, difficult to move because of their size and weight, and easy to detect. Although Russia acknowledges that 50 to 100 of its one-kiloton "suitcase" nuclear weapons are missing, the challenges associated with purchasing, moving, and detonating these devices are formidable. Sabotage at nuclear power stations is possible, but given tight security, multiple safety systems, and thick concrete housings surrounding the reactors, the threat is relatively low.

Simple radiologic devices, such as those used by hospitals for radiation therapy or commercial companies for industrial radiography, are more readily accessible. These sources are plentiful and often found in small, easily concealed containers. They do not detonate on their own and give no warning of their presence unless they are dispersed by a conventional explosive (radiologic dispersal device). Thefts of radiotherapy sources have occurred in the United States. Accidental dispersion from a stolen hospital therapy source in Brazil resulted in the screening of 112,000 people for contamination. A total of 249 people were found to be exposed—four of whom ultimately died. Placement of such a device at an information kiosk in a crowded mall during a busy holiday shopping season would silently expose countless persons to significant radiation.

Clinical Features

Ionizing radiation, regardless of its type, causes injury at the cellular level, usually by damaging DNA. Rapidly dividing cells are the most sensitive. Patients have symptoms within hours to days, depending on the dose. Common syndromes associated with radiation exposure include cutaneous (burns), hematologic (bone marrow failure), gastrointestinal (e.g., vomiting and gastrointestinal bleeding), and at extreme doses, neurologic (seizure, coma, death). Reviews of medical treatment for radiologic casualties can be found elsewhere (Chapter 134).

Management

A basic emergency department (ED) radiation protocol should address decontamination, triage, staff safety, personal protective equipment (PPE), and diagnostic procedures that emphasize radiation monitoring. Victims presenting to the ED will suffer from three types of exposure: irradiation, internal contamination, and external contamination. Irradiated victims have been exposed to a beam of radiation, similar to someone undergoing a chest x-ray examination. They are not radioactive and pose no threat to ED personnel.

Contaminated patients are more challenging, and early involvement of the radiation safety officer is critical. This individual evaluates the degree of the victim's contamination and monitors radioactivity levels throughout the decontamination process. Internally contaminated patients present a therapeutic challenge because they have radioactive material inside their bodies (e.g., lungs and gastrointestinal tract) or

incorporated into their cells. They should be placed in an isolation room where all secretions and body fluids can be collected. Various medications are available for administration to internally contaminated patients that can limit uptake or facilitate removal of certain radioactive elements. These medications include Prussian blue (Radiogardase) for cesium and thallium ingestions, diethylenetriaminepentaacetic acid (DTPA) for plutonium exposure, and potassium iodide for ^{131}I exposure for patients under 40 years of age within a few hours of exposure. Radiation Emergency Assistance Center/Training Site (REAC/TS; http://orise.orau.gov/reacts/) is always available at 865-576-3131 (emergency number: 865-576-1005) to provide assistance to health care providers.

Externally contaminated victims have radioactive material on their skin or clothing and are decontaminated by removal of clothing and washing with soap and water. Medical stabilization and lifesaving interventions take precedence over decontamination. Washing by protected personnel should continue until monitoring shows a level no more than double the background rate or when no further decrease is happening after multiple decontamination attempts. If wounds are present, they are decontaminated first, along with mucous membranes. It is imperative to remove foreign bodies. After the wounds are covered with a sterile, waterproof dressing, the remaining skin is washed. Hospitals should be prepared to decontaminate patients because historical data suggest that up to 80% of patients do not receive this intervention before arrival. Decontamination before hospital entry is crucial because these individuals can expose caregivers to radiation and contaminate the entire hospital through the ventilation system. Removal of clothing and covering of the head with a surgical cap can reduce contamination by 80% to permit stabilization in the decontamination unit, but complete decontamination should occur before exposure of unprotected staff if the patient's medical condition permits.

Initial triage of radiation casualties is based on their overall condition, not on exposure.[6] Even patients who have received a lethal dose of radiation do not die immediately as a consequence of the ionizing exposure. Therefore, a patient in acute distress from a myocardial infarction, sepsis, or a combined radiation-blast injury would be triaged ahead of a radiation victim with stable vital signs, regardless of the dose received. If a radiation casualty also suffers a severe injury or illness, immediate intervention is required. Most of the immediate morbidity and mortality associated with a radiologic dispersion device is related to traumatic injuries from the explosion and not the radiation exposure.

In addition to contaminated patients, the radiation safety officer is responsible for monitoring exposure to hospital staff. All personnel involved in the care of contaminated patients should wear dosimeters, which measure the amount of radiation received by the wearer. The safety officer tracks the amount of radiation received by each staff member and can remove a health care worker from the area if exposure exceeds Occupational Safety and Health Administration (OSHA) guidelines. Radiation monitoring is complex, and the radiation safety officer should be involved as early as possible. Hospitals should consider conducting disaster drills that include casualties suffering radiation injuries.

Although many radioactive elements are candidates for use in a terrorist attack, iodine-131 (^{131}I) and related isotopes deserve additional discussion because of heightened interest and ease of ^{131}I effective therapy. ^{131}I is found after a nuclear detonation or in reactor fuel rods. Although it is not impossible, the probability that terrorists could tap either of these sources is small. The use of ^{131}I in a radiologic dispersal device is unlikely because of its short half-life (eight days). The large number of childhood thyroid cancers that occurred after the accident at the Chernobyl nuclear power plant resulted, to a significant degree, from situations that will be unlikely to occur in the United States. These include delayed reporting of a breach in the reactor containment vessel preventing timely evacuation of all exposed populations; failure to effectively prevent ingestion of contaminated milk and vegetables; and presence of significant iodine deficiency in the exposed population.

The risk to children in communities surrounding the Fukushima nuclear power plant is an issue that will require long-term monitoring, though it is believed that exposures were not high enough to increase the incidence of long-term effects (cancer) beyond the background rate. Nonetheless, treatment of children aimed at preventing thyroid cancer after potential exposure to ^{131}I should be performed (Table e15.2). Caveats for use of this table include increasing the amount of potassium iodide (KI) for adolescents approaching 70 kg to the adult dose (130 mg) and monitoring thyroid-stimulating hormone and free thyroxine (T_4) levels in neonates. Nonpregnant adults older than 40 years of age are unlikely to benefit from this intervention; therefore, current recommendations are to withhold KI unless doses over 5 Gy are received.

Biologic Weapons

Foundations

By convention, biologic weapons are divided into three groups: bacteria, viruses, and toxins. A characteristic shared by these agents is their ability to be dispersed as an aerosol. Because this is the most effective means to expose a large population, aerosol dispersal is the route that terrorists would most likely use to deploy such weapons. Victims, unaware of the exposure to a biologic weapon, commonly present to the ED with nonspecific influenza-like illness (ILI). Dermal contact and ingestion are also potential pathways for exposure, and some agents are harmful via these routes. People infected in the 2001 United States anthrax attacks were inoculated through aerosol and dermal exposures. It is logistically more difficult to produce large casualty numbers by nonrespiratory portals of entry, so agents spread primarily by injection or through the gastrointestinal tract are less likely candidates for wide deployment. If the goal is to disrupt the economy or to spread fear among the population, then almost any type of release will suffice, whether or not mortality occurs.

TABLE E15.2 Treatment with Potassium Iodide for Radioactive Iodine Exposure

Subpopulation	Predicted Exposure (cGy)	Potassium Iodide Dose (mg)	Number of 130-mg Tablets
Adults >40 years old	>500	130	1
Adults 18 to 40 years old	≥10	130	1
Pregnant and lactating women	≥5	130	1
Children 3 to 18 years old	≥5	65	½
Children 1 month to 3 years old	≥5	32	¼
Neonates, birth to 1 month old	≥5	16	⅛

BOX E15.3 Signs Suggesting Biologic Weapon Deployment

Syndromes
Pulmonary symptoms, pneumonia
Rashes
Sepsis syndrome
ILI symptoms

Epidemiology
Multiple, simultaneous events
Dead animals
Large numbers of patients with high toxicity and death rate

BOX E15.4 Recommendations for Prevention of In-Hospital Transmission of Contagious Agents

Isolate patient in single room with adjoining anteroom.
Have handwashing facilities and personal protective equipment (PPE) available in anteroom.
Use negative air pressure if possible.
Use strict barrier precautions: PPE, gowns, gloves, high-efficiency particulate air (HEPA) filter respirators, shoe covers, protective eyewear, N95 masks, or powered air purifying respirator (PAPR).
Alert hospital departments that generate aerosols: Laboratory (centrifuges), pathology (autopsies).
For some agents (i.e., Ebola) all skin surfaces must be covered by PPE.

Clinical Features

Patients exposed to biologic agents usually present with vague symptoms associated with an ILI.[7] Unless a biologic attack is announced or suspected, the ED staff may not realize that they are treating victims. It is not always possible to distinguish natural occurrences from engineered outbreaks of diseases. Examples of non-terrorist-related occurrences of anthrax include cutaneous disease in intravenous heroin users in Europe, an outbreak of cutaneous anthrax in Bangladesh in 2010 with more than 400 cases, and isolated infections in drum makers after using contaminated animal hides. Because of the challenges in identifying the true etiology of acute events, personnel should consider the possibility, especially when warning signs are present (Box e15.3). For example, large numbers of patients suddenly presenting with "the flu" outside of the influenza season should cause concern. For these reasons, health surveillance is paramount in identifying agents and potential sources. National monitoring programs such as BioWatch (proposed to be replaced by BioDetection 21 by 2025) monitor the ambient air for infectious agents. ED leadership should have a working relationship with local and state health departments as well as with local law enforcement and stay apprised of Centers for Disease Control and Prevention (CDC) and Department of Homeland Security guidelines.

Management

Several infectious agents with potential for use as biologic weapons can spread in a hospital environment. Examples include Ebola and smallpox. Hospitals need protocols for PPE and patient isolation to ensure a safe environment. Such protocols are similar to those applied to other infectious diseases (Box e15.4) in non-terrorist events (e.g., the 2014 Ebola outbreak). Implementation of such precautions is credited with halting the in-hospital spread of the Ebola virus in the 1995 Zaire outbreak. Decontamination is not a priority unless the exposure is acute. Standard precautions are usually sufficient, and special suits (e.g., levels A and B) are generally unnecessary, though Ebola precautions require covering all cutaneous surfaces.[8] Table e15.3 shows the recommended isolation precautions for each infectious agent.

TABLE E15.3 Recommended Isolation Precautions for Biologic Agents

Infectious Agent	Recommended Isolation Precautions
Anthrax	Cutaneous infection: contact precautions Pulmonary infection: standard precautions Gastrointestinal infection: standard precautions
Botulism	Standard precautions
Plague	Standard and droplet precautions*
Smallpox	Standard, contact, and airborne precautions
Tularemia	Standard precautions
Viral hemorrhagic fevers	Standard, contact, and airborne precautions

* Some experts recommend airborne precautions due to potential for aersolization.

Whereas the CDC lists six Category A (high threat) agents (anthrax *[Bacillus anthracis],* botulism [*Clostridium botulinum* toxin], plague *[Yersinia pestis],* smallpox [variola major], tularemia *[Francisella tularensis],* and viral hemorrhagic fevers [filoviruses (e.g., Ebola, Marburg)] and arenaviruses [e.g., Lassa, Machupo]), this chapter focuses on three biologic agents—anthrax, plague, and smallpox—that represent the greatest interest.[7]

Anthrax

Foundations. *Bacillus anthracis,* a gram-positive, spore-forming bacterium, is the causative agent of anthrax ("woolsorter's disease"). The spores are extremely hardy and can survive for years in the environment. The disease is caused by exposure to the spores, not the bacilli, in their vegetative state. It is normally a disease of sheep, cattle, and horses and is rarely seen in developed countries because of animal and human vaccination programs. Disease in humans can occur when spores are inhaled, ingested, or inoculated into the skin. The spores germinate into bacilli inside macrophages. The bacteria then produce disease by releasing toxins (e.g., protective antigen, edema factor, and lethal factor) that cause edema and cell death.

Russia and the United States have developed anthrax into a biologic weapon. The effectiveness of this agent was clearly demonstrated by two events: an accidental release of spores from a biologic weapons facility in the former Soviet Union town of Sverdlovsk in 1979 and the intentional distribution of anthrax spores through the mail along the eastern seaboard of the United States in 2001.[4] After the Sverdlovsk release, at least 66 adults died downwind from the compound during the next several weeks, and animal cases of anthrax were reported 30 miles away. The ability of non-state-sponsored terrorist groups to develop anthrax as a weapon is uncertain. The Japanese organization Aum Shinrikyo made several unsuccessful attempts to disperse anthrax throughout Tokyo. The individual believed responsible for the United States anthrax attack was not a foreign national. This is consistent with the fact that the strain of anthrax used in the attack (Ames strain) was developed by the United States government.

Inhalational anthrax is the most lethal form of the disease and is caused by inhalation of spores into the lungs. The mortality rate was thought to exceed 90%. However, data from the 2001 anthrax exposure call this figure into question (5 deaths in 11 cases). Although the actual mortality rate is unknown, and would depend on availability of intensive care resources, it is probably in the 50% range. The minimum

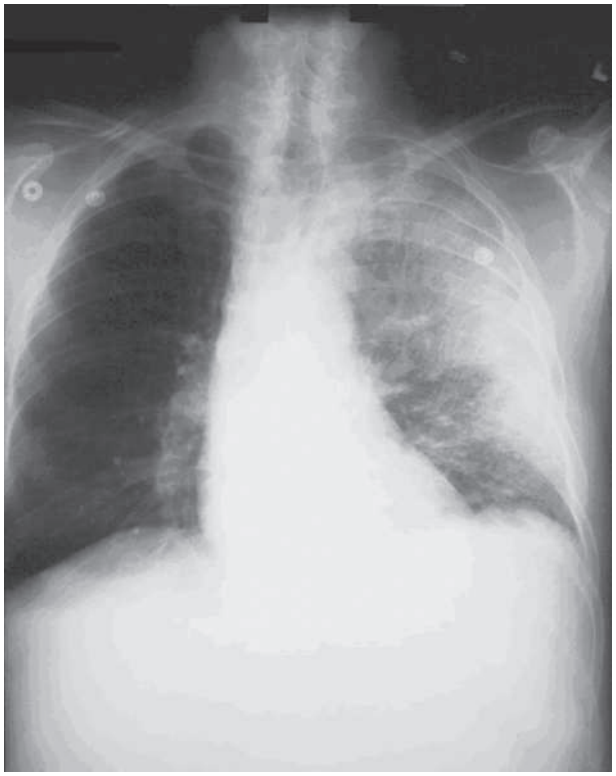

Fig. e15.1 Chest radiograph of anthrax patient showing diffuse left lung consolidation consistent with pneumonia. There is no mediastinal widening. (Courtesy Centers for Disease Control and Prevention.)

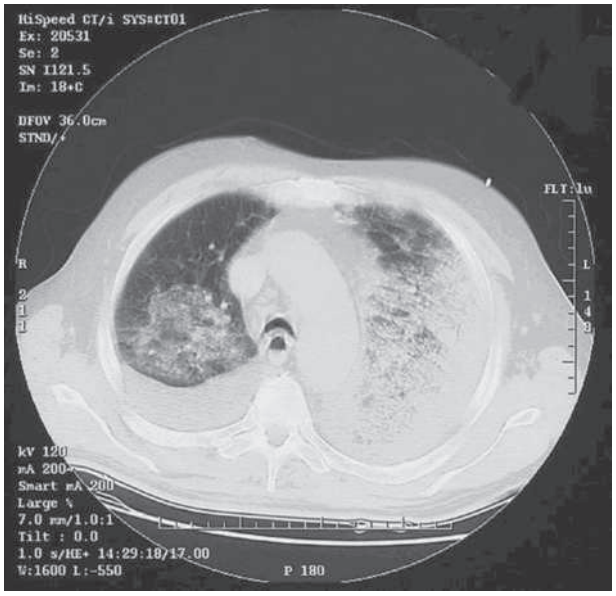

Fig. e15.2 Chest computed tomography (CT) scan of an anthrax patient showing pulmonary consolidation and effusions. (Courtesy Centers for Disease Control and Prevention.)

Fig. e15.3 Adult with cutaneous anthrax. (Courtesy Centers for Disease Control and Prevention.)

number of spores required to produce disease is unknown. The original number quoted in the literature—1000 spores—appears high given the experience following the 2001 anthrax event.

Clinical Features. After phagocytosis by macrophages, the spores germinate and are transported to the tracheobronchial lymph nodes, where the bacteria multiply. During the next 2 to 10 days, patients have an ILI with malaise, fever, and nonproductive cough. This initial phase can be delayed for more than one month. Within 24 to 48 hours of the initiation of symptoms, abrupt deterioration occurs with overwhelming sepsis, shock, hemorrhagic mediastinitis, dyspnea, and stridor. A chest radiograph obtained at this time may show a widened mediastinum and hilar adenopathy, but typical radiographic findings are not dramatic and are easy to miss (Fig. e15.1). Computed tomography (CT) scanning of the chest is more sensitive and should be performed if the disease is suspected. Bloody pleural effusions can also occur, and examination of the lung fields frequently reveals consolidation. This can easily be confused with severe community acquired pneumonia (Fig. e15.2). Death usually results within three days, and 50% of patients have hemorrhagic meningitis. Human-to-human transmission has not been reported with inhalational anthrax.

Initial diagnosis is generally made clinically on the basis of an influenza-like or septic illness; a suspicious chest radiograph or CT scan demonstrating hilar adenopathy, infiltrates, or pleural effusions; and a reason to consider anthrax in the first place (e.g., current outbreak or warning from authorities). Several clinical algorithms exist that attempt to separate patients with influenza from those with anthrax. Because these are based on a handful of anthrax cases, their usefulness is uncertain. Sputum culture, Gram stain, and blood cultures are not helpful until late in the course of the disease. Tests to confirm the diagnosis of inhalational anthrax include the polymerase chain reaction (PCR) for identification of anthrax markers in pleural fluid, serologic detection of immunoglobulin to protective antigen, and immunohistochemical testing of biopsy specimens. Recombinase polymerase amplification (RPA) assays for rapid identification of *B. anthracis* in a field setting have proven both sensitive and specific.[9]

In addition to inhalational anthrax, cutaneous anthrax can occur in any area where large numbers of spores are released. This form of the disease occurs when spores are introduced into the skin, usually through open wounds or abrasions. The mortality rate is approximately 20% without treatment but decreases to 1% with treatment. After an incubation period of one to five days, a papule develops, progressing to form a large vesicle during the next several days. Severe edema occurs around the lesion and is associated with regional lymphadenitis. The lesions are not tender, and the patient may or may not be febrile (Fig. e15.3). After approximately one week, the lesion ruptures, forming a black eschar (thus the name *anthrax,* from the Greek word for "coal"). In the next two or three weeks, either the eschar sloughs off and the illness resolves or the organism disseminates and the patient dies.

Antibiotics do not halt the progression of local disease; they prevent dissemination and death. As with inhalational anthrax, the diagnosis is predominantly clinical. Confirmation is established by culture of the lesion, punch biopsy, or serologic testing. A total of 11 cutaneous anthrax cases occurred in the United States after the 2001 attack.

Cases of gastrointestinal anthrax and oropharyngeal anthrax are also possible after a terrorist attack. These rare manifestations usually occur with the ingestion of insufficiently cooked, contaminated meat. The mortality rate is approximately 50%. After ingestion, the spores are transported to regional lymphatic tissue, where symptoms develop after a two-to-five-day incubation period. Patients with oropharyngeal anthrax present with sore throat and neck swelling from cervical and submandibular lymphadenitis. The tonsils are also frequently involved, and symptoms are associated with fever and toxicity. Dysphagia and respiratory distress often follow. Gastrointestinal anthrax begins with nausea, vomiting, and fever associated with mesenteric lymphadenitis. Patients then experience severe abdominal pain, hematemesis, ascites, and bloody diarrhea, and may present with an acute abdomen.

Management. Traditional treatment of anthrax infection has been with penicillin. However, weapons-grade anthrax is probably resistant to penicillin (although this was not the case with the 2001 United States attack). Current treatment recommendations reflect this fact (Box e15.5). These consensus recommendations include fluoroquinolones and tetracycline for all children, regardless of age. Balancing the potential risks of such drugs against the consequences of infection by drug-resistant anthrax strains, the benefits justify the recommendations. Chest tube drainage of pleural effusions improved mortality in the United States anthrax attack, though numbers were limited. CDC recommendations also include antitoxin therapy, although a 2017 meta-analysis did not show improved mortality.[10] Supportive therapy with vasopressor medications, and possibly tracheal intubation with mechanical ventilation, may be necessary.

Treatment is continued for 60 days, or until the patient has received three doses of the anthrax vaccine, given on days 0, 14, and 28. The complete vaccine course requires 18 months. This treatment regimen is also recommended for children and pregnant women. If the anthrax strain proves susceptible, patients can be switched to intravenous penicillin or oral amoxicillin. In vitro studies suggest that ofloxacin or levofloxacin can be substituted for ciprofloxacin.

For postexposure prophylaxis, oral ciprofloxacin (500 mg) or doxycycline (100 mg) twice a day (better tolerated) is recommended. Amoxicillin can be substituted if sensitive strains are identified. Antibiotic prophylaxis is to continue for 60 days or until patients have received at least three doses of the vaccine. The vaccine is approved by the US Food and Drug Administration (FDA) for adults, but not for children. However, it could become available for use in the pediatric population under the Investigational New Drug process if needed. A review by the National Academy of Medicine (formerly the Institute of Medicine [IOM]) found the vaccine both safe and effective for prophylaxis against inhalational anthrax in adults. The 2015 CDC guideline, "Clinical Framework and Medical Countermeasure Use During an Anthrax Mass-Casualty Incident," provides useful information for scarce resource allocation decisions.[11]

Plague

Fundamentals. Plague has been a human pathogen since antiquity. Many regions of the world, including Asia and India, are witnessing the third pandemic of plague, and this affliction is endemic in the western half of the United States. Plague is caused by *Yersinia pestis,* a gram-negative bacillus. It is normally a disease of rodents that is transmitted to humans through the bite of an infected flea or by inhalation. Three forms of the disease exist: pneumonic, bubonic, and septicemic plague.

BOX E15.5 Treatment of Anthrax

Cutaneous Anthrax Without Toxicity

Adults

Ciprofloxacin, 500 mg PO bid; *or* doxycycline, 100 mg PO bid; *or* amoxicillin, 500 mg PO tid.

Children

Ciprofloxacin, 20 to 30 mg/kg/day PO divided bid (maximum 1 g); *or* doxycycline, 4.4 mg/kg/day PO divided bid (maximum 200 mg); *or* amoxicillin, 20 to 40 mg/kg/day PO divided tid (maximum 1500 mg).

All doses are given for 7 to 10 days.

Inhalational, Cutaneous, or Gastrointestinal Anthrax with Toxicity

For adults and children, consider the antibody-based therapies raxibacumab and anthrax immune globulin in addition to IV antibiotics.

Adults

Ciprofloxacin, 400 mg IV every 12 hours; *or* doxycycline, 100 mg IV every 12 hours; *or* penicillin G, 4 million units IV every 4 hours.

For patients without meningitis, add a second drug that inhibits protein synthesis, such as linezolid or clindamycin. For patients with meningitis, add a third drug to this regimen that penetrates the CNS, such as meropenem.

Children

Ciprofloxacin, 20 mg/kg/day IV divided every 12 hours (maximum 800 mg); *or* doxycycline, 4.4 mg/kg/day IV divided every 12 hours (maximum 200 mg); *or* penicillin G, 250,000 to 400,000 units/kg/day IV divided every 4 hours (maximum 24 million units).

For patients without meningitis, add second drug that inhibits protein synthesis, such as linezolid or clindamycin. For patients with meningitis, add a third drug to this regimen that penetrates the CNS, such as meropenem.

All doses are given until toxicity resolves, then switch to oral form. Treat for 60 days or until the patient receives three doses of vaccine.

Postexposure Prophylaxis

The same drugs and dosage are prescribed as for cutaneous anthrax without toxicity. Treat for 60 days or until the patient receives three doses of vaccine.

CNS, Central nervous system; *IV,* intravenous; *PO, per os* (by mouth).

The bacteria do not form spores and die rapidly in the environment. However, they are viable for days in dry sputum, flea feces, and human remains. Dogs are relatively resistant to infection, but cats are highly susceptible and can form a reservoir for maintaining the disease in a human population. Recovery is followed by temporary immunity.

Clinical Features. Primary pneumonic plague results when bacilli are inhaled into the lungs. The mortality rate approaches 100% if it is not treated early. Pneumonic plague will be the most frequently encountered form of the disease because terrorists are likely to use aerosolization as the method of dispersal. After an incubation period of 24 to 96 hours, victims have sudden onset of fever, chills, and an ILI. This is followed within 24 hours by a fulminant pneumonia associated with hemoptysis, systemic toxicity, respiratory failure, circulatory collapse, and death. The pneumonia is classically lobar, but any radiographic pattern is possible, including acute respiratory distress syndrome. Six to ten percent of victims have plague meningitis. Coagulation abnormalities and hepatocellular injury occur. The coagulopathy is characterized by ecchymoses, disseminated intravascular coagulation, and acral gangrene ("black death"). The gangrene is caused by bacterial production of the coagulase enzyme in areas of the body where the temperature drops below 98.6°F (37°C). This induces blood to clot in

Fig. e15.4 Child with bubonic plague demonstrating axillary bubo. (Courtesy Frederick M. Burkle, Jr., MD, MPH.)

fingers, toes, and the nose with resultant infarction and gangrene. If the victims survive, long-term rehabilitation is required. Pneumonic plague is transmissible human to human.

Bubonic plague occurs when organisms are inoculated into the skin, usually from a flea bite. During the two-to-three-day incubation period, the bacilli migrate to regional lymph nodes, where they multiply and cause inflammation and necrosis of lymphatic tissue, resulting in large, tender nodes, or buboes. Typically, buboes develop in the groin, axilla, or cervical region and are so painful that the patient will refrain from moving the affected area (Fig. e15.4). Individuals experience fever, chills, and weakness. In approximately 25% of patients, vesicles or ulcerations occur at the site of the flea bite. The buboes are usually nonfluctuant but can rarely suppurate. Organisms can be aspirated from the nodes for diagnosis, but incision and drainage are not recommended because the lymphadenitis resolves with antibiotic treatment, and practitioners could become infected if they are exposed during the procedure.

During the next week or more, the bacteria disseminate in approximately 50% of patients with bubonic plague. These victims have septicemic plague or secondary pneumonic plague and die if they are untreated. Those with septicemic plague experience endotoxemia, shock, disseminated intravascular coagulation, and coma. If bacteremia does not occur, most victims recover. A small percentage of those infected by fleas have septicemic plague without detectable buboes. Direct human-to-human transmission does not occur with bubonic or septicemic plague. However, both of these conditions can lead to secondary pneumonic plague, which is communicable. Therefore, isolation for the first 48 hours is recommended for all patients with plague.

Differential Diagnosis. The preliminary diagnosis of plague is clinical. Few diseases other than plague cause fulminant gram-negative pneumonia associated with hemoptysis in previously healthy individuals. Other diseases cause lymphadenopathy and the differential diagnosis for such conditions includes cat-scratch disease, tularemia, and staphylococcal or streptococcal infections. The presence of extremely tender lymphadenopathy and the toxicity of the patient is strongly suggestive of plague. Once the disease is suspected, Gram stain and culture of sputum, blood, cerebrospinal fluid, or lymph node aspirate are helpful. State health departments or CDC can test specimens for the presence of the capsular antigen by direct fluorescent antibody staining or polymerase chain reaction (PCR). Because all laboratory tests require several days to complete, initial management decisions are based on clinical findings.

Management. Antibiotic treatment is essentially identical for all three types of plague (Box e15.6). The same caveats for the use of fluoroquinolones and tetracycline in children with anthrax apply to plague. In the case of pneumonic and septicemic plague, treatment should be started within 24 hours of symptoms for outcome to be improved. Antibiotics are given for a minimum of 10 days. As patients improve, intravenous therapy can be transitioned to oral antibiotics to complete the course. Respiratory isolation of patients with pneumonic plague is necessary for 4 days after beginning antibiotics to guarantee sterilization of sputum. Patients with septicemic and bubonic plague require isolation for 48 hours. If they do not have pneumonia or draining lesions during this time, isolation can be discontinued. Nonseptic patients with mild bubonic plague can be treated at home with oral doxycycline or tetracycline for 10 days.

The mainstay of prophylaxis against plague remains oral antibiotics. Older vaccines were discontinued due to short-lived efficacy. Newer vaccines are in development but have not been approved for public use as of early 2022.[12] The drugs for prophylaxis are tetracycline, doxycycline, ciprofloxacin, chloramphenicol, and possibly trimethoprim-sulfamethoxazole for children.

BOX E15.6 Treatment of Plague

Parenteral Therapy

Adults

Streptomycin,[a] 1 g IM bid
Gentamicin, 5 mg/kg once daily IM or IV
Doxycycline, 100 mg IV bid
Ciprofloxacin, 400 mg IV bid
Chloramphenicol, 25 mg/kg IV qid

Children

Streptomycin,[a] 15 mg/kg IM bid (maximum 2 g/day)
Gentamicin, 2.5 mg/kg IM or IV tid
Doxycycline, 2.2 mg/kg IV bid (maximum 200 mg/day)
Ciprofloxacin, 15 mg/kg IV bid (maximum 800 mg/day)
Chloramphenicol, 25 mg/kg IV qid

Pregnant Women

Same as above but exclude streptomycin and chloramphenicol

Oral Therapy

Adults

Doxycycline, 100 mg bid
Ciprofloxacin, 500 mg bid
Chloramphenicol, 25 mg/kg qid

Children

Doxycycline, 2.2 mg/kg bid (maximum 200 mg/day)
Ciprofloxacin, 20 mg/kg bid (maximum 1 g/day)
Chloramphenicol, 25 mg/kg qid

Pregnant Women

Same as above but exclude chloramphenicol

[a]Although streptomycin is recommended as first-line treatment, it may not be readily available.
IM, Intramuscular; *IV,* intravenous.

Smallpox

Foundations. Smallpox was eradicated in 1980. The only known repositories of the variola virus, the etiologic agent of smallpox, are in the United States and Russia. Russia was successful in weaponizing the virus, which may have been sold or smuggled out of the country. The effectiveness of Russia's weaponized strain was demonstrated in 1971 when an individual became infected while traveling on a ship 15 km

downwind from a Soviet bioweapons test site (Vozrozhdeniye Island in the Aral Sea). In July 2014, several vials of smallpox were discovered in an unused storage room at the National Institutes of Health in Bethesda, MD, raising serious concerns about the security of the virus. It has also been shown that reconstituting DNA to create a lab-grown smallpox virus is possible.[13] Most of the United States' population is no longer fully immune to infection because vaccination against smallpox ceased in 1972 for nonmilitary personnel. Given its high infectivity and lethality, this makes smallpox an excellent biologic weapon.

The variola virus is spread as an aerosol. It can survive for 24 hours, and possibly 48 hours, in the environment. The occurrence of smallpox in hospital employees whose only exposure was handling of laundry from infected people is testimony to its viability. Approximately 30% of exposed people become ill. The R_0 of smallpox is 3.5 to 20—in other words, one infected person has the potential to infect up to 20 other individuals. People are infectious from the time the rash first appears until the scabs fall off (one or two weeks). Anyone exposed to smallpox should be closely monitored by public health authorities for 17 days to rule out infection.

Clinical Features. The disease manifests clinically in several forms. Variola major and variola minor represent 90% of the cases. Variola major is the classic form, a more severe illness with a mortality rate of 30%. Variola minor is a milder form, with less toxicity, fewer pox, and a mortality rate of 1%. Two other forms of the disease, hemorrhagic and malignant (or flat) smallpox, are seen in 10% of cases; the mortality rate is greater than 90%. Patients with hemorrhagic smallpox have symptoms earlier and become toxic quickly. Instead of pox, their rash is characterized by petechiae and hemorrhage. Death occurs in 5 to 6 days. Those with malignant smallpox have a similar course, but their rash is characterized by soft, flattened lesions that do not progress to pustules. If they survive, the lesions resolve without forming scabs.

The infection begins when the virus is inhaled. After migrating to regional lymph nodes, the virus replicates for 3 or 4 days and then asymptomatically spreads to the spleen, bone marrow, other lymphoid tissue, and liver. A second viremia occurs 8 to 12 days later and is associated with fever, prostration, and headache. Mental status changes can occur. During this phase, which lasts 2 or 3 days, the virus localizes to the skin and pharyngeal mucosa. A maculopapular rash soon appears, which becomes vesicular and finally pustular. In contrast to chickenpox, the rash first appears on the face and forearms, later spreading to the legs and trunk. All the lesions in any one area of the body are at the same stage (Fig. e15.5). During the next 8 to 14 days, the pustules crust over and separate from the skin, leaving pitted scars.

A clinical algorithm developed by CDC can assist in assessing the probability that an individual has smallpox (Table e15.4).[14] A patient with all three major criteria is at high risk and should be isolated and reported to public health authorities and law enforcement agencies (for criminal investigation) as soon as possible. If smallpox cannot be ruled out after evaluation, the patient should be treated as high risk.

Differential Diagnosis. As with anthrax and plague, the initial diagnosis of smallpox is clinical. Other illnesses resembling smallpox include chickenpox, herpes simplex, and monkeypox. Unlike with variola, the rash associated with chickenpox (varicella) is seen first on the trunk and then spreads to the extremities and face. In addition, the pustules are in different stages of evolution in any one area of the body. If the first case seen is hemorrhagic or malignant smallpox, the diagnosis will probably be missed until more typical cases present.

Diagnostic Testing. For confirmation of the diagnosis, vesicular fluid or scabs are sent for electron microscopic examination or tissue culture. Polymerase chain reaction techniques are also useful for rapid viral identification, with sensitivities and specificities in the 98% range.

Fig. e15.5 Man with smallpox. (From the Centers for Disease Control and Prevention Public Health Image Library.)

TABLE E15.4 Evaluating Patients for Smallpox: Acute, Generalized Vesicular or Pustular Rash Illness Protocol

3 Major Criteria	5 Minor Criteria
Febrile prodrome: Fever of ≥101°F, 1–4 days prior to rash onset with at least prostration, headache, backache, chills, vomiting or severe abdominal pain	Centrifugal distribution of lesions
Classic smallpox lesions: Deep-seated, firm/hard, round well-circumscribed vesicles or pustules; lesions may umbilicate or become confluent	First lesions on the oral mucosal palate, face, or forearms
Lesions in same stage of development: On any one part of the body all lesions in same stage of development	Patient appears toxic or moribund
	Slow evolution of lesions from macule, to papule, to vesicle (1–2 days each stage)
	Lesions on the palms and soles

Risk Level	Criteria
Low	No febrile prodrome OR has febrile prodrome AND < 4 MINOR criteria
Moderate	Febrile prodrome AND one other MAJOR smallpox criterion OR if the patient has a febrile prodrome AND ≥ 4 MINOR criteria
High	Febrile prodrome AND classic smallpox lesions AND lesions in the same stage of development

Management. No proven therapy exists for humans infected with smallpox who become symptomatic. However, antiviral agents such as tecovirimat and cidofovir show promise. Oral tecovirimat has been given FDA approval based on the Animal Efficacy Rule.[15] In mice exposed to a lethal cowpox challenge, administration of an oral lipid prodrug of cidofovir in modest doses once a day for 5 days produced 100% survival. Vaccinia immune globulin (VIG) has no role in the treatment of active disease. Some practitioners suggest that most smallpox patients should be isolated at home or other nonhospital facilities because the virus spreads easily in a hospital environment and the disease is currently untreatable.

The best strategy for containment of the disease is vaccination of the susceptible population. Vaccination of an immunocompetent

individual within 3 days of exposure will prevent or significantly ameliorate illness. Vaccination up to 7 days after exposure may prevent death. Complications from vaccination with vaccinia virus occur and can be fatal. Groups at risk for these adverse consequences include pregnant women and people with eczema, human immunodeficiency virus (HIV) infection, and immunosuppressive conditions (e.g., malignant disease, chronic steroid use, and hereditary immunodeficiencies). Given the seriousness of the disease, the current recommendation is to vaccinate these individuals if there is risk of exposure and simultaneously administer 0.3 mL/kg of VIG intramuscularly. For people who have complications from the vaccine (e.g., progressive vaccinia, ocular autoinoculation, and eczema vaccinatum), the dose of VIG is 0.6 mL/kg intramuscularly and is divided over 24 to 36 hours. Ribavirin can be administered but is considered experimental. VIG is not indicated for vaccinia-associated encephalitis.

The smallpox vaccine supply situation has improved dramatically in the United States. CDC has replaced the traditional smallpox vaccine (Dryvax) with a next-generation product, ACAM2000, in sufficient quantity to immunize the United States population. A British company developed the second-generation vaccine from the same vaccinia virus used in Dryvax but grown in cell cultures. Consequently, its use can still produce the same adverse reactions as Dryvax. To improve the vaccine's safety profile, work has commenced on production of an improved vaccine based on a different vaccinia strain. Two new candidate vaccines, LC16 and Modified Vaccinia Ankara (MVA), show promise. Studies demonstrate improved safety and immunogenicity in populations for whom the traditional vaccine is contraindicated. The virus used in the MVA vaccine is so attenuated that it does not replicate in a human host. The MVA vaccine has received FDA approval (brand name Jynneos) after passing a Phase 3 trial in 2018 and is stored in the Strategic National Stockpile.

Chemical Weapons

Unlike victims of biologic weapons, casualties exposed to chemical agents manifest symptoms quickly, ranging from immediately to a few hours after chemical contact. Therefore, surveillance and recognition are less problematic. The challenge is decontamination and treatment. The Office of the Assistant Secretary for Preparedness and Response, Biomedical Advanced Research and Development Authority created the Primary Response Incident Scene Management (PRISM) series to provide evidence-based guidance on mass patient decontamination procedures.[16]

Terrorism with chemical weapons produces casualties similar to those seen in hazardous materials incidents, and medical management is comparable. However, the unique features of such events, including the volume of patients and the risk of hospital contamination, necessitate additional preparation. For example, in 1995, the Tokyo subway sarin attack resulted in 11 deaths and more than 5000 patients converging on local EDs. Although the majority of these patients had subclinical exposure or psychological symptoms alone, the health care system was severely stressed. Secondary contamination by direct contact or vaporization occurred in ambulances and at the hospitals.

Health care facilities should have protocols in place to manage the eventuality of chemically contaminated patients (Box e15.7). Recommendations for levels of PPE and types of decontamination facilities necessary in a hospital setting have advanced, but evidence-based recommendations remain inconclusive. Per the Environmental Protection Agency, collection of wastewater from the decontamination process in a containment vessel is ideal but not required if this would impede necessary and appropriate actions to protect human life (https://www.epa.gov/sites/production/files/2013-11/documents/onepage.pdf).

BOX E15.7 Emergency Department Preparedness for Chemical Weapons of Mass Destruction

- Community-based hospital coalition planning
- Personnel trained in recognition, mass casualty triage, and treatment
- Decontamination facility with protocols (e.g., runoff water, warm water, patient privacy)
- Personal protective equipment (PPE) readily accessible and compliant with regulations
- Rapid access to antidotes, cyanide antidote kits, and anticonvulsants
- Hospital incident management system in place
- Knowledge of how to access experts quickly

The four basic classes of chemical compounds are nerve agents, vesicants (blistering), cyanides (previously referred to as blood agents), and pulmonary intoxicants (previously referred to as choking agents). Although all have potential for use as weapons, nerve agents and vesicants are thought to represent the greatest threat.

Nerve Agents (Sarin, Tabun, Soman, and VX)

Fundamentals. Nerve agents are organophosphates. They inhibit the enzyme acetylcholinesterase, blocking the degradation of acetylcholine at the postsynaptic membrane. Acetylcholine accumulates, resulting in overstimulation of muscarinic and nicotinic receptors.

Clinical Features. Symptoms are receptor dependent. Stimulation of muscarinic receptors produces miosis, salivation, rhinorrhea, lacrimation, bronchorrhea, bronchospasm, vomiting, and defecation. The major life threat associated with this syndrome is ventilatory compromise from profound bronchorrhea and bronchoconstriction. Stimulation of nicotinic receptors produces muscle fasciculations, flaccid paralysis, tachycardia, and hypertension. Unlike with typical organophosphates, exposure to nerve agents has not been associated with urination. In addition, bradycardia is rare, and miosis does not respond to systemic therapy.

Nerve agents also cause direct central nervous system (CNS) toxicity that is manifested as seizures, coma, and apnea. In survivors, residual CNS effects are manifested as psychological changes that can last 4 to 6 weeks. These manifestations are caused by chemical effects, not stress.

A preliminary diagnosis of nerve agent exposure is based on clinical findings. Important features include muscle fasciculations and miosis, which are sufficient to justify treatment pending further evaluation. Diagnosis is confirmed by measurement of red blood cell cholinesterase levels. This test may not be readily available, and results are difficult to interpret without a baseline level because significant variation exists within normal populations. Therefore, treatment should begin before test results are known.

Terrorists are most likely to use the nerve agents sarin (designated GB) and VX. Sarin is a liquid at room temperature but represents primarily a vapor threat because of its high volatility. Symptoms occur within seconds after inhalation of vapor and peak at 5 minutes. There are no delayed effects; patients remaining asymptomatic one hour after possible chemical contact have not received a clinically significant exposure and can be sent home. VX is a thick liquid with low volatility. It represents a threat only in liquid form. In general, victims have symptoms after skin exposure. The median lethal dose (LD_{50}) for VX is 0.04 mg/kg. Death from doses of this size occurs in less than 30 minutes. Delayed symptoms can occur, so individuals should be observed for 18 hours before potential intoxication can be ruled out.

BOX E15.8 Type and Degree of Nerve Agent Exposure

Vapor Exposure (Sarin)

Mild: Rhinorrhea and miosis

Moderate: Mild symptoms plus increased secretions, wheezing or dyspnea, muscle weakness or fasciculations, or gastrointestinal effects

Severe: Apnea, seizures, loss of consciousness, flaccid paralysis, or major involvement of two organ systems

Liquid Exposure (VX)

Mild: Localized sweating and fasciculations where a drop touches the skin; no miosis; may be delayed for 18 hours

Moderate: Gastrointestinal effects; miosis uncommon; may be delayed for 18 hours

Severe: Apnea, seizures, loss of consciousness, flaccid paralysis, or major involvement of two organ systems; occurs in less than 30 minutes at or above median lethal dose (LD_{50})

BOX E15.9 Treatment of Nerve Agent Exposure

Vapor

Mild: Observe for 1 hour, then release; no treatment

Moderate: One or two Mark 1 kits IM; *or* atropine, 2 to 4 mg IV, may repeat every 5 to 10 minutes as needed; *and* 2-PAM, 1 g IV during 30 minutes, may repeat every hour as needed

Severe: Three Mark 1 kits IM and one diazepam autoinjector IM; *or* atropine, 6 mg IV, may repeat 2-mg boluses IV every 5 to 10 minutes; *and* 2-PAM, 1 g IV during 30 minutes, repeat every hour for total of 3 g; *and* midazolam or diazepam, 5 mg IV, or midazolam 10 mg IM, may repeat as needed

Liquid

Mild: One Mark 1 kit IM; *or* atropine, 2 mg IV; *and* 2-PAM, 1 g IV during 30 minutes

Moderate: Same as for vapor

Severe: Same as for vapor

Pediatric Doses

Atropine, 0.02 mg/kg IV

2-PAM, 20 to 40 mg/kg IV during 20 to 30 minutes

Midazolam, 0.15 mg/kg IV; *or* diazepam, 0.2 to 0.3 mg/kg IV

[a]Give atropine before attempting intubation. Otherwise, airway resistance will inhibit ventilation. Continue atropine until secretions are dry (usually 20 mg). In hypoxic patients, IV atropine has been reported to cause ventricular fibrillation, so consider use of IM atropine.
IM, Intramuscular; *IV,* intravenous.

Management. Decontamination of victims exposed to sarin vapor requires removal of clothing. People contaminated with VX or liquid sarin should have their clothing removed and then be decontaminated by using showers. When the level of exposure or the involved agent is uncertain, full decontamination is recommended. Reactive skin decontamination lotion (RSDL) is FDA-approved to remove or neutralize some nerve agents. Responders caring for patients in the presence of liquid sarin exposure may require level A or B protective suits.

Pretreatment with pyridostigmine acts to carbamylate acetylcholinesterase preventing nerve agent binding. The treatment of nerve agent victims depends on the form (liquid or vapor) and level of exposure (mild, moderate, or severe) (Box e15.8). Three drugs are the mainstay of treatment: atropine for the muscarinic effects (improves ventilation), pralidoxime chloride (2-PAM) for the nicotinic effects (reverses paralysis), and diazepam for the prevention and treatment of seizures (Box e15.9). The dose of atropine is titrated to the drying of respiratory secretions and not to heart rate or pupil size, thus it is indicated even in tachycardic patients. Exceptionally high doses exceeding 50 mg of atropine may be required. 2-PAM is most effective if it is administered within 4 to 6 hours of sarin exposure. After this period, the drug's impact wanes because of "aging," defined as the permanent attachment of sarin to the acetylcholinesterase enzyme.[17] Hypertension can occur during 2-PAM administration and is controlled by intravenous phentolamine, 5 mg for adults and 1 mg in repeated doses for children. In 2009, investigators published data that question the efficacy of oximes in the treatment of commercial insecticide exposure. The use of oximes did not improve clinically important outcomes.[18] Whether these results apply to nerve agents remains uncertain. Midazolam may be a more effective benzodiazepine for control and prevention of seizures, and it may replace diazepam as the drug of choice for treatment of severe nerve agent toxicity in future guidelines.[19]

An autoinjector kit (Mark 1) approved by the FDA consists of two cartridges, one containing atropine (2 mg) and the other 2-PAM (600 mg). Mark 1 kits are available as part of civilian pharmaceutical caches strategically located throughout the United States. A newer version with both drugs combined in a single autoinjector (Antidote Treatment Nerve Agent Auto-Injector referred to as DuoDote) will gradually replace the Mark 1 kits. An autoinjector containing 10 mg of diazepam is an additional option if intravenous access is not possible. Doses should be adjusted for pediatric and geriatric patients. Atropine autoinjectors are manufactured in three doses (2 mg, 1 mg, and 0.5 mg) for these groups. Use of the Mark 1 kits to treat children and the elderly can be problematic because of difficulty adjusting the dose. An alternative solution is to inject the medication into a sterile vial. The drug can then be re-aspirated in an appropriate amount for the patient's weight or age before administration.

Vesicants (Mustard)

Foundations. Vesicants (blistering agents) are chemical warfare agents that induce blister formation on contact with skin. Terrorists could use several of these compounds, but sulfur mustard is considered the most likely. Mustard is a liquid at room temperature but has both liquid and vapor toxicity. Injury from mustard exposure occurs in 1 or 2 minutes, but symptoms do not develop for 4 to 8 hours.

Clinical Features. The exact mechanism is unknown, but the agent damages DNA, causing eventual cell death. These effects are similar to radiation exposure and often described as "radiomimetic." Mustard has both local and systemic toxicity. Local effects occur from direct exposure to the skin, eyes, and airway. Systemic effects result from the impact of absorbed mustard on the bone marrow.

Management. Single- and three-color detector papers exist for individual use. Treatment is supportive and includes decontamination (to prevent secondary contamination) and airway maintenance. The patient should be decontaminated by removal of clothing and use of RSDL. If RSDL is not available, washing with copious water or a dilute bleach (1 : 10 hypochlorite) solution is acceptable. More concentrated bleach solutions are contraindicated because they can cause skin damage. Decontamination immediately after exposure, ideally at the scene, prevents further injury to the patient, but delayed decontamination is indicated to protect staff. No specific antidote for mustard is currently available. Silverlon, a silver-plated nylon dressing, was FDA-approved in 2019 for treatment of cutaneous injuries.

Eye damage from mustard exposure varies from conjunctivitis to corneal ulcer and perforation; however, only 1% of patients have

permanent eye damage. Ninety percent of ocular injuries will heal within 2 weeks to 2 months of exposure without sequelae. Severe pain is frequently associated with mustard injury including that from significant blepharospasm. Irrigation is beneficial if it is performed within minutes of exposure but ineffective once symptoms occur. Standard treatment includes mydriatics, topical antibiotics, oral analgesics, and petroleum jelly applied to the lids to prevent adhesions. Commercially available topical antibiotic/glucocorticoid ophthalmologic ointments have demonstrated efficacy when applied early in animal models. Application of this drug combination in the first few hours to days of exposure appears to reduce inflammation and subsequent injury. Continued use of topical steroids should occur under the supervision of an ophthalmologist.

The hallmark of mustard injury is skin blisters resembling second-degree burns. Within 4 to 8 hours of exposure, erythema and burning occur, followed by vesicle and bullae formation. Most vapor injuries do not involve the entire dermis, so wounds will not require skin grafting. If liquid exposure occurs to skin, full-thickness burns may result. Treatment is supportive and includes standard burn wound management, analgesia, and tetanus prophylaxis. An important exception is fluid resuscitation. Fluid losses from mustard injury are much less than those associated with thermal burns. Therefore, standard burn formulas for fluid administration do not apply, and caution should be used to avoid overhydration. Topical application of calamine lotion, corticosteroid preparations, or silver sulfadiazine can help relieve severe itching associated with lesions.

The degree of airway injury after mustard exposure is dose dependent. Mild exposure causes irritation of the nose, sinuses, and pharynx and can be treated with cool, humidified mist. Moderate exposure extends to the larynx and upper trachea and may require treatment with oxygen, continuous positive airway pressure, or even intubation. Severe exposure involves the lungs, producing hemorrhagic necrosis of the bronchioles. Pulmonary edema is rare. Intubation is usually required, and patients may benefit from positive end-expiratory pressure and inline bronchodilators. Steroids are of questionable benefit, and antibiotics should only be administered for established infection.

Systemic toxicity from mustard is caused by bone marrow suppression. Absorbed mustard kills stem cells, causing the white blood cell count to decline after three to five days. Survival is rare if the white blood cell count falls below 200, which generally occurs when more than 50% of the total body surface area is involved from exposure to a liquid agent. Colony-stimulating factors may aid in recovery. Death after mustard exposure usually results from secondary infection and respiratory failure. Exposed patients are at risk for future cancer development and routine monitoring should be established.

Cyanides (Blood Agents)

Foundations. Cyanide molecules, most typically hydrogen cyanide or cyanogen chloride, bind to cytochromes within mitochondria and inhibit cellular oxygen use.

Clinical Features. Low-dose exposures result in tachypnea, headache, dizziness, vomiting, and anxiety. Symptoms subside when the patient is removed from the source. At higher doses, the symptoms progress to seizures, respiratory arrest, and asystole within minutes of exposure. Significant metabolic acidosis is a hallmark finding. Central nervous system damage may result leading to chronic, Parkinson-like symptoms.

Management. Victims should be removed from the area, have their clothing discarded, and receive oxygen. If no improvement occurs, the cyanide antidote should be administered. This has traditionally been the sequential administration of amyl nitrate 0.3 mL ampule inhaled, sodium nitrite 300 mg IV, and sodium thiosulfate 12.5 g IV. However, the FDA has approved intravenous hydroxocobalamin for first-line treatment of cyanide exposure. The initial dose is 5 g and can be repeated if necessary.[20]

Pulmonary Intoxicants (Phosgene and Chlorine)

Foundations. Pulmonary or choking agents cause an inflammatory reaction when they come into direct contact with the eyes and upper airway. They can be life-threatening if inhaled.

Clinical Features. Exposure to pulmonary intoxicants results in a latent period between 20 minutes and 24 hours, dependent on the chemical, amount of exposure, and physical activity of the patient. The destruction of the bronchiolar epithelium by the chemical leads to fluid leakage into the pulmonary interstitium, then into the alveoli, causing pulmonary edema. Edema usually peaks at 12 hours, then starts to resolve 24 to 48 hours after onset. If the patient survives, little to no permanent lung damage is observed.

Management. Clothing should be removed to prevent secondary exposure. Strict activity limitation, including litter evacuation followed by bed rest, is mandatory to minimize pulmonary damage. No specific antidote exists. Treatment is mainly supportive and consists of airway maintenance, bronchodilator administration, positive-pressure ventilation, and eye irrigation. Steroids may decrease severity of exposure effects.[21]

Blast Injuries from Conventional Explosives

Foundations

As noted previously, the most likely terrorist scenario that emergency physicians will encounter is victims of conventional weapons resulting in bomb and blast injuries. Although military personnel commonly have training and experience in managing patients suffering from blast injuries, most civilian emergency physicians will find these types of presentations to be unfamiliar; thus, an overview of key features is beneficial.

Clinical Features

Blast injuries have several unique features, including that bombings can cause multiple, simultaneous, life-threatening injuries on large groups of people and severe injuries can be subtle. Following an explosion, pressure waves and blast winds are generated and spread in all directions. Severity of injuries depends on the method of delivery (incendiary, explosive), the environment (open versus closed, such as inside a bus with the doors shut; other environmental hazards), and distance from the detonation.

Classically, four categories of injury are described (Table e15.5), though some authors have described a fifth category resulting from a hyperinflammatory state due to toxic materials absorbed by the body.

Management

Although combined injuries may coexist, an understanding of management of the four primary types will guide treatment. Detection of severe injuries can be difficult in some cases with subtle presentations;

TABLE E15.5 Categories of Blast Injury

Primary	Unique to high-order explosives; results from the impact of the over-pressurization wave with body surfaces
Secondary	Results from flying debris and bomb fragments
Tertiary	Results from individuals being thrown by the blast wind
Quaternary	All explosion-related injuries, illnesses, or diseases not due to primary, secondary, or tertiary mechanisms (includes exacerbations or complications of existing conditions)

treatment in each instance consists of standard management of each type of injury or illness, respectively.

Primary Blast Injury. Primary blast injury produces barotrauma, with air-containing organs such as auditory, pulmonary, and gastrointestinal being the most susceptible. Resultant hearing loss can make casualty triage and management challenging.

Blast Lung. Blast lung injury is a major cause of morbidity and mortality both at the scene and at the hospital among initial survivors. Symptoms are usually present at the time of evaluation, but can have an onset several hours after the explosion. Lethal lung injury can occur without external signs of trauma and initial chest radiographs are abnormal in only 70% of cases.[22] Pulmonary contusions are the primary manifestation of blast lung. For open space bombings, contusions tend to be more severe on the side that received the blast wave, whereas in closed space explosions, they are generally bilateral. Treatment is standard supportive care. If intubation is necessary, lung protective strategies should be utilized (i.e., low tidal volumes and plateau pressure below 30 cm H_2O).

Other common primary blast injuries include tympanic membrane rupture, middle ear damage, abdominal hemorrhage and organ perforation, traumatic brain injury, and concussion. Although rupture of the tympanic membrane was initially thought to be a reliable marker of injury severity, this has been disproven. Crush injury and crush syndrome can occur and are described elsewhere (Chapter 116).

Secondary Blast Injury. Secondary blast injury is the most common cause of morbidity and mortality following a blast event. These injuries are caused by flying debris generated by the explosion. Wounds should be considered to be contaminated and therefore patients treated with antibiotics, tetanus, and hepatitis B prophylaxis (e.g., if shrapnel from an infected suicide bomber is embedded in a patient). Unlike hepatitis B, HIV does not seem to be transmitted in this manner.

Tertiary Blast Injury. Tertiary injuries result from individuals being thrown by the blast wind. The most common types of tertiary blast injuries are head injuries and fractures.

Quaternary Blast Injury. Quaternary blast injuries comprise all explosion-related injuries, illnesses, or diseases not due to primary, secondary, or tertiary mechanisms. This includes exacerbation or complications of existing conditions.

CHAPTER E15: QUESTIONS AND ANSWERS

1. Three patients arrive at triage simultaneously: One has received a 4 Gy work-related irradiation exposure from a food sterilizer but no other injury; one is experiencing an acute ST elevation myocardial infarction (MI); and one likely has urosepsis but with a stable blood pressure and heart rate of 105 beats/min. Which of these actions is your first priority?
   a. Activate the cardiac catheterization team.
   b. Decontaminate the irradiated victim before placing him in a room.
   c. Initiate intravenous (IV) fluid bolus and prepare for intubation of the radiation-exposed patient.
   d. Place a central venous catheter in the urosepsis patient.

Answer: A. Even patients who have received a lethal radiation dose do not die quickly as a consequence of the ionizing exposure. Patients should be triaged according to severity of the medical conditions and/or vital sign derangements. Here, the patient with the MI is most acute and should be the highest priority necessitating activation of the cardiac catheterization team. The radiation-exposed patient was not contaminated, just irradiated. As such, decontamination and isolation are unnecessary. Although the victim has received the LD_{50} dose of ionizing radiation, no significant injury will result just after exposure, so this patient does not take priority over the MI patient at this point and intubation is not indicated. The septic patient is not critically ill and should not be treated ahead of the MI patient.

2. Which of the following statements best describes issues in management of anthrax infection?
   a. Antibiotics do not change the mortality of cutaneous disease.
   b. Cutaneous anthrax lesions are nontender.
   c. Doxycycline or ciprofloxacin are both options for single-agent treatment of symptomatic inhalational anthrax.
   d. Sputum culture and Gram stain obtained early in the disease help differentiate inhalational anthrax.

Answer: B. Cutaneous anthrax causes a severe, although nontender, peripheral vesicle that progresses to an eschar accompanied by regional adenopathy. Antibiotics lower the mortality from cutaneous anthrax twenty-fold. For inhalational, gastrointestinal, and cutaneous anthrax with toxicity, intravenous (IV) treatment is with ciprofloxacin or doxycycline plus at least two other agents. Regarding inhalational anthrax, mechanical ventilation may not improve mortality and sputum cultures and Gram stains are not helpful until late in the disease.

3. Several children ages 5 to 8 years old have definitely been exposed to anthrax spores. Health department officials have brought these children to the emergency department (ED). They are all ambulatory with normal vital signs and without symptoms. Which of the following is the most appropriate management?
   a. Admission for parenteral penicillin G
   b. Doxycycline for 5 days
   c. Outpatient ciprofloxacin for 60 days or until the children have received three doses of vaccine
   d. Penicillin VK for 7 to 10 days

Answer: C. See Box e15.5. For children without toxicity, ciprofloxacin, doxycycline, or amoxicillin orally is indicated for a minimum of 60 days or until the child has received three doses of vaccine. The vaccine has not been approved for children but may be indicated to reduce the long-term exposure to antibiotics. Note that weaponized anthrax may be penicillin-resistant.

4. An individual is exposed to sarin vapor. She presents complaining of difficulty with vision, salivation, vomiting, and the urge to defecate. The most appropriate treatment for this patient is which of the following?
   a. 5 mg diazepam intravenous (IV)
   B. 6 mg atropine IV and 1 g 2-PAM IV every hour for a total dose of 3 g
   C. 10 mg diazepam intramuscular (IM) via autoinjector
   D. One or two Mark 1 or the DuoDote autoinjector kits IM

Answer: D. The victim described would be characterized as a moderate exposure to sarin vapor. Treatment is indicated with one or two Mark 1 or DuoDote autoinjectors IM. Observation would not be appropriate. Diazepam is not indicated for moderate exposures. If an IV is established, the initial treatment is atropine 2 to 4 mg IV and 2-PAM 1 g IV.

5. Which of the following statements regarding blast injury is true?
   a. Classically, there are three different types of blast injury.
   b. Primary blast injury is caused by flying debris and bomb fragments.
   c. Exacerbation of asthma is an example of tertiary blast injury.
   d. Secondary blast injury is the most common cause of morbidity and mortality following a blast event.

Answer: D. Of the four types of blast injury, secondary blast injury is the most common cause of morbidity and mortality. These injuries are caused by flying debris generated by the explosion. An asthma exacerbation could be considered a quaternary injury in the correct setting. Tympanic membrane rupture is not an accurate predictor of internal injuries in blast events.

Tactical Emergency Medical Support and Urban Search and Rescue

Tactical Emergency Medical Support and Urban Search and Rescue

Nelson Tang and Matthew Levy

KEY CONCEPTS

- Tactical emergency medical support (TEMS) facilitates the overall success and safety of law enforcement missions during all phases of a tactical operation through the delivery of preventive, urgent, and emergency medical care.
- A fundamental principle in tactical medicine is that the medical mission may be subordinate to the overall law enforcement mission.
- Tactical combat casualty care (TCCC) has adapted civilian advanced life support principles to provide medical care during a hostile force encounter. Its goals are to treat the casualty, prevent additional casualties, and complete the mission.
- TCCC is divided into three phases of care: care under fire (CUF), tactical field care (TFC), and combat casualty evacuation care (CASEVAC).
- Tactical emergency casualty care (TECC) addresses casualty management during high-threat civilian tactical and rescue operations and is divided into three phases; direct threat, indirect threat, and evacuation care.
- Urban search and rescue (USAR) encompasses responding to, locating, reaching, medically treating, and safely extricating victims entrapped by collapsed structures. The primary role of the emergency clinician is support of the health and welfare of the team members, including canines.
- USAR teams often treat crush syndrome, particulate inhalation, hazardous materials exposures, and blast injuries.
- In crush syndrome, treatment with fluids begins prior to extrication to avoid life-threatening complications once the patient is extricated.

PRINCIPLES

Background

A confluence of domestic incidents in the mid-1960s of unprecedented violence and scale demonstrated to law enforcement agencies in the United States the necessity of increased preparedness and specialized response capabilities. Law enforcement agencies in the United States today have near-immediate access to highly trained individuals and special equipment to respond to high-threat and operationally complex situations. Often referred to as special weapons and tactics (SWAT) teams, police tactical units are tasked with responses to high-threat crime and violence, including the prevalence of military grade weapons, taking of hostages, and organized terrorist activities.

National leaders within law enforcement, emergency medicine, and emergency medical services (EMS) have supported the development of dedicated medical support for tactical teams. Position papers from the National Tactical Officers Association (NTOA), National Association of EMS Physicians (NAEMSP), and American College of Emergency Physicians (ACEP) all support tactical emergency medical support (TEMS) as an essential component to help maintain the health and safety of law enforcement personnel, suspects of crime, and the general public. Today, the breadth of law enforcement tactical missions commonly includes hostage or barricade situations, high-risk warrant service, active shooter incidents, violent felon apprehension, civil disturbances, dignitary and executive protection, maritime and dive operations, and explosive ordnance disposal.

Tactical emergency medical support is now viewed as an essential adjunct to law enforcement operations and public safety.[1,2] Professional medical engagement in the area of TEMS continues to attain formal recognition and physician competency is an established requirement of subspecialty certification in emergency medical services (EMS). The efficacy of tactically trained medical providers and their roles have been described in a growing number of unconventional prehospital scenarios including responses to national disasters and national special security events (NSSE).[3]

Organizational Principles and Objectives

Tactical medicine augments high-threat law enforcement operations through medical threat assessments, delivering immediate emergency medical care, and promoting the safety and health of law enforcement personnel. Tactically trained medical personnel achieve their objectives through mission preplanning, clinical practices developed or adapted specifically for law enforcement operations, and establishing critical interfaces between police, conventional EMS, and the emergency health care system.

The broad goals of TEMS are to facilitate the overall success and safety of law enforcement missions during all phases of a tactical operation through the delivery of preventive, urgent, and emergency medical care. The basic approaches used by tactical medicine providers were initially developed by the military for small unit operations and have been widely applied to civilian law enforcement. In the operational setting, TEMS provides medical risk surveillance, injury and illness prevention, resource identification and coordination, and rapid access to emergency medical care.

A fundamental tenet of tactical medicine is that the medical support mission may be subordinate to the overall requirements and constraints of the law enforcement mission. In contrast to conventional EMS and in-hospital practices, where the sole consideration is typically the health and welfare of individual patients, the essential priority in a tactical mission is the success of the law enforcement objective. When a casualty occurs during a tactical operation, medical providers may be directed to delay or modify medical interventions until the tactical commander determines that rendering care will not jeopardize the overall mission.

SPECIAL ISSUES

Tactical Emergency Medical Support Providers and Scopes of Practice

A key consideration in TEMS concerns the level or type of medical provider to be deployed for operational medical support. Most commonly,

tactical medicine is rendered by experienced emergency medical personnel with EMS backgrounds, trained at either the basic life support (BLS) or advanced life support (ALS) level. BLS providers are generally more plentiful, with fewer requirements for initial and ongoing training, whereas ALS providers are typically fewer, more difficult to train, and costly to maintain. Larger law enforcement agencies may deploy a mix of BLS and ALS personnel. True multitiered programs in TEMS are rare, not accounting for the potential operational role of tactical physicians or the agency medical director.

Jurisdictional EMS standards typically dictate many or all of the interventions commonly found within the ALS scope of practice. Nevertheless, intensively trained BLS providers with focused expansions of clinical practice have demonstrated effectiveness in providing operational medical support for federal law enforcement. TEMS medical directors maintain the authority to train BLS providers with judiciously enhanced medical skill sets deemed essential for care in the tactical environment.

Given that the overall volume of patient encounters in tactical medicine is relatively low, TEMS-specific protocols and training paradigms have historically been developed with a paucity of data and often based on anecdotal evidence. Although the impetus for the development of many tactical medicine programs was the risk of traumatic injuries during law enforcement operations, opportunities to provide more comprehensive medical support beyond the narrow scope of trauma care have emerged. There has been increasing evidence to justify broadened medical training, protocols, and expanded clinical skills sets for tactical medics.

Two distinct subsets of encounters occur in TEMS—low-frequency/high-acuity (e.g., gunshot wounds or falls from height) and high-frequency/low-acuity (e.g., sprains and strains or environmental exposures). Management of low-frequency/high-acuity patient encounters requires proficiency in complex lifesaving interventions; however, advanced clinical skills are difficult to maintain in low-volume EMS systems. Because TEMS providers typically also serve as law enforcement officers, resources including time, funding, and opportunities to maintain clinical skills are often insufficient.

By contrast, high-frequency/low-acuity patient encounters are not medically emergent or even urgent in many cases. Because patient populations encountered in TEMS are very often law enforcement officers, the impact of even these low-acuity medical issues on overall tactical team performance, capacity, or time can be significant. Unfortunately, the assessment and management of low-acuity medical complaints are often out of the scope of training and clinical practice of conventional EMS providers. The challenge for medical directors and law enforcement agencies is to ensure that protocols, training, and ultimately provider capabilities are sufficiently adept to manage the breadth of anticipated clinical encounters in TEMS.

Medical Oversight of Tactical Emergency Medical Support

As a subspecialty area of prehospital medicine and law enforcement operations, TEMS programs carry special administrative and medical oversight requirements. Qualified physician leadership and medical control, as in conventional EMS, is an essential component of tactical emergency medical support. Unique qualifications and expanded responsibilities exist for tactical medical directors. The ability to thoughtfully and proactively manage enhanced provider scopes of practice, adjuncts to conventional EMS interventions, and integration with existing health system and public safety infrastructures are equally important.

The successful integration of emergency medicine into law enforcement operations is a complex process that mandates effective medical leadership. All fundamental tenets of medical director accountability in EMS apply to tactical emergency medical support programs.[4] The added challenges of directing care in the law enforcement arena and potential need for augmented capacities of TEMS providers call for additional qualifications of physicians responsible for such programs. Of foremost significance, the TEMS medical director must understand the central mission of the law enforcement agency. TEMS medical directors must formulate and implement clinical policies, protocols, and training sufficient for TEMS providers to deliver effective preventive, urgent, and emergent medical care in the dynamic law enforcement environment. Additionally, they must be proficient in the formulation of operational medical plans and have a superior understanding of special operations and tactical procedures.

Casualty Care

Tactical combat casualty care (TCCC) originated as a project within naval special warfare, and tactically appropriate battlefield trauma care guidelines were published in 1996. These were later continued by the US Special Operations Command and used today throughout the Department of Defense. TCCC adapted civilian ALS principles to provide medical care during a hostile force encounter. These combat trauma care guidelines combine advanced trauma care with good small-unit tactics, balancing the need to treat casualties against the risks of providing such treatment within the context of an ongoing operation.[5] The three major goals of TCCC are to treat the casualty, prevent additional casualties, and complete the mission.

The treatment principles of TCCC were developed based on the recognition that preventable deaths in combat scenarios occur from uncontrolled hemorrhage due to extremity wounds, tension pneumothorax, and airway compromise from maxillofacial trauma. TCCC recognizes that the tactical objective of neutralizing a hostile threat generally takes precedence over providing definitive medical care. TCCC divides the level of medical care provided during a hostile force encounter into three phases—care under fire (CUF), tactical field care (TFC), and combat casualty evacuation care (CASEVAC).

Care Under Fire

CUF is the first phase of casualty care that is rendered while tactical operators are under direct hostile fire (Fig. e16.1). CUF encourages the casualty to remain engaged in the operation, seeking cover and concealment, and returning fire, if possible. Immediate lifesaving maneuvers that may be rendered by a casualty ("self-aid") or a nearby tactical operator ("buddy aid") are emphasized in this phase. Because uncontrolled hemorrhage from extremity wounds is a leading cause of preventable battlefield deaths, CUF emphasizes control of life-threatening bleeding with early use of a tourniquet. Airway management while under fire is preferentially deferred until the TFC phase. Both CPR and cervical spine immobilization are usually contraindicated in the presence of an ongoing hostile threat.

Tactical Field Care

TFC begins once operators, who remain at risk of injury, are no longer under direct hostile fire and is most often rendered by trained medical providers. Assessment and treatment priorities include assessing the casualty for unrecognized hemorrhage and controlling all sources of bleeding, and treating through the use of tourniquets and topical hemostatic agents (Fig. e16.2). Attention is directed toward establishing or maintaining an unobstructed airway by using simple maneuvers, such as inserting a nasopharyngeal airway and/or placing the casualty in a recovery position. Casualties with unilateral blunt or penetrating chest trauma in respiratory distress are rapidly evaluated for tension pneumothorax or sucking chest wounds and undergo needle

Fig. e16.1 Care under fire—direct threat phase of care. (Courtesy Nelson Tang, with permission.)

Fig. e16.2 Tactical field care—indirect threat phase of care. (Courtesy Nelson Tang, with permission.)

decompression when indicated, or are treated with an occlusive dressing, as necessary. When possible, intravenous (IV) or intraosseous access is established to administer fluids and/or medications. Grossly contaminated wounds, open fractures, or penetrating abdominal trauma may receive empirical IV antibiotics, especially if evacuation and transport times are prolonged. The need to perform a complete physical examination (secondary survey) is balanced against the risk of hypothermia, which should be actively managed using layered coverings and warmed IV fluids.

Combat Casualty Evacuation Care

CASEVAC is the care rendered while the casualty is being evacuated by ambulance or helicopter to undergo definitive care at a prestaged landing zone or casualty collection point (Fig. e16.3). Interventions and therapeutics during the CASEVAC phase most closely approximate conventional EMS care and include continued ALS while en route to receiving facilities, most often trauma centers. The situational need for medical care, severity of specific injuries, numbers of casualties, and local system practices determine whether the TEMS provider accompanies an injured law enforcement officer to the hospital to act as the patient's advocate, as well as a liaison to tactical command.

Fig. e16.3 Combat casualty evacuation care—evacuation phase of care. (Courtesy Nelson Tang, with permission.)

Committee for Tactical Emergency Casualty Care

Whereas TCCC is widely accepted in the military combat setting, it is not directly applicable to the civilian environment. Recognizing this, a diverse group of first responders, law enforcement leaders, and tactical medicine experts convened in May 2011 to create the Tactical Emergency Casualty Care (TECC) guidelines, a set of best practice recommendations for casualty management during high-threat civilian tactical and rescue operations. Based on principles originally derived from its military analog, TECC guidelines consider key differences in the civilian environment, including resource allocation, patient population, and scope of practice. TECC is applied in three phases—direct threat, indirect threat, and evacuation care. The Committee for Tactical Emergency Casualty Care (C-TECC) meets formally twice per year to critically evaluate emerging evidence and update its consensus open-access guidelines.[6]

Direct Threat Care. To meet the specific operational scenarios and terminology used in the civilian sector, the first phase of care under TECC is termed *direct threat care*. The priorities of direct threat care emphasize mitigating the threat, moving the wounded to an area of relative safety, and managing hemorrhage using tourniquets. Emphasis is placed on the importance of various rescue and patient movement techniques, as well as rapid airway opening and positioning techniques, if operationally feasible. Treatment and operational requirements are the same for all levels of providers during this phase of care.

Indirect Threat Care. Indirect threat care can be initiated once the casualty is in a relatively safe area, with proper cover and less chance of rescuers being injured or patients sustaining additional injuries. Similar to TCCC, assessment and treatment priorities in this phase focus on the preventable causes of death. Four different levels of providers are assigned to scope of practice and skill sets based on level of training and certification—law enforcement officer, emergency medical responder (or equivalent), emergency medical technician (EMT), and advanced EMT-paramedic.

Evacuation Care. The final phase of care under TECC is called evacuation care, when the casualty is moved to a definitive treatment facility. Most additional interventions during this phase of care are similar to those performed during normal EMS operations. However, reassessment of prior interventions and hypothermia management are emphasized.

Tactical Team Health

Historically developed to address the well-recognized potential for lethal injuries intrinsic to tactical operations, the initial near-singular focus of TEMS was training and preparation to render lifesaving trauma care. Tactical medicine today is much broader in scope, drawing from clinical principles and practices of preventive, sports, occupational, and emergency medicine. The broad objectives of such programs are to support the overall success of the tactical mission by optimizing the health and wellness of the operational team as well as providing immediate emergency medical and trauma care.

Core tactical medicine responsibilities include the health surveillance of law enforcement personnel and delivery of preventive and routine medical care. It is common today for TEMS providers to manage issues such as sleep-rest cycles, hydration and nutrition, vaccinations, environmental exposures, and preexisting medical conditions for the tactical teams. High-volume TEMS programs have demonstrated that tactical medics most frequently encounter law enforcement officers as patients, validating these programs as ones designed to protect the health and welfare of the team.

Integration With Emergency Medical Services Infrastructure

Aside from federal teams, TEMS programs generally operate within the framework of existing local EMS systems and abide by established mechanisms for administrative and medical oversight. More often than not, TEMS may be a specialty function or service of the existing EMS system. Even if a law enforcement agency has intrinsic tactical medical assets and potential jurisdictional authority to expand established EMS protocols or scopes of practice, from quality management and system-based perspectives, it is preferable for TEMS programs to operate in overall concert with the local infrastructure. Close and collaborative working relationships enhance quality of care, promote patient safety, and optimize transitions of care and mutual aid responses.

Although concepts of operational security (OPSEC) are intrinsic to law enforcement and security personnel, they may be less familiar to EMS and other health care providers. OPSEC governs how sensitive information, even unclassified, is handled and protected. In the law enforcement context, there can be issues related to OPSEC that preclude full disclosure of all TEMS-related capabilities and activities in all cases. Nevertheless, focused outreach and effective communication on the part of the TEMS medical director can be tremendously valuable for system integration and interagency public safety cooperation.

EMS policies and protocols are typically administered at the state or regional level, thereby resulting in significant jurisdictional variation. In many cases, EMS protocols, provider certifications, duties, and scopes of practice are matters of legislative governance.[7] Specific local protocols, including the provision of TEMS care, are often guided by factors such as population, geography, resources, and medical oversight.[8] If expanded scopes of practice are invoked, it is the responsibility of the TEMS medical director to ensure that advanced procedures and protocols are justified to support force protection and mission safety.

Due to the special requirements for operating in the austere tactical environment, TEMS providers are often trained and authorized to perform therapeutic procedures that may be unconventional when compared to standard EMS. Procedures such as supraglottic airways, needle thoracostomy, tourniquets, topical hemostatic agents, intraosseous vascular access, and field-expedient splinting and wound closure are often deployed in TEMS for lifesaving care. Additionally, specialized capabilities such as medical threat assessment, remote patient assessment, forensics and evidence preservation, "hasty decontamination," and hazardous materials management have all been described.

Active Shooter Incidents

The prevalence of hostile mass casualty events, such as school, workplace, and public venue shootings, seems to be an ever-increasing phenomenon worldwide. Determining potential strategies for prevention remains a massive undertaking for medicine and law enforcement alike. The destructive capacity of persons armed with conventional weapons is now well recognized and must also be addressed using public safety and public health approaches.

Although ideally suited to function within the operationally austere conditions of law enforcement SWAT missions, TEMS remains a relatively small and selective component of the multidimensional response to a mass casualty active shooter incident. Just as a SWAT team is not likely to be the first law enforcement element to arrive at such an incident, TEMS providers will generally not be the first medical responders on the scene. Additionally, TEMS providers are usually small in number and logistically embedded with the tactical team. Studies of active shooter events in the United States have noted that first responders and conventional EMS must be capable of reaching casualties quicker and initiating lifesaving procedures sooner. Consensus panels have been convened to formulate best practices from military and civilian TEMS lessons learned.[6] EMS systems have developed "rescue task force" models to enable its providers to respond to active hostile situations using personal protective equipment, with law enforcement officers providing security and deploying medical approaches adapted from TEMS principles.

Active shooter scenarios are expected to result in multiple casualties to include victims, assailants, and law enforcement personnel. As medical professionals, TEMS providers must balance duties to render in-depth care to individual patients against the stark recognition that the most effective means to preserving life is the neutralization of ongoing hostile threats by law enforcement. Casualty numbers will vary by incident and may overwhelm the capacity of specialized TEMS elements. In these instances, dynamic situational contexts may shift the role of the TEMS provider from a primary responder to an advanced triage officer, potentially providing brief immediate lifesaving interventions while identifying zones of care, establishing casualty collection points, and integrating EMS resources as situations permit. Technical aspects of how these are accomplished rely on local and agency procedures, evolving best practice recommendations, and specific team capabilities.

Future Directions

High-threat practice settings in TEMS drove the early adoption of clinical practices that are now commonplace in both EMS and hospital emergency departments alike. These have included novel topical hemostatic agents, highly effective tourniquets, rapid intraosseous access devices, and enhanced supraglottic airways.

Despite rapidly growing recognition of its efficacy, the development of TEMS programs and capabilities remains a collateral responsibility for most law enforcement agencies and personnel around the country. TEMS programs often remain informal initiatives, existing under the auspices of ad hoc agreements between local law enforcement and a medical entity, with limited funding and constrained personnel resources. Widespread medical acceptance of the TEMS mission remains a goal and continued professional development of qualified physician leadership is essential.

URBAN SEARCH AND RESCUE

Urban search and rescue (USAR) is a unique and specialized discipline that encompasses responding to, locating, accessing, medically treating, and safely extricating victims primarily entrapped by collapsed or potentially unstable structures. USAR teams possess the most cutting-edge advanced technical rescue training, equipment, and expertise. In addition, USAR teams maintain a posture with intrinsic austerity and robustness which allows them to function nearly self-sufficiently in the often resource-limited postdisaster environments. By its very nature, USAR is an all-hazards discipline capable of response to a broad range of emergency situations and disasters that may result in structural collapse and human entrapment. Examples of such situations include natural disasters such as earthquakes and hurricanes, and human-made disasters (both intentional such as terrorist attacks and unintentional such as industrial incidents). These situations can result in a multitude of response scenarios, often at the same time. For example, in the aftermath of a hurricane, USAR personnel may be called upon to extricate persons entrapped in collapsed structures, while facing hazardous materials, standing water, and impassable roadways.[9] USAR teams also maintain additional specialty rescue capabilities and proficiencies such as trench rescue.

In the 1980s, Fairfax County Fire and Rescue (Virginia) and Metro-Dade County Fire Department (Florida) created elite search and rescue teams. These teams worked with the Office of Foreign Disaster Assistance and were deployed to disaster scenes internationally. In 1989, the Federal Emergency Management Agency (FEMA) established the National Urban Search and Rescue Response System after recognizing that there was a lack of teams for urban disasters. The model structures local emergency rescue personnel into response task forces. In 1991, USAR was incorporated into the National Response Plan (NRP), which has since been superseded by the National Response Framework in 2008. The National Response Framework is organized into 15 annexes referred to as emergency support functions (ESFs). Search and Rescue Annex is ESF 9. Any of the ESFs can be used during a disaster. A total of 28 USAR teams comprise the federal government's USAR system. Activation of USAR teams occurs when local and state resources have been overwhelmed during a disaster and there has been a request from a state governor to the US president for the activation of federal response assets. On-call teams maintain a response posture to be able to gather at a rally point and deploy to disaster sites within hours of notification. When deployed, teams are capable of being fully self-sufficient including food, water, fuel, shelter, and transportation resources.

Components and Structure of an Urban Search and Rescue Team

When activated, the responding USAR team must mobilize quickly, possibly within as little as 6 hours, without placing additional demands on the already stressed infrastructure at the area of deployment. Figure e16.4 shows the organizational structure of a FEMA USAR team.[9] FEMA will typically deploy the three closest task forces within 6 hours of notification. The length of deployment is typically 10 to 14 days. Each task force consists of two 31-person teams, four canines, and a comprehensive equipment cache. USAR task force members work in four areas of specialization—search (discovering live survivors after a disaster), rescue (safely rescuing and transporting victims from areas of high water or collapsed structures), technical (structural specialists shoring up structures so sites are safe for rescuers), and medical (caring for victims during and after a rescue, prior to being transferred to medical resources such as a disaster medical assistance team [DMAT]). Coordination and cooperation with local resources and other teams is critical. Thus, the USAR team is integrated into the Incident Command System (ICS) at the disaster.

An effective USAR team has properly trained personnel and appropriate equipment. The equipment cache allows the task force to be totally self-sufficient for the first 72 hours and be capable of 24-hour operations for 10 days. The standardized FEMA equipment cache is divided into five groups—rescue, medical, technical, communications, and logistics equipment. The medical equipment cache was designed to treat the unique medical needs of entrapped victims, as well as sustaining the medical needs of the team itself. The medical cache contains enough supplies to handle 10 critical cases, 15 moderate cases, and 25 minor cases. The cost of an entire cache is approximately $7 million.[10]

The *search* team is responsible for developing and implementing a plan to search the area for victims, as well as identifying probable areas where victims may be found. The search team can be subdivided into two teams, a canine search team and technical search team. The canine team uses specially trained dogs to locate trapped victims. The technical team uses specialized microphones, listening devices, cameras, and fiberoptic devices to locate victims in confined spaces.

The *rescue* team is composed of rescue specialists. Once a victim or potential victim is located, the rescue team is responsible for establishing a safe entrance and egress from the victim's position and for extraction. The rescue team works in conjunction with the technical team to shore and stabilize unstable walls and structures.

The technical team includes structural specialists, hazardous materials specialists, heavy rigging and equipment specialists, technical information specialists, and communications specialists, who work collaboratively to ensure a safe and efficient operation. The logistics team is responsible for all the equipment needs, including inventory, issuing, and record keeping. Finally, the medical component is composed of personnel including paramedics and physicians who are responsible for the medical needs of the task force personnel and victims.

Medical Team Operations in Urban Search and Rescue

The USAR emergency clinician works with the team leadership to help address the considerations and unique circumstances faced by the team during deployment. To be effective in this role, the clinician must maintain familiarity with the capabilities and training of all the members on the team and the ICS. Often during a disaster, the medical team will work in conjunction with the search and rescue teams. USAR team emergency clinicians have two primary objectives during a search and rescue: The first is to provide care in direct support of the team members who will often be working to stabilize trapped victims medically for prolonged periods of time. In this setting, the emergency clinician may also be at the patient's side to help care for the victim. The second objective is to provide broader medical support for the health and welfare of other team members during team deployments. USAR emergency clinicians participate in training programs which include working in confined space and learning about medical scenarios and clinical situations that will likely be encountered during a USAR deployment (Fig. e16.5). The medical team also undergoes basic veterinary training prior to deployment.

Medical Team Tasks

Predeployment

During this phase of team operations, the medical team's focus is to ensure the entire USAR team is fit and functional for deployment. In addition, the medical team works with the medical equipment cache to keep it organized and up to date.[10] The potential medical threats in the deployed area must also be addressed (e.g., endemic diseases, water contamination, insect threats, existing medical support), and medical intelligence information needs to be collected and addressed (Box e16.1). Plans to address transfer and transport of victims, and for fatality management, are also developed during the predeployment phase.

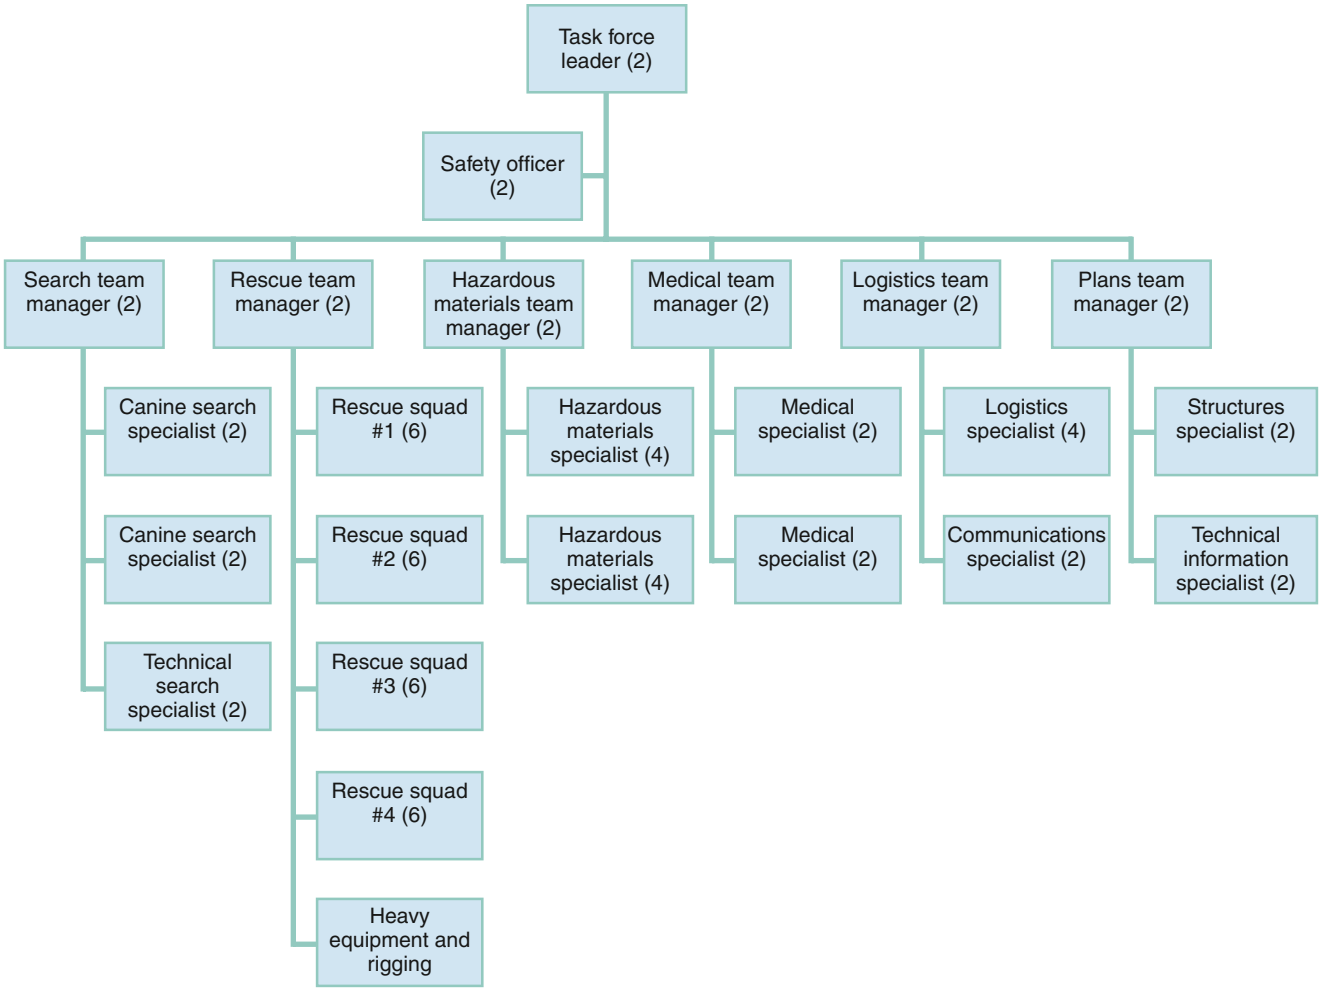

Fig. e16.4 Structure and organization of a Federal Emergency Management Agency (FEMA) urban search and rescue team.

Deployment

During deployment, the medical team's focus is on supporting the USAR team's mission and objectives. A medical action plan, which may include information regarding medical evacuation and local EMS resources, serves to help ensure successful operations. The medical team must also assess the adequacy of team members' rest and sleep, as well as the psychological effects of the situation.[10] The USAR medical assets must also integrate with the overall medical response, which is coordinated by ESF 8, Public Health and Medical Services. This includes interfacing with existing emergency medical resources, disaster medical assistance teams, military resources, and public health.

Confined Space Rescue

Special technical rescue situations, such as confined space (areas with limited access and ventilation) rescue is a key capability of USAR teams. As the USAR team works in these challenging and high-risk situations, the team's emergency clinician and medical personnel must be aware of issues related to team and victim safety, air purification, and structural dynamics related to collapse or impending collapse. Medical personnel may be asked to provide subject matter expertise on medically related issues including the cessation of rescue operations based on a decreasing likelihood of finding survivors. These multifactorial decisions should be based on individual characteristics of the event and should not rely on predefined time frames.

Specific Medical Challenges

USAR teams will typically respond to the aftermath of earthquakes, collapsed structures, terrorist bombings, hurricanes, and other natural and human-made disasters. Many of the medical conditions are similar to those encountered in the emergency department and are managed accordingly. The following clinical problems occur with much greater frequency in the USAR environment: crush injuries, compartment syndrome (see Chapter 41), particulate inhalation, hazardous materials exposures (see Chapter 148), and blast injuries (see Chapter e15).

Crush Injury and Crush Syndrome

Crush syndrome is the body's systemic manifestations caused by crushed muscle tissue, and often occurs when blood flow is restored to the crushed tissue and toxins are released in the body's circulation. The amount of time required for crush syndrome to develop depends on the amount of pressure and patient factors. Under some circumstances, it can occur within 1 hour, but often takes 4 to 6 hours to develop. Crush syndrome is estimated to occur in 3% to 20% of earthquake victims and upwards of 40% of survivors of multistory building collapses. Early victim hydration before, during, and after extrication can mitigate the nephrotoxicity of crush syndrome.

The major causes of early death from crush syndrome occur from hypovolemia due to third spacing of fluid, dysrhythmias due to severe metabolic acidosis, and hyperkalemia. When the crushed area of the body is released, toxic intracellular contents enter into the systemic

BOX E16.1 Predeployment Medical Intelligence Gathering

- Type of disaster and predicted numbers and types of potential victims
- Capabilities of team to deal with medical aspects of the situation, including dealing with injured team members
- Local emergency departments' level of functioning; trauma center status and location
- Local EMS resources
- Location of planned triage staging area
- Communications with local resources (e.g., EMS, police, emergency departments, fire and rescue)
- Weather, environment, or hazardous materials issues
- Availability of other resources (e.g., military, Medevac, NDMS, DMAT)

DMAT, Disaster medical assistance team; *EMS,* emergency medical services; *NDMS,* National Disaster Medical System.

circulation. Victims may be trapped for days with a severe crush injury and appear stable when they are reached by rescuers but deteriorate soon after being rescued. Delayed causes of death include renal failure, acute respiratory distress syndrome, sepsis, ischemic organ injury, disseminated intravascular coagulation, and electrolyte disturbances.

Early aggressive therapy is essential for the prevention and management of crush syndrome; this should begin before extrication. All victims who have an obvious crush injury or who are immobilized for 4 hours or more should be considered to have a crush injury. The severity of the crush syndrome increases with the amount of body area crushed. Once a victim is located, the medical team needs to be actively involved with the rescue process and treatment should be started before extrication. Continuous cardiac monitoring is recommended and can be performed in a confined space. Hydration is started along with the usual management of hyperkalemia (e.g., insulin and glucose, calcium, ion exchange resins, β-agonists,). An average-sized adult may require up to 12 L/day of fluids to sustain a forced diuresis of 8 L/day to prevent renal complications. Continued monitoring of the patient's vital signs, hydration status, and urine output should be used to guide fluid administration.

Environmental and Hazardous Materials Exposures

In the aftermath of a structural collapse, large amounts of dust and particulate matter are often released. Victims encountered by USAR teams within collapsed structures should be assumed to have some sort of dust contamination. Evaluation of the airway for any evidence of burns or hazardous materials exposure should be routine. During the extrication process, patients should be fitted with dust and particle masks, and their airway monitored for deterioration. If intubation is considered, it should be done early, before edema obstructs the airway and prior to a prolonged extrication, when accessing the victim may be difficult.

Chemical, explosive, and radiologic agents represent other potential threats to the USAR team. Hazardous materials may be released from many sources, such as manufacturing plants, industrial sites, or transportation vehicles. Explosions and fires from disrupted gas lines or other flammable and explosive gases and liquids can also present significant hazards. Radiation is a danger that may threaten search and rescue operations, as demonstrated by the Fukushima nuclear reactor radiation leak after the earthquake in Japan in 2011.

Medical teams are integral to the success of the USAR capability. USAR deployments are often highly challenging, and the prerequisite specialized training is rigorous. The USAR emergency clinician must be prepared and specifically trained to work in confined spaces and other challenging situations in austere conditions.

CHAPTER E16: QUESTIONS AND ANSWERS

1. Which of the following is a priority for the tactical emergency medical support (TEMS) provider in caring for a victim shot during a hostage incident?
   a. Bag-valve-mask ventilation
   b. Cervical spine stabilization
   c. Intravenous access and fluid resuscitation
   d. Tourniquet application to bleeding extremity

Answer: D. This scenario describes care rendered by TEMS in the hot zone, or care under fire; thus, conventional care sequences do not apply. Priorities include mitigation of threats, tourniquet use for serious bleeding, and evacuation to a safer location.

2. A 41-year-old man has been trapped under a piece of large crane that overturned during a partial construction site collapse. The patient has been trapped for over 7 hours and the rescue team is actively working to extricate him. His right leg is both mangled and pinned up to the level of his pelvis. He is conscious, in pain, has a systolic blood pressure of 140, a heart rate 112, SpO_2 97%, RR 20. He received pain medication and fluid resuscitation. The monitor shows a widening QRS interval. Which of the following treatments should be initiated?
   a. Blood products
   b. Calcium
   c. Epinephrine
   d. Hypertonic saline

Answer: B. Prolonged entrapment raises the concern for crush injury, which increases after 4 hours of immobilization. Continuous cardiac monitoring during extrication is indicated to monitor the development of arrhythmias which may occur in the setting of hyperkalemia. Evidence of hyperkalemia should be treated and includes calcium. There is no clinical evidence to suggest hemorrhagic shock or uncontrolled bleeding to warrant blood product administration. Fluid resuscitation may help prevent the hypotension associated with release of the entrapped limb(s) and should be initiated before extrication.

3. The principles of TEMS have largely developed from which type of incidents?
   a. Civilian multicasualty events
   b. Military conflicts
   c. Natural disasters
   d. Pandemics

Answer: B. The principles of TEMS have largely developed from lessons learned during military conflicts and most closely emulate the medical support structure of military special operations units.

4. Which of the following reflects an important distinction between tactical medicine and stand EMS practice?
   a. Airway compromise is treated before hemorrhage.
   b. Medical care may be delayed in order to accomplish the law enforcement mission.
   c. Care under fire requires the immediate movement of patients from the scene.
   d. Tourniquet use is secondary to other forms of hemorrhage control.

Answer: B. A fundamental principle in tactical medicine is that the medical mission may be subordinate to the overall law enforcement mission. In contrast to conventional EMS and hospital practices, in which the sole priority is usually the health and welfare of the patient, the essential priority in a tactical mission is the success of the law enforcement objective. When a casualty occurs during a tactical operation, medical providers may be directed to delay or modify medical care until the tactical commander determines that rendering care will not jeopardize the overall mission. Bleeding control is emphasized with rapid use of tourniquets. In care under fire patients should not be moved unless the danger is alleviated.

5. Which of the following is the primary responsibility of the USAR team emergency clinician?
   a. Ensuring a public health framework exists for the region
   b. Ensuring that entering a collapsed building is safe
   c. Medical treatment of entrapped victims
   d. Supporting the health and welfare of team members

Answer: D. The USAR team emergency clinician must be familiar with the types of medical conditions that may be encountered by the team. The USAR team emergency clinician has a primary responsibility to the team members should they require medical attention. Secondarily, treatment of entrapped patients can be done but is not their primary mission. Ensuring broader elements of a public framework in a disaster-affected area is typically beyond the conventional role of the USAR clinician, though this individual may liaison with other health and medical personnel in the same geographic area of operations.
